Parathyroid carcinoma surgery consists of either parathyroidectomy or en bloc resection of the tumor and ipsilateral thyroid lobe with care to avoid rupturing the tumor capsule. If the surgical margins are not clear of tumor, postoperative neck radiation therapy may be given. Local and distant metastases may be debulked or irradiated. Chemotherapy has been ineffective for patients with distant metastases. Immunotherapy with anti-hPTH monoclonal antibodies is a treatment option.

Complications—Serum PTH levels fall below normal in 70% of patients within hours after successful surgery, commonly causing hypocalcemic paresthesias or even tetany. Hypocalcemia tends to occur the evening after surgery or on the next day. Frequent postoperative monitoring of serum calcium (or serum calcium plus albumin) is advisable beginning the evening after surgery. Once hypercalcemia has resolved, liquid or chewable calcium carbonate is given orally to reduce the likelihood of hypocalcemia. Symptomatic hypocalcemia is treated with larger doses of calcium; calcitriol (0.25–1 mcg daily orally) may be added, with the dosage depending on symptom severity. Magnesium salts are sometimes required postoperatively, since adequate magnesium is required for functional recovery of the remaining suppressed parathyroid glands.

In about 12% of patients having successful parathyroid surgery, PTH levels rise above normal (while serum calcium is normal or low) by 1 week postoperatively. This secondary hyperparathyroidism is probably due to "hungry bones" and is treated with calcium and vitamin D preparations. Such therapy is usually needed only for 3–6 months but is required long term by some patients.

Hyperthyroidism commonly occurs immediately following parathyroid surgery. It is caused by release of stored thyroid hormone during surgical manipulation of the thyroid. In symptomatic patients, short-term treatment with propranolol may be required for several days.

Prognosis

Patients with symptomatic hyperparathyroidism usually experience worsening disease (eg, nephrolithiasis) unless they have treatment. Conversely, the majority of completely asymptomatic patients with a serum calcium below 11.0 mg/dL (2.75 mmol/L) remain stable with follow-up. However, worsening hypercalcemia, hypercalciuria, and reductions in cortical BMD develop in about one-third of asymptomatic patients. Therefore, asymptomatic patients must be monitored carefully and treated with oral hydration and mobilization.

Surgical removal of apparently single sporadic parathyroid adenomas is successful in 94%.

The bones, in spite of severe cyst formation, deformity, and fracture, will heal if hyperparathyroidism is successfully treated. Kidney damage may progress even after removal of a parathyroid adenoma.

Parathyroid carcinoma is associated with 5- and 10-year survival rates of 78% and 49%, respectively. A positive surgical margins or metastases predict a very poor 5-year survival.

When to Refer

Refer to parathyroid surgeon for parathyroidectomy.

When to Admit

Patients with severe hypercalcemia for intravenous hydration.

METABOLIC BONE DISEASE

The term "metabolic bone disease" refers to conditions producing diffuse reductions or increases in bone density that affect bone integrity. **Conditions causing reduced bone density** include osteopenia/osteoporosis and osteomalacia. Osteoporosis is characterized by reduction in both bone matrix and mineral, whereas in osteomalacia the bone matrix is intact but bone mineral is decreased. **Conditions causing increased bone density** are less common and include osteopetrosis and fluorosis. Disorders such as fibrous dysplasia and Paget disease of bone also involve disorganized bone and abnormal bone quality. Some metabolic bone disease includes disruption in calcium or phosphate homeostasis. Metabolic bone diseases may cause bone pain and fractures.

OSTEOPOROSIS & OSTEOPENIA

ESSENTIALS OF DIAGNOSIS

- Asymptomatic until a fracture has occurred.
- Fracture risk may be estimated by FRAX tool.
- Diagnosed by DXA bone density scanning.
- Serum calcium, phosphorus, PTH, and 25-OHD levels may be normal process.

General Considerations

Osteoporosis is a disorder of low bone mass and bone microstructural deterioration, resulting in reduced bone strength and predisposition to fracture. In the United States, osteoporosis causes over 1.6 million fractures annually, which have a tremendous medical and economic impact. Common sites of fragility fractures (those due to a fall or lesser trauma) are the vertebrae, forearm, and hip, but any anatomic site may be affected. Vertebral fractures are the most common osteoporotic fracture. Hip fracture in older adults can be particularly devastating with a 25% mortality by 1-year post-fracture; of those patients who survive, only half recover their pre-fracture functional status.

The risk for fragility fracture varies with age, sex, and race and ethnicity. Age is a strong risk factor. In women, there is an accelerated decline in bone mass at menopause due to the drop in estrogen, followed by a continued lower rate of decline. Because women are at higher risk for fracture than men, osteoporosis often goes unsuspected, undiagnosed, and untreated in men because widespread assumptions by providers and patients that osteoporosis is solely associated with postmenopausal women. Fracture risk is lower in Latino/Latina and Black adults than White adults.

Osteoporosis in postmenopausal women and older men is often due to the effects of aging and the decline in the protective effects of sex steroids. However, a variety of other factors can contribute to loss of bone mass or integrity (Table 30–2). Secondary osteoporosis refers to bone loss due to specific clinical conditions or medications.

Dual X-ray absorptiometry (DXA) is a low-radiation, inexpensive imaging test which measures bone mineral

  - Thalassemia major

[1] See Table 30–3 for causes of osteomalacia.

density (BMD). DXA is the basis for the diagnosis of osteoporosis and a strong risk predictor of osteoporotic fracture. DXA screening should be performed on all women ≥ 65 years of age, and in younger postmenopausal women with an estimated fracture risk that approximates that of a 65-year-old White woman without other risk factors. DXA is also appropriate for some older men with risk factors. Although routine DXA screening is not routinely performed in premenopausal women and young men, it is warranted in patients with fragility fractures.

DXA is used to measure BMD at the lumbar spine, the proximal femur, and, in some clinical situations, at the distal forearm. In postmenopausal women and men 50 years and older, osteoporosis is defined if BMD at the total lumbar spine, femoral neck, or total hip is ≥ 2.5 standard deviations below the mean for a young adult reference population (T-score of -2.5 or lower). Low bone mass or "osteopenia" is defined as a T-score between -1.0 and -2.49. In premenopausal women or men younger than 50, T-scores are not used to diagnose osteoporosis because the relationships between BMD and fracture risk are less well defined. Instead, Z-scores are used, in which the BMD is expressed the as standard deviations from an age- and sex-matched reference population, with a Z-score 2.0 or lower referred to as "low bone mass for age." The diagnosis of osteoporosis in a premenopausal woman or man younger than 50 generally requires both a low bone mass for age (Z-score) and demonstrated skeletal fragility (ie, a fragility fracture).

Use of T-scores to diagnose osteoporosis and osteopenia (low bone mass) is limited in their failure to account for factors beyond BMD that contribute to skeletal fragility, including age, personal history of fracture, and parental history of hip fracture. Fracture risk estimators such as the Fracture Risk Assessment Tool (FRAX) account for these other risk factors. For a postmenopausal woman or man 50 years or over, FRAX predicts 10-year risks of major osteoporotic fracture and hip fracture. The National Osteoporosis Foundation recommends that pharmacologic therapy for osteoporosis be considered for postmenopausal women and men 50 and over who have: osteoporosis by T-score; or osteopenia with a personal history of hip or vertebral fracture; or a 10-year risk of major osteoporotic fracture of at least 20% or hip fracture of at least 3%.

Clinical Findings

A. Symptoms and Signs

Osteoporosis is asymptomatic until a fracture occurs. Fractures can be painful and reduce independence and quality of life. Vertebral fractures may be painful or asymptomatic, presenting as loss of height or kyphosis, or diagnosed incidentally on radiograph. Even when asymptomatic, vertebral fractures are associated with a substantially higher risk of future fracture (vertebral or nonvertebral).

B. Laboratory Findings

Laboratory testing is required to evaluate for secondary causes of osteoporosis or and to rule out osteomalacia. Basic testing should include serum determinations for calcium, albumin, phosphate, creatinine, PTH, 25-OHD, TSH, and alkaline phosphatase. In men, a morning total testosterone level evaluates for hypogonadism.

The extent of further laboratory work-up depends on the clinical suspicion for a secondary cause of low bone mass or osteoporosis. A serum protein electrophoresis to evaluate for myeloma, may be appropriate in the setting of vertebral fracture or when kidney disease or hypercalcemia are present. Determination of 24-hour urinary calcium level may provide valuable additional information in the setting of primary or secondary hyperparathyroidism. When there is suggestive history, signs, or symptoms, additional laboratory testing may be warranted to rule out Cushing syndrome or celiac disease. In patients with severe osteoporosis (severely low BMD, multiple fractures, or both) or in premenopausal women and younger men with demonstrated skeletal fragility, a more extensive search for an underlying process may be appropriate.

Biochemical markers of bone turnover are available at commercial laboratories, including CTX (serum C-telopeptide of type 1 collagen), a marker for bone resorption; and P1NP (serum N-propeptide of type 1 procollagen), a marker for bone formation. They are not generally helpful in diagnosis but can be useful measures of medication adherence and efficacy. A clinical response to treatment is expected if the CTX and P1NP drop by at least 50% after commencing therapy. Specimens should be obtained in the morning, fasting, using the same laboratory for sequential testing.

C. Imaging

DXA, as **described above**, **is used to measure BMD for screening, diagnosis, or monitoring** treatment response. Quantitative CT (QCT) of the spine and hips measures volumetric bone density and can be useful in patients for whom degenerative disk disease interferes with the accurate measurement of spinal areal BMD by DXA. Vertebral radiographs may be helpful for detection of asymptomatic compression fractures.

Differential Diagnosis

Osteoporosis and osteomalacia are indistinguishable by bone densitometry. (See Rickets & Osteomalacia.) They must be differentiated based on clinical history and other laboratory testing, or tetracycline-labeled iliac crest bone biopsy, which is infrequently performed.

Prevention & Treatment

A. Nonpharmacologic Measures

For prevention and treatment of osteoporosis, the diet should be adequate in protein, total calories, calcium, and vitamin D. Recommended dietary allowance for calcium is 1300 mg daily during adolescence, 1000 mg for adult women through age 50 years and men through age 70, and 1200 mg for women age 51 and older and men 70 and older. This intake can be achieved from dietary sources, including fortified foods, or from a combination of diet and supplements. Measurement of calcium concentration in the blood is not useful in determining whether calcium intake is adequate, as homeostatic mechanisms usually ensure that calcium concentration stays within normal range. At elevated PTH due to secondary hyperparathyroidism or low 24-hour urinary calcium may indicate that calcium intake or intestinal absorption is inadequate.

Recommended daily allowance for vitamin D in adults is 600 IU per day up to age 70 years and 800 IU per day for those 71 and older. As with calcium, this intake can be achieved from dietary sources, including fortified foods, or from a combination of diet and supplements. Adequacy of vitamin D intake can be assessed by measurement of serum 25-OHD level. For the general population, a 25-OHD level of ≥ 20 ng/mL is considered adequate. For patients with osteoporosis or osteopenia, a goal of ≥ 30 ng/mL is recommended. Levels higher than 60 ng/mL should be avoided as they do not provide additional benefits for fracture reduction and may cause hypercalciuria (with risk for nephrolithiasis) or hypercalcemia.

Pharmacologic corticosteroids should be avoided or reduced in dose and duration if possible. Cigarette smoking cessation is essential. Excessive alcohol intake must be avoided. Exercise is strongly recommended both for its direct effects on bone strength and its reduction of fall risk through improved balance and body strength. Other fall prevention measures include adequate home lighting, handrails on stairs, handholds in bathrooms, and appropriate walking aids (canes or walkers) for patients with weakness or balance problems. Medications that cause orthostasis, dizziness, or confusion should be avoided.

B. Pharmacologic Measures

Pharmacologic treatment should be considered for: patients with osteoporosis on DXA. It also should be considered in postmenopausal women and men ≥ 50 years with osteopenia and a high risk for fracture demonstrated either by a fragility fracture of the hip or spine, or by a FRAX-determined 10-year risk of hip fracture > 3%, or risk of major osteoporotic fracture > 20%. Select premenopausal women or men younger than 50 with low bone mass for age and demonstrated skeletal fragility may also benefit from treatment.

For patients at high risk of fracture, first-line therapy generally is with a bisphosphonate. Patients at very high risk of fracture are candidates for anabolic therapy with teriparatide or abaloparatide, or for therapy with the mixed antiresorptive/anabolic agent romosozumab.

1. Bisphosphonates—Bisphosphonates are antiresorptive medications that inhibit osteoclast-induced bone resorption. They are the first-line therapy for patients with high enough risk for fracture to warrant pharmacologic therapy. Available in oral and IV formulations, bisphosphonates increase bone density significantly and all reduce the incidence of vertebral fractures; all but ibandronate have been demonstrated to also reduce the risk of nonvertebral fractures. Bisphosphonates are also effective in preventing corticosteroid-induced osteoporosis.

Oral bisphosphonates include alendronate, risedronate, and ibandronate. Alendronate is administered orally once weekly; risedronate may be given weekly or monthly; and ibandronate is taken once monthly. To ensure intestinal absorption, oral bisphosphonates must be taken in the morning with at least 8 oz of plain water and at least 40 minutes before consumption of food or other medications or supplements (particularly those containing calcium). The patient must remain upright after taking bisphosphonates to reduce the risk of esophagitis. Oral bisphosphonates are relatively contraindicated in patients with CrCl < 30 mL/min.

Intravenous bisphosphonates are available for patients who cannot take oral bisphosphonates. Zoledronic acid is most commonly used and is a potent osteoclast inhibitor. It is administered once yearly in a dose of 5 mg intravenously over at least 15–30 minutes. In a study of postmenopausal women with osteoporosis, once yearly intravenous zoledronic acid reduced the 3-year incidence of hip fractures by 41% (from 2.5% to 1.4%) and clinical vertebral fractures by 77% (from 2.6% to 0.5%). IV bisphosphonates are relatively contraindicated in patients with CrCl < 35 mL/min.

Because of the very rare but serious potential side effects of cumulative doses of antiresorptive therapy described below (including atypical fractures of the femur, osteonecrosis of the jaw), the benefit and risk of bisphosphonate treatment is reassessed after approximately 3 years of IV bisphosphonate or 4–5 years of oral bisphosphonate therapy. If the patient is deemed to be at continued high risk of fracture as assessed by repeat DXA bone densitometry and evaluation or the current clinical history, continued bisphosphonate therapy for a total of 8–10 years may be appropriate. Alternatively, if risk is more moderate, a bisphosphonate "drug holiday" may be pursued.

SIDE EFFECTS OF BISPHOSPHONATES—Oral bisphosphonates can cause nausea, chest pain, and hoarseness. Erosive esophagus can occur, particularly in patients with hiatal hernia and gastroesophageal reflux.

After the first intravenous infusion of zoledronic acid, symptoms of an acute-phase response occurs in 42% of patients, usually within the first day or two including fever, chills, or flushing (20%); musculoskeletal pain (20%); nausea, vomiting, or diarrhea (8%); and nonspecific symptoms such as fatigue, dyspnea, edema, headache, or dizziness (22%). Although they may last up to several days, the symptoms are transient and resolve spontaneously. They may recur with subsequent doses but diminish in intensity with time. Symptoms may be treated with acetaminophen or NSAIDs. Patients who experience an especially severe acute-phase response can be given prophylactic corticosteroids (eg, intravenous hydrocortisone) immediately prior to subsequent bisphosphonate infusions.

Osteonecrosis of the jaw is a rare complication of antiresorptive therapy. After tooth extraction or implantation, a painful, necrotic, nonhealing lesion of the mandible or maxilla occurs. The risk is increased with older age, in women, and in patients concomitantly receiving chemotherapy or corticosteroid therapy. About 95% of medication-related osteonecrosis of the jaw has occurred with high-dose bisphosphonate therapy for treatment of malignancy. Only 5% of cases have occurred in patients receiving bisphosphonates for osteoporosis. The incidence of osteonecrosis is about 1:100,000 patients treated for osteoporosis with oral bisphosphonates versus 1:100 in patients being treated for cancer with intravenous bisphosphonates. With this risk in mind, patients should be queried about dental health prior to initiation of antiresorptive therapy and examined by a dentist if appropriate. If dental extractions are needed or implants are planned, those procedures should be completed before initiation of the antiresorptive medication.

Atypical fractures of the femur are another rare complication of antiresorptive therapy. Atypical fractures are often subtrochanteric, occur with little or no trauma, and are usually transverse as opposed to the more typical comminuted or spiral femoral shaft fractures. Patients may have prodromal thigh pain prior to the fracture. The risk for atypical femoral fractures is higher among Asian women, patients taking chronic glucocorticoid therapy, and those receiving bisphosphonate treatment for > 5 years. Although atypical femoral fractures are a serious consideration, the risk is outweighed by the benefits of bisphosphonates. In a large cohort analysis, for every 10,000 women taking bisphosphonates for 3 years, 149 hip fractures were prevented and 2 atypical femur fractures occurred in White women, while 91 hip fractures were prevented and 8 atypical femur fractures occurred in Asian women.

Bisphosphonate (and other antiresorptive) therapy can induce hypocalcemia, particularly in the setting of vitamin D deficiency and if calcium intake or absorption is low. Therefore, vitamin D deficiency should be corrected before starting therapy, and adequate calcium and vitamin D intake are crucial (from supplements, if needed), especially with IV bisphosphonate therapy.

2. Denosumab—Denosumab is a monoclonal antibody that inhibits the proliferation and maturation of preosteoclasts into mature osteoclast bone-resorbing cells. It is indicated for treatment of osteoporosis and considered an alternative to bisphosphonates for treatment of patients at high risk of fracture. It also is FDA-approved for patients with high fracture risk who are receiving sex hormone suppression therapy for breast cancer or prostate cancer. Treatment reduces vertebral fractures by 68% and hip fractures by 40%. Denosumab is administered in doses of 60 mg subcutaneously every 6 months.

Denosumab is relatively well tolerated. There is a small incidence of flu-like symptoms (8%), eczema, and cellulitis. Like bisphosphonates, rare cases of osteonecrosis of the jaw and atypical femoral fractures have been reported. Hypocalcemia may occur, particularly in the setting of vitamin D deficiency and if calcium intake or absorption is low. Therefore, vitamin D deficiency should be corrected before starting the medication, and adequate calcium and vitamin D intake (from supplements if needed) are crucial.

Unlike bisphosphonates, denosumab can be given to patients with stage 4 and 5 CKD; however, the risk of hypocalcemia in this population is heightened. A large retrospective cohort study of women on dialysis reported severe hypocalcemia (serum calcium level < 7.5 mg/dL [1.88 mmol/L]) in 41% receiving denosumab (some resulting in life-threatening events, hospitalizations, and death) versus 2% receiving oral bisphosphonates. In 2024, the FDA issued a black box warning about the risk of severe hypocalcemia in patients with advanced CKD, especially those with related mineral bone disorder.

Importantly, following a missed dose or discontinuation of denosumab, there is accelerated bone loss with an increased risk of multiple vertebral fractures. Therefore, denosumab must be given on-schedule without the "drug holidays" applied to bisphosphonate therapy. Once started, denosumab should either be continued indefinitely, or transitioned to another antiresorptive agent (eg, a bisphosphonate), with the intensity and duration of the other therapy dependent on the duration of the denosumab treatment.

3. Other antiresorptive agents—Estrogen has antiresorptive effects, and menopausal hormone therapy with conjugated equine estrogens increases BMD and reduces risk of hip and vertebral fractures. Because alternate therapies for osteoporosis exist without the potential risks of estrogen, estrogen is no longer prescribed for the purpose of treating osteoporosis.

Selective estrogen receptor modulators (SERMS) act as estrogens in some tissues but block estrogens in other tissues. Raloxifene, taken orally daily, is FDA approved for the treatment of postmenopausal osteoporosis. It reduces the risk of vertebral fractures by about 40% but does not reduce the risk of nonvertebral fractures. Unlike estrogen, raloxifene does not reduce hot flushes or relieve vaginal dryness, but it does not cause endometrial hyperplasia, and risk of breast cancer is reduced 76% in women taking raloxifene for 3 years. Raloxifene increases the risk for thromboembolism. Bazedoxifene is available in a fixed-dose combination with conjugated estrogens and is FDA approved for the prevention of osteoporosis in postmenopausal women with an intact uterus.

Intranasal and injectable **calcitonin** are approved for osteoporosis treatment, although they are used infrequently because they have not been shown to reduce nonvertebral or hip fractures, and they have various side effects. Calcitonin may provide some analgesia in patients with pain from vertebral compression fractures. The intranasal spray may cause rhinitis and epistaxis, and the injectable form may cause flu-like symptoms and local injection reactions. Calcitonin increases overall risk of malignancy by about 1.1% and has been withdrawn from the market in Canada and Europe.

4. PTH and PTHrP analogs—Teriparatide and abaloparatide are analogs of PTH and PTHrP, respectively. These analogs are anabolic agents that stimulate bone formation, particularly in the spine. They are options for patients with osteoporosis who are at very high fracture risk, particularly those who have severely low BMD of the spine or have suffered vertebral fracture. Patients self-administer subcutaneous teriparatide or abaloparatide daily for up to 2 years, using a prefilled pen. Following this anabolic agent treatment course, treatment with an antiresorptive agent (usually a bisphosphonate or denosumab) is provided. Teriparatide is also FDA approved for the treatment of glucocorticoid-induced osteoporosis.

Side effects of teriparatide and abaloparatide include hypercalcemia and hypercalciuria. In patients with a history of nephrolithiasis, caution is advised and investigation warranted before prescribing these agents. Patients are excluded from receiving teriparatide or abaloparatide if they have an increased risk of osteosarcoma due to the following: Paget disease of bone, prior radiation therapy to bones, open epiphyses, or a past history of skeletal malignancies.

5. Romosozumab—Romosozumab is an injectable monoclonal antibody that inhibits sclerostin, increasing new bone formation and decreasing bone resorption (ie, it is a mixed anabolic/antiresorptive agent). It is administered once monthly for 12 months in a clinical setting, following which antiresorptive therapy is provided either with a bisphosphonate or denosuamb. In one large cohort of women with osteoporosis and fragility fractures, romosozumab treatment for 12 months followed by alendronate for 12 months resulted in a 48% lower risk of vertebral fractures and a 38% lower risk of hip fracture compared to women receiving alendronate alone. Romosozumab is reserved for patients with severe osteoporosis, such as those with osteoporosis on DXA plus a history of fragility fracture. Because of a potential increased risk of major adverse cardiovascular events, a black box warning cautions that it should not be used in patients who have had an MI or stroke within the previous year.

Prognosis

DXA monitoring in an untreated patient can determine whether there is a clinically meaningful decrease in bone density over time. Although DXS can measure improvements in bone density among patients undergoing pharmacologic treatment for osteoporosis, the reduction in fracture risk afforded by treatment is only partially explained by an increase in BMD; randomized trial data demonstrate that patients with little or no significant increase in BMD in response to bisphosphonate therapy still have reduced fracture risk compared to placebo. Osteoporosis should ideally be prevented since it can be only partially reversed.

RICKETS & OSTEOMALACIA

ESSENTIALS OF DIAGNOSIS

- Low bone density from defective mineralization.
- Caused by deficiency in calcium, phosphorus, or low alkaline phosphatase.
- **Rickets:** defective bone mineralization in childhood or adolescence before epiphyseal fusion.
- **Osteomalacia:** defective bone mineralization in adults with fused epiphyses.
- Bone pain; painful proximal muscle weakness (especially pelvic girdle).
- Low serum 25-hydroxy-vitamin D (25-OHD), hypocalcemia, hypocalciuria, hypophosphatemia, secondary hyperparathyroidism.
- Classic radiologic features may be present.

General Considerations

Defective mineralization of the growing skeleton in childhood causes permanent bone deformities (rickets). Defective skeletal mineralization in adults (acquired) is known as osteomalacia. Both are caused by inadequate calcium or phosphate mineralization of bone osteoid.

Etiology

Causes of osteomalacia are listed in Table 30–3.

A. Vitamin D Deficiency & Disorders

Vitamin D deficiency is the most common cause of osteomalacia. In some cases, its cause is low exposure to sunlight caused by urbanization, living at high latitudes, winter season, institutionalization, sunscreen use, or very modest dressing. Other risk factors for vitamin D deficiency include older age, obesity, dark skin, inadequate dietary

Table 30–3. Causes of osteomalacia.[1]

Vitamin D disorders
Insufficient sunlight exposure
Nutritional vitamin D deficiency: vegan diet, starvation
Intestinal malabsorption: aging, bariatric surgery, celiac disease, pancreatic enzyme deficiency
Kidney: CKD, nephrotic syndrome
Drugs: Phenytoin, carbamazepine, valproate, or barbiturate therapy (chronic)
Vitamin D–dependent rickets types 1 and 2
Dietary calcium deficiency
Phosphate homeostasis disorders
Intestinal malabsorption
Nutritional deficiency of phosphorus
Adefovir therapy for hepatitis B
Alcohol use disorder
Diuretics
FGF23-related: tumoral hypophosphatemic osteomalacia, X-linked hypophosphatemic rickets
Hyperparathyroidism
Phosphate-binding antacid therapy
Renal tubular loss: Fanconi syndrome, oral contraceptives (idiosyncratic), parenteral iron, renal tubular acidosis
Other disorders: glycogen storage diseases, neurofibromatosis, paraproteinemias, Wilson disease
Inhibitors of mineralization
Aluminum toxicity
Bisphosphonates
Disorders of bone matrix
Hypophosphatasia
Axial osteomalacia
Fibrogenesis imperfecta ossium

[1] See Table 30–2 for causes of osteoporosis.

intake (malnutrition, vegan diets), and intestinal malabsorption. Anticonvulsants may inhibit the hepatic production of 25-OHD. About 36% of adults in the United States are deficient in vitamin D.

Vitamin D–dependent rickets type 1 is caused by a rare autosomal recessive disorder with a defect in the renal enzyme 1-α-hydroxylase leading to defective synthesis of $1,25(OH)_2D$. Vitamin D–dependent rickets type 2 (hereditary $1,25[OH]_2D$-resistant rickets) is caused by a germline mutation in the $1,25(OH)_2D$ receptor.

B. Calcium Deficiency

Recommended dietary allowances for calcium are 1300 mg daily during adolescence, 1000 mg for adult women up through age 50 years and men up through age 70, and 1200 mg for women age 51 and older and men 70 and older. Patients who have deficient calcium intake may develop rickets (childhood) or osteomalacia (adulthood) even in the presence of sufficient vitamin D. A nutritional deficiency of calcium can occur in vegans and in any severely malnourished patient. Some degree of calcium deficiency is common in older adults, since intestinal calcium absorption declines with age.

C. Phosphate Homeostasis Disorders

Osteomalacia develops in patients with hypophosphatemia due to lack of sufficient phosphate to mineralize bone osteoid. Such patients typically have musculoskeletal pain and muscle weakness and are prone to fractures.

1. Genetic disorders—Fibroblast growth factor-23 (FGF23) is a phosphaturic factor (phosphatonin) that is secreted by bone osteoblasts in response to elevated serum phosphate levels. Various germline mutations can result in high serum FGF23 levels, causing hypophosphatemia and bone mineral depletion.

2. Tumor-induced osteomalacia—This rare paraneoplastic syndrome can be caused by a variety of mesenchymal tumors (87% benign) and malignancies that secrete FGF23 and cause marked hypophosphatemia and hyperphosphaturia due to renal phosphate wasting. Such tumors are usually phosphaturic mesenchymal tumors (70%). Such tumors are often small and difficult to find, frequently lying in the sinuses or extremities.

3. Secondary hypophosphatemia—With calcium or vitamin D deficiency, calciopenia stimulates counterregulatory PTH secretion, resulting in hypophosphatemia due to renal phosphate wasting. Hypophosphatemia causes impaired bone mineralization and hypertrophy of chondrocytes at active growth plates, resulting in the bulbous enlargement at costochondral junctions that is seen with rickets.

4. Other causes of hypophosphatemia—Hypophosphatemia can be caused by alcohol use disorder, poor nutrition, and prolonged parenteral nutrition. Tenofovir therapy (tenofovir disoproxil fumarate more so than tenofovir alafenamide) can cause renal phosphate wasting and hypophosphatemia. Hypophosphatemia can also be caused by chelation of phosphate in the gut by aluminum hydroxide antacids, calcium acetate, or sevelamer hydrochloride. Excessive renal phosphate losses are also seen in proximal renal tubular acidosis, Fanconi syndrome, intravenous iron, and in some women using oral contraceptives.

D. Inhibition of Mineralization

Bone mineralization is inhibited by aluminum. Osteomalacia may occur in patients receiving long-term renal hemodialysis with tap water dialysate or from aluminum-containing antacids used to reduce phosphate levels.

E. Disorders of Bone Matrix

Hypophosphatasia is a heritable rickets or osteomalacia characterized by low activity of the tissue-nonspecific isoenzyme of alkaline phosphatase. There is a range of severity, with perinatal, infantile, childhood, and adult presentations. Adult hypophosphatasia can present in adulthood with premature loss of teeth, metatarsal stress fractures, thigh pain due to femoral pseudofractures, or arthritis due to chondrocalcinosis. Bone density is low, and the osteomalacia is commonly misdiagnosed as osteoporosis. Serum alkaline phosphatase is low (below 40 U/L in adults and often < 20 U/L in severe cases). The differential diagnosis includes other causes of low serum alkaline phosphatase, such as early pregnancy, hypothyroidism, myeloma, severe anemia, or vitamin D intoxication; alkaline phosphatase may also be low in a patient who has been treated with an antiresorptive medication like a bisphosphonate.

Clinical Findings

Older children and adolescents can have bone pain and muscle weakness and may develop the skeletal deformities of classic rickets, such as delayed longitudinal growth. Hypertrophy of chondrocytes at growth plates causes bulbous enlargements of joints with bowed legs or knock-knees. Thickening at the costochondral joints can cause widening of the chest and deformities known as a “rachitic rosary.” Kyphoscoliosis or lumbar lordosis is common.

In adults, osteomalacia is initially asymptomatic. Nonspecific complaints include fatigue, reduced endurance and muscle strength, and pain in the bones involving their shoulders ribs, low back, and thighs develop. Pathologic fractures can occur with little or no trauma.

Hypocalcemia causes a reduced quality of life, with fatigue, irritability, depression, anxiety, cognitive impairment, lethargy, and paresthesias in the circumoral area, hands, and feet. More severe manifestations of hypocalcemia include muscle weakness or cramps, carpopedal spasm, convulsions, tetany, laryngospasm, and stridor. Primary or secondary hypophosphatemia can cause severe major muscle weakness, reduced endurance, dysphagia, diplopia, cardiomyopathy, and respiratory muscle weakness. Patients may also have impaired cognition.

Diagnostic Tests

DXA is used to determine the presence of low bone density that can be due to osteoporosis, osteomalacia, or both.

Serum is obtained for calcium, albumin, phosphate, alkaline phosphatase, PTH, and 25-OHD determinations.

Vitamin D *deficiency* is defined as a serum 25-OHD < 20 ng/mL (50 nmol/L). Patients with severe osteomalacia may have chronic severe vitamin D deficiency (serum 25-OHD under 12 ng/mL [25 nmol/L]).

Patients with otherwise unexplained hypophosphatemia should have a measurement of serum or plasma fibroblast growth factor 23 (FGF23). Patients with high FGF23 levels can have genetic testing for X-linked hypophosphatemic rickets (*PHEX*), autosomal dominant hypophosphatemic rickets (*FGF23*), and autosomal recessive hypophosphatemic rickets (*DMP1*). In patients with hypophosphatemia without such mutations, searching for a tumor causing tumor-induced osteomalacia is reasonable, particularly in patients with bone pain or fractures.

Patients with hypophosphatasia have low serum levels of alkaline phosphatase (below 40 U/L in adults and below 20 U/L in severe cases). However, immediately following a fracture, serum alkaline phosphatase rises and may obscure the diagnosis. Provided vitamin B_6 is not being supplemented, an elevated pyridoxal 5'-phosphate is a good marker for the disease. Serum calcium is usually normal. The diagnosis is confirmed with genetic testing for mutations in the *TNSALP* gene.

Differential Diagnosis

Osteomalacia often coexists with osteoporosis. The relative contribution of the two entities to diminished bone density may not be apparent until treatment (eg, repleting vitamin D deficiency) since a dramatic rise in bone density is often seen with therapy for osteomalacia. Phosphate deficiency must be distinguished from hypophosphatemia seen in hyperparathyroidism.

Prevention & Treatment

In children and adolescents, empiric vitamin D supplementation is suggested to prevent nutritional rickets. This may include intake of vitamin D-fortified foods or daily intake of a vitamin D supplement. In adults, recommended daily allowance for vitamin D is 600 international units (IU) per day up to age 70 years, then 800 IU per day for those 71 and older. Humans naturally receive about 90% of their vitamin D from sunlight; vitamin D supplementation may be appropriate in patients who are sunlight-deprived or using sunscreen. Patients at risk for vitamin D deficiency or who have metabolic bone disease should have 25-OHD levels monitored.

The main natural food source of vitamin D is fish, particularly salmon, mackerel, cod liver oil, and sardines or tuna canned in oil. Most commercial cow's milk is fortified with vitamin D.

Most vitamin D supplements contain cholecalciferol (vitamin D_3), which is the preferred form for supplementation and treatment. Common supplement doses are 1000 IU or 2000 IU daily, but due to variable absorption and metabolism, a person with low 25-OHD levels may need more. Severe vitamin D deficiency can be treated with high-dose capsules of 50,000 IU each, which are more commonly ergocalciferol (D_2) than choleclaciferol. A common repletion course is 50,000 IU orally once or twice weekly for 8–12 doses. It is ideal to provide a daily supplement (eg, 1000–2000 IU daily) concurrently and extending after the short-term high-dose repletion course, so that 25-OHD levels do not fall again as soon as the repletion course ends. Serum levels of 25-OHD should be monitored, and the dosage of vitamin D adjusted to achieve and maintain a goal level of at least 20 ng/mL in the general population and 30–60 ng/mL in those with metabolic bone disease.

Patients with malabsorption or poor nutrition may need supplemental calcium in addition to vitamin D, which may be in the form of calcium carbonate or citrate.

In hypophosphatemic rickets or osteomalacia, nutritional deficiencies are corrected, aluminum-containing antacids are discontinued, and patients with renal tubular acidosis are given bicarbonate therapy.

For patients with tumoral hypophosphatemia, resection of the tumor normalizes serum phosphate levels; about 20% experience recurrence, usually in the same location. With both tumoral and genetic FGF23-related hypophosphatemia, therapy with burosumab improves osteomalacia.

Patients with hypophosphatasia may be treated with asfotase alfa, which replaces the deficient enzyme. Teriparatide can improve bone pain and fracture healing. Bisphosphonates are contraindicated.

PAGET DISEASE OF BONE (Osteitis Deformans)

ESSENTIALS OF DIAGNOSIS

- Often asymptomatic.
- Bone pain may be the first symptom.
- Kyphosis, bowed tibias, large head, deafness, and fractures.
- Serum calcium and phosphate normal; elevated alkaline phosphatase and biochemical markers of bone turnover.
- Osteolytic or sclerotic lesions, expanded bones on radiographs.

General Considerations

Paget disease of bone is manifested by one or more localized bony lesions having high bone turnover and disorganized osteoid formation. The involved bone first has increased osteoclast activity, causing lytic lesions that may progress at about 1 cm/year. Increased osteoblastic activity follows, producing a high rate of disorganized bone formation. Involved bones become vascular, weak, and deformed.

Eventually, there is a final burned-out phase with markedly reduced bone cell activity and abnormal bones that may be enlarged with skeletal deformity.

The prevalence of Paget disease has declined over the recent decades. It is most common in the United Kingdom and in areas of European migration, and it is rare in Africa, Asia, and Scandinavia. In the United States, Paget disease affects about 1% of White persons over age 55 years, with it increasing prevalence over age 40 years. Most cases are discovered incidentally during radiology imaging or because of incidentally discovered elevations in serum alkaline phosphatase.

Clinical Findings

A. Symptoms and Signs

Paget disease is mild and asymptomatic in about 75% of cases. It involves multiple bones (polyostotic) in 72% and only a single bone (monostotic) in 28%. It occurs most commonly in the sacrum, vertebrae, femur, skull, pelvis, and humerus. The disease typically involves affected bones simultaneously and tends not to involve additional bones during its course. When symptomatic, pain, often described as aching, deep, and worse at night, is the usual initial symptom. Increased vascularity over the involved bones may cause increased warmth. Joint surfaces can be involved and cause arthritic pain. The poor bone quality can lead to bowing deformities of the femurs or tibias, kyphosis, and fractures, particularly of weight-bearing bones. If the skull is involved, the patient may report headaches and an increased head size. Involvement of the temporal bone can damage the cochlea, causing hearing loss.

B. Laboratory Findings

Serum total alkaline phosphatase and bone alkaline phosphatase levels are usually elevated, often markedly so. Other biochemical markers of bone turnover such as the C-terminal telopeptide of type 1 collagen (CTx) are also usually elevated. Serum calcium and phosphate are typically normal in untreated disease, although hypercalcemia may result if a patient sustains a fracture and is on bedrest. Treatment with a bisphosphonate may cause hypocalcemia and secondary hyperparathyroidism, particularly if there is concomitant vitamin D deficiency; thus, serum 25-OH vitamin D should be measured and deficiencies addressed.

C. Imaging

Plain x-rays or CT scans demonstrate osteolytic lesions in Paget disease, with focal radiolucencies. These may include advancing flame-shaped lytic lesions in long bones or "osteoporosis circumscripta" in the skull. In vertebrae, the lesions may display a "clover" or "heart" appearance ("Mickey Mouse sign"), helping distinguish them from bone metastases. Bone lesions can have a lytic phase, mixed phase, or sclerotic phase. The affected bones eventually become thickened and deformed. Radionuclide bone scans (eg, Technetium-99m pyrophosphate) are helpful in delineating activity of bone lesions and finding additional lesions in other locations.

Differential Diagnosis

Paget disease must be differentiated from primary bone lesions (eg, osteogenic sarcoma, plasma cell myeloma, and fibrous dysplasia) and from secondary bone lesions (eg, osteitis fibrosa cystica and metastatic carcinoma to bone). Rare familial types of sclerosing bone dysplasias share phenotypic homologies with Paget disease of bone.

Complications

If immobilization occurs, hypercalcemia and hypercalcemia (with risk of renal calculi) may develop. Arthritis frequently develops in joints adjacent to involved bone.

Skull involvement may cause hearing loss or cranial nerve palsies. Surgery for fractured long bones may be complicated by excessive blood loss from these vascular lytic lesions.

Sarcoma or giant cell tumor develops in < 1% of long-standing lesions.

Treatment

Treatment is with a bisphosphonate, which suppresses osteoclast activity. Indications for treatment are to relieve symptoms or to prevent future complications. Some asymptomatic patients may require only clinical surveillance, but those who have significant involvement of the skull, weight-bearing long bones, or vertebrae may benefit from medical therapy.

Zoledronic acid is the treatment of choice for Paget disease and is superior to other bisphosphonates. Administered intravenously as a single 5-mg dose, it normalizes the serum alkaline phosphatase in 89% of patients by 6 months and in 98% by 2 years. In some patients, biochemical remission will be achieved with a single dose of zoledronic acid. If the serum alkaline phosphatase level rises above normal or increases > 25% above the nadir level, the infusion may be repeated.

Following intravenous zoledronic acid, patients frequently experience a flu-like reaction of fever, headache, myalgia, bone pain, or a combination of these, which may be treated with acetaminophen or NSAIDs. Bisphosphonate-induced hypocalcemia may be severe, especially if the patient has vitamin D deficiency or is taking a loop diuretic. Therefore, vitamin D deficiency should be corrected before administering the bisphosphonate, and adequate supplementation of calcium and vitamin D is crucial, especially in the initial days and weeks following treatment.

Prognosis

The prognosis is good, but relapse can occur after an initial successful treatment with bisphosphonate. By 6.5 years after initial therapy, the recurrence rate is 12.5% after treatment with zoledronic acid and 62% after risedronate. Patients must be monitored long term, measuring serum alkaline phosphatase every 6–12 months. In the most severe forms, marked deformity, intractable pain, and high-output HF occur if not treated with bisphosphonates.

MULTIPLE ENDOCRINE NEOPLASIA (MEN)

MEN TYPES 1–4

ESSENTIALS OF DIAGNOSIS

- **MEN 1:** tumors of the parathyroid glands, endocrine pancreas and duodenum, anterior pituitary, adrenal, thyroid; carcinoid tumors; lipomas and facial angiofibromas.
- **MEN 2:** medullary thyroid cancer, hyperparathyroidism, pheochromocytoma, Hirschsprung disease.
- **MEN 3:** medullary thyroid cancer, pheochromocytoma, Marfan-like habitus, mucosal neuromas, intestinal ganglioneuroma, delayed puberty.
- **MEN 4:** tumors of the parathyroid glands, anterior pituitary gland, adrenal gland, ovary, testicle, kidney.

Syndromes of MEN are inherited as autosomal dominant traits that cause a predisposition to the development of tumors of two or more different endocrine glands (Table 30–4). MEN syndromes are caused by germline mutations and tumors arising when additional somatic mutations occur in predisposed organs. Patients with MEN should have genetic testing so that their first-degree relatives may then be tested for the specific mutation.

1. MEN 1

Multiple endocrine neoplasia type 1 (MEN 1, Wermer syndrome) is a tumor syndrome with a prevalence of 2–10 per 100,000 persons in the United States. About 90% of affected patients harbor a detectable germline mutation in the *menin* gene.

The presentation of MEN 1 is variable, even in the same kindred. Affected patients are prone to many different tumors, particularly involving the parathyroids, endocrine pancreas and duodenum, and anterior pituitary (Table 30–4). Incidental adrenal nodules are found in about 50% of affected patients but are rarely secretory. The initial biochemical manifestations (usually hypercalcemia) can often be detected as early as age 14–18 years in patients with a MEN 1 gene mutation, although clinical manifestations usually present in the third or fourth decade.

Hyperparathyroidism is the first clinical manifestation of MEN 1 in two-thirds of affected patients, but it may present at any time of life.

GEP-NETs and carcinoids occur in up to 70% of patients with MEN 1. The GEP-NETs may secrete only pancreatic polypeptide or be nonsecretory altogether (20–55%). Gastrinomas occur in about 40% of patients with MEN 1. Concurrent hypercalcemia, due to hyperparathyroidism in MEN 1, stimulates gastrin and worsens gastric acid secretion; control of the hypercalcemia often reduces serum gastrin levels and gastric acid secretion. Carcinoid tumors can arise in the lung or abdomen and can metastasize, especially to the liver.

Insulinomas occur in about 10% of patients with MEN 1. Extrapancreatic neuroendocrine tumors are common in MEN 1; they are frequently malignant and include carcinoid tumors (usually in foregut locations [69%], such as the lung, thymus, duodenum, or stomach).

Table 30–4. Multiple endocrine neoplasia (MEN) syndromes: incidence of tumor types.

Tumor Type	MEN 1	MEN 2 (MEN 2A)	MEN 3 (MEN 2B)	MEN 4
Parathyroid	95%	20–50%	Rare	Common
Pancreatic	54%			Common
Pituitary	42%			Common
Medullary thyroid carcinoma		> 90%	80%	
Pheochromocytoma	Rare	20–35%	60%	
Mucosal and GI ganglioneuromas		Rare	> 90%	
Subcutaneous lipoma	30%			
Adrenocortical adenoma	30%			Common
Thoracic carcinoid	15%			
Thyroid adenoma	55%			Common
Facial angiofibromas and collagenomas	85%			
Breast cancer	27%			

Pituitary adenomas are the presenting tumor in 29% of patients with MEN 1 and eventually are found in about 42% of patients with MEN 1. About 42% of pituitary adenomas are nonsecretory. Nonsecretory pituitary microadenomas (< 1 cm and detected on routine MRI screening) are usually indolent; 25% of nonsecretory pituitary adenomas are macroadenomas (1 cm or more) and more aggressive.

Adrenal adenomas or hyperplasia occur in about 40% of patients with MEN 1; 50% are bilateral. They are generally benign and nonfunctional. These adrenal lesions are ACTH-independent.

Thymic neuroendocrine tumors occur in 3.4% of affected patients, with a 10-year survival of 25%. Lung neuroendocrine tumors occur in 13%, with a 10-year survival of 71%. Benign thyroid adenomas or multinodular goiter occurs in 55% of MEN 1 patients.

Nonendocrine tumors occur commonly in MEN 1, particularly small head-neck angiofibromas (85%) and lipomas (30%). Collagenomas are common (70%), presenting as firm dermal nodules. Affected patients may also be more prone to meningiomas, breast cancer, colorectal cancers, prostate cancer, and malignant melanomas.

2. MEN 2 (formerly MEN 2A)

Multiple endocrine neoplasia type 2 (MEN 2A, Sipple syndrome) is a rare autosomal-dominant tumor syndrome that arises in patients with a germline gain-of-function *ret* protooncogene mutation. Genetic testing identifies about 95% of affected individuals.

Medullary thyroid carcinoma (> 90%); hyperparathyroidism (30%), with hyperplasia or adenomas of multiple parathyroid glands developing in most cases; pheochromocytomas (30%), which are often bilateral and frequently asymptomatic; and Hirschsprung disease may develop. No patients with MEN 2 should receive therapy for diabetes with GLP-1 agonists, as they may increase the risk for medullary thyroid carcinoma. Before any surgical procedure, MEN 2 (2A) carriers should be screened for pheochromocytoma (see above) and for medullary thyroid carcinoma.

3. MEN 3 (formerly MEN 2B)

Multiple endocrine neoplasia type 3 (MEN 2B) is a familial, autosomal dominant multiglandular syndrome that is also caused by a germline gain-of-function mutation of the *ret* protooncogene. MEN 3 (2B) is characterized by mucosal neuromas (in > 90% of cases) with bumpy and enlarged lips and tongue, Marfan-like habitus (75% of cases), and adrenal pheochromocytomas (60%) that are rarely malignant and often bilateral. Patients also have intestinal abnormalities (75%) such as intestinal ganglioneuromas, skeletal abnormalities (87%), and delayed puberty (43%). Medullary thyroid carcinoma (80%) is aggressive and presents early in life.

4. MEN 4

Multiple endocrine neoplasia type 4 (MEN 4) is a rare autosomal-dominant familial tumor syndrome caused by germline mutations in the gene *CDKN1B*. Affected patients are particularly prone to parathyroid adenomas (80%), pituitary adenomas, pancreatic neuroendocrine tumors, and adrenal tumors. Unlike patients with MEN 1, those with MEN 4 are also prone to renal tumors, testicular cancer, neuroendocrine cervical carcinoma, and primary ovarian failure.

CLINICAL USE OF GLUCOCORTICOIDS

Prolonged treatment with high-dose corticosteroids causes toxic effects that can be life threatening. Besides oral and parenteral administration, transdermal and inhaled corticosteroids have some systemic absorption and can cause similar adverse effects. Patients should be thoroughly informed of the major possible side effects of treatment: insomnia, cognitive and personality changes, weight gain with central obesity, skin thinning and bruising, striae, muscle weakness, polyuria, renal calculi, diabetes mellitus, glaucoma, cataracts, sex hormone suppression, candidiasis, and opportunistic infections (Table 30–5). Prolonged high-dose corticosteroids also increase the risk of hypertension, dyslipidemia, MI, stroke, atrial fibrillation or flutter, and HF. Gastric ulceration is more common with high-dose corticosteroids, particularly when patients take NSAIDs concurrently. High-dose inhaled corticosteroids predispose to oral thrush and pulmonary nontuberculous mycobacterial infection. To reduce risks, the dosage and duration of corticosteroid administration must be minimized. Immediately following inhaled corticosteroids, proper mouthwashing and gargling can reduce systemic absorption.

Prolonged oral, inhaled, intravenous, or high-dose topical corticosteroid therapy commonly suppresses pituitary ACTH secretion, causing secondary adrenal insufficiency. Abrupt discontinuation of long-term corticosteroid therapy may cause a withdrawal syndrome with symptoms of adrenal insufficiency, hypotension, nausea, arthralgias, pruritus, and fatigue. Adrenal crisis occurs in 5–10% of such patients yearly, with an estimated 6% associated mortality.

Most corticosteroids (dexamethasone, prednisone, hydrocortisone, deflazacort, budesonide) are metabolized by the enzyme CYP34A. When drugs that inhibit CYP34A are administered along with even modest doses of corticosteroids (oral, inhaled, intravenous), the blood levels of the corticosteroids rise and can cause iatrogenic Cushing syndrome and secondary adrenal insufficiency. Medications that strongly inhibit CYP34A include itraconazole, ketoconazole, nefazodone, protease inhibitors, and cobicistat.

In pregnancy, corticosteroids taken by the mother are transmitted across the placenta to the fetus, causing adverse effects on fetal growth and development as well as childhood cognition and behavior. Therefore, women who are

Table 30–5. Management of patients receiving systemic corticosteroids.

Recommendations for prescribing

- Do not administer systemic corticosteroids unless absolutely indicated or more conservative measures have failed.
- Keep dosage and duration of administration to the minimum required for adequate treatment.

Monitoring recommendations

- Screen for tuberculosis with a purified protein derivative (PPD) test or interferon gamma release assay before commencing long-term corticosteroid therapy.
- Screen for pregnancy in reproductive age women; recommend contraceptive measures.
- Screen for diabetes mellitus before treatment and then every 3–4 months.
- Screen for hypertension before treatment and every 3–4 months.
- Screen for glaucoma and cataracts before treatment, 3 months after treatment inception, and then at least yearly.
- Monitor plasma potassium for hypokalemia and treat as indicated.
- Obtain bone densitometry before treatment and then periodically. Treat osteoporosis.
- Weigh daily. Use dietary measures to avoid obesity and optimize nutrition.
- Measure height frequently and obtain bone densitometry by DXA every 1–2 years to document the degree of axial spine demineralization and compression.
- Watch for fungal or yeast infections of skin, nails, mouth, vagina, and rectum, and treat appropriately.
- With dosage reduction, watch for signs of adrenal insufficiency or corticosteroid withdrawal syndrome.

Patient information

- Prepare the patient and family for possible adverse effects on mood, memory, and cognitive function.
- Teach the patient about the symptoms of hyperglycemia.
- Inform the patient about other possible side effects, particularly weight gain, osteoporosis, and aseptic necrosis of bone.
- Counsel to avoid smoking and excessive ethanol consumption.

Prophylactic measures

- Institute a vigorous physical exercise and isometric regimen tailored to each patient's abilities or disabilities.
- Administer calcium (1 g elemental calcium) and vitamin D_3, 400–800 units orally daily.
  - Check spot morning urine for calcium; alter dosage to keep urine calcium concentration < 30 mg/dL (< 7.5 mmol/L).
  - If the patient is receiving thiazide diuretics, check for hypercalcemia, and administer only 500 mg elemental calcium daily.
- If the patient has preexistent osteoporosis or has been receiving corticosteroids for ≥ 3 months, consider prophylaxis:
  - Bisphosphonate such as alendronate (70 mg every week orally), zoledronic acid (5 mg every year intravenously) for up to 3–5 years; Or
  - Teriparatide, 20 mcg subcutaneously daily for up to 2 years
- Avoid prolonged bed rest that will accelerate muscle weakness and bone mineral loss. Ambulate early after fractures.
- Avoid elective surgery, if possible. Vitamin A in a daily dose of 20,000 units orally for 1 week may improve wound healing, but it is not prescribed in pregnancy.
- Fall prevention strategies: walking assistance (cane, walker, wheelchair, handrails) when required due to weakness or balance problems; avoid activities that could cause falls or other trauma.
- For ulcer prophylaxis, if administering corticosteroids with NSAIDs, prescribe a PPI (not required for corticosteroids alone). Avoid large doses of antacids containing aluminum hydroxide (many popular brands) because aluminum hydroxide binds phosphate and may cause a hypophosphatemic osteomalacia that can compound corticosteroid osteoporosis.
- Treat hypogonadism.
- Treat infections aggressively. Consider unusual pathogens.
- Treat edema as indicated.

to receive high-dose corticosteroids should be screened for pregnancy and counseled to use contraception.

Osteoporotic fractures (especially vertebral) ultimately occur in about 40% of patients receiving long-term glucocorticoid therapy. Osteoporotic fractures can occur even in patients receiving long-term glucocorticoid therapy at relatively low doses (eg, 5–7.5 mg prednisone daily). The risk of vertebral fractures increases 14-fold and the risk of hip fractures increases 3-fold. Patients at increased risk for glucocorticoid-induced osteoporotic fractures include those who are over age 60 or who have a low BMI, pretreatment osteoporosis, a family history of osteoporosis, or concurrent disease that limits mobility. Avascular necrosis of bone (especially hips) develops in about 15% of patients who receive glucocorticoids at high doses (eg, prednisone 15 mg daily or more) for > 1 month with cumulative prednisone doses of 10 g or more.

Bisphosphonates (eg, oral alendronate or intravenous zoledronic acid) may prevent the development of osteoporosis among patients receiving prolonged courses of glucocorticoids (Table 30–5). Denosumab inhibits bone resorption but may increase the risk of infection compared to bisphosphonates; therefore, the use of denosumab is not recommended for patients at an increased risk for infection. The anabolic agent teriparatide is FDA approved for treatment of glucocorticoid-induced osteoporosis.

Humphrey MB et al. 2022 American College of Rheumatology guideline for the prevention and treatment of glucocorticoid-induced osteoporosis. Arthritis Care Res (Hoboken). 2023;75:2405. [PMID: 37884467]

Male Hypogonadism & Gynecomastia, Hirsutism & Virilization

31

Paul A. Fitzgerald, MD

MALE HYPOGONADISM

ESSENTIALS OF DIAGNOSIS

- Diminished libido and erections.
- Fatigue, depression, reduced exercise endurance.
- Testes small or normal in size.
- Low serum total testosterone or free testosterone.
- Hypogonadotropic hypogonadism: low or normal serum LH and FSH.
- Hypergonadotropic hypogonadism: testicular failure, high serum LH and FSH.

General Considerations

Male hypogonadism is caused by deficient testosterone secretion by the testes. It may be due to (1) insufficient gonadotropin secretion by the pituitary (hypogonadotropic); (2) pathology in the testes (hypergonadotropic); or (3) both (Table 31–1). Partial male hypogonadism may be difficult to distinguish from the physiologic reduction in serum testosterone seen in normal aging, obesity, and illness.

Etiology

A. Hypogonadotropic Hypogonadism (Low Testosterone with Normal or Low LH)

A deficiency in FSH and LH may be isolated or associated with other pituitary hormonal abnormalities (see Chapter 29). Hypogonadotropic hypogonadism can be primary, defined as failure to enter puberty by age 14, or it can be acquired. Causes of primary hypogonadotropic hypogonadism include congenital hypopituitarism, isolated hypogonadotropic hypogonadism, or simple constitutional delay of growth and puberty. Causes of acquired hypogonadotropic hypogonadism include genetic conditions, which account for about 40% of cases of isolated and idiopathic disease with a serum testosterone level < 150 ng/dL (5.2 nmol/L) (Table 31–1).

Partial male hypogonadotropic hypogonadism is defined as a serum testosterone in the range of 150–300 ng/dL (5.2–10.4 nmol/L). The main causes of acquired partial male hypogonadotropic hypogonadism include obesity, poor health, or normal aging, such that it is termed **age-related hypogonadism**. Hypogonadism also occurs commonly in patients with **opioid use disorder**. Other etiologies include pituitary or hypothalamic damage from factors such as tumors or traumatic brain injury (see Chapter 29). Spermatogenesis is usually preserved.

B. Hypergonadotropic Hypogonadism (Testicular Failure with High LH)

A failure of the testicular Leydig cells to secrete adequate testosterone causes a rise in LH and FSH. Acquired conditions that can cause testicular failure are listed in Table 31–1. Male hypergonadotropic hypogonadism can be caused by XY gonadal dysgenesis, partial 17-ketosteroid reductase deficiency, and a congenital partial deficiency in the steroidogenic enzyme CYP17 (17-hydroxylase). In men who have had a unilateral orchiectomy for cancer, the remaining testicle frequently fails, even in the absence of radiation or chemotherapy.

Klinefelter syndrome (47,XXY and its variants) is the most common chromosomal abnormality among males, with an incidence of about 1:500 (see Chapter 45). Although puberty occurs at the normal time, the degree of virilization is variable. Serum testosterone is usually low and gonadotropins are elevated. Adult men usually have somewhat reduced facial and pubic hair. Over 95% have azoospermia or severe oligospermia, although some sperm production is often present in their early teens. Other common findings include tall stature and abnormal body proportions that are unusual for hypogonadal men (eg, height > 3 cm greater than arm span).

XY gonadal dysgenesis describes several conditions that result in the failure of the testes to develop normally. *SRY* is a gene on the Y chromosome that initiates male sexual development. Mutations in *SRY* result in testicular dysgenesis. Affected individuals lack testosterone, which results in sex reversal: female external genitalia with a blind vaginal pouch, no uterus, and intra-abdominal dysgenetic gonads.

Table 31–1. Causes of male hypogonadism.

Hypogonadotropic (Low or Normal LH)	Hypergonadotropic (High LH)
Aging	Aging
Alcohol	Autoimmunity
Chronic illness	Anorchia (bilateral)
Constitutional delay of growth and puberty	Chemotherapy
Cushing syndrome	Idiopathic
Drugs	Klinefelter syndrome
Estrogen	Leprosy
GnRH agonist (leuprolide)	Lymphoma
Ketoconazole	Male climacteric
Marijuana	Myotonic dystrophy
Opioids (oral, injected, or intrathecal)	Noonan syndrome
Prior androgens	Orchiectomy (bilateral or unilateral)
Spironolactone	Orchitis
Genetic conditions[1]	Radiation or radioisotope therapy
Granulomatous diseases	Sertoli cell-only syndrome
Hemochromatosis	Testicular trauma
Hypopituitarism	Tuberculosis
Hypothalamic or pituitary tumors	Uremia
Hypo-, hyperthyroidism	Viral infections (mumps)
Idiopathic	XY gonadal dysgenesis
Kidney disease	
Lymphocytic hypophysitis	
Major medical or surgical illnesses	
Malnourishment	
Obesity (BMI > 30)	

[1] See text for discussion.
GnRH, gonadotropin-releasing hormone.

Affected individuals appear as normal girls until their lack of pubertal development and amenorrhea leads to the diagnosis. Intra-abdominal rudimentary testes have an increased risk of developing a malignancy and are usually resected.

C. Androgen Insensitivity

Partial resistance to testosterone is a rare condition in which phenotypic males have variable degrees of apparent hypogonadism, hypospadias, cryptorchism, and gynecomastia. Serum testosterone levels are normal.

▶ Clinical Findings

A. Symptoms and Signs

Hypogonadism that is congenital or acquired during childhood presents as delayed puberty. Men with acquired hypogonadism have variable manifestations, known as “testosterone deficiency syndrome.” Most men experience decreased libido. Others report erectile dysfunction, poor morning erection, or hot sweats. Men often have depression, fatigue, or decreased ability to perform vigorous physical activity. The presenting complaint may also be infertility, gynecomastia, headache, fracture, or other symptoms related to the cause or result of the hypogonadism. The patient’s history often gives a clue to the cause (Table 31–1).

Physical signs associated with hypogonadism may include decreased body, axillary, beard, or pubic hair, but only after years of severe hypogonadism. Men with hypogonadism lose muscle mass and gain weight due to an increase in subcutaneous fat. Examination should include measurements of arm span and height. Testicular size should be assessed with an orchidometer (normal volume is about 10–25 mL; normal length is 3–5 cm). Testicular size may decrease but usually remains within the normal range in men with postpubertal hypogonadotropic hypogonadism, but it may be diminished with testicular injury or Klinefelter syndrome. The testes must be palpated for masses and examined for evidence of trauma, infiltrative lesions (eg, lymphoma), or infection (eg, leprosy, tuberculosis).

B. Laboratory Findings

Serum testosterone circulates as “free” hormone and hormone bound to sex hormone–binding globulin. Serum total and free testosterone levels in men are highest at age 20–30 years. Thereafter, serum testosterone levels decline variably by an average of 1–2% annually; serum free testosterone levels decline even faster since sex hormone–binding globulin increases with age. In evaluating laboratory values for total and free testosterone, it is important to compare with age-adjusted reference ranges. Normal ranges for serum testosterone have been derived from non-fasting morning blood specimens, which tend to be the highest of the day.

The evaluation for hypogonadism begins with a morning (before 10 AM) blood draw for serum “ultrasensitive” total testosterone and free testosterone measurement. Serum total testosterone normal reference ranges vary with the lab and assay. **Serum *total* testosterone levels** are considered low if they are < 300 ng/dL (8.3 nmol/L); levels between 300 ng/dL and 350 ng/dL (12 nmol/L) are considered borderline low. **Serum *free* testosterone levels** are considered low if they are < 35 pg/mL (120 pmol/L); levels between 35 pg/mL and 40 pg/mL (140 pmol/L) are considered borderline low. A low serum testosterone or free testosterone should be verified with a repeat morning non-fasting assay, along with serum LH and PRL levels.

The main comorbid conditions that contribute to a decline in serum testosterone with aging include type 2 diabetes, obesity, metabolic syndrome, CVD, COPD, renal insufficiency, cancer, and opioids. After age 70, LH levels tend to rise, indicating a contribution of primary gonadal dysfunction. Testing for serum free testosterone is especially important for detecting hypogonadism in older men, who generally have high levels of sex hormone binding globulin. Serum LH levels are high in patients with hypergonadotropic hypogonadism but low or inappropriately normal in men with hypogonadotropic hypogonadism or normal aging. High serum estradiol levels are seen in men with obesity-related hypogonadotropic hypogonadism.

Mild anemia is common in men with hypogonadism. For men with long-standing severe male hypogonadism, osteoporosis is common, so bone densitometry is recommended.

1. Hypogonadotropic hypogonadism—A serum PRL determination is obtained to screen for a pituitary prolactinoma (see Table 29–1). Men with no discernible cause for hypogonadotropic hypogonadism should be screened for hemochromatosis. Adult men with hypogonadotropic hypogonadism should have an MRI of the pituitary/hypothalamus to search for a mass lesion in presence of one or more of the following: (1) severe hypogonadism (total testosterone below 150 ng/mL [5.2 nmol/L]), (2) elevated serum PRL, (3) other pituitary hormone deficiencies, or (4) symptoms of a mass lesion (headaches or visual field deficits).

2. Hypergonadotropic hypogonadism—Men with hypergonadotropic hypogonadism have low serum testosterone levels with a compensatory increase in FSH and LH. Klinefelter syndrome can be confirmed by karyotyping or by measurement of leukocyte XIST. Testicular biopsy is usually reserved for younger patients in whom the reason for primary hypogonadism is unclear.

Treatment

Testosterone replacement is reasonable for boys who have not entered puberty by age 14 years. It is also beneficial for most men with primary testicular failure (hypergonadotropic hypogonadism). Testosterone replacement or gonadal stimulation therapy is also warranted for men with severe hypogonadotropic hypogonadism of any etiology with serum testosterone levels < 150 ng/mL (5.2 nmol/L). Testosterone therapy should also be considered for men with low or low-normal serum testosterone or free testosterone, along with elevated serum LH levels. For other men without elevated serum LH levels and an average of at least two morning serum total testosterone levels below 275 ng/dL (9.5 nmol/L, “physiologic hypogonadism”), a trial of testosterone therapy may be considered, particularly if they have at least three of the following six symptoms: erectile dysfunction, poor morning erection, low libido, depression, fatigue, and inability to perform vigorous activity. Prior to treatment, it is prudent to screen for prostate cancer with a serum PSA in men over age 40.

Testosterone replacement should be continued only if patients clearly derive clinical benefit from therapy. Therapy can be adjusted with an aim to improve clinical symptoms while maintaining normal serum levels of testosterone or free testosterone. Men with physiologic low-normal serum testosterone levels above 325 ng/dL (11.3 nmol/L) are unlikely to benefit from testosterone therapy.

Drug interactions can occur. Testosterone should be administered cautiously to men receiving coumadin, since the combination can increase the INR and risk of bleeding. Testosterone can predispose to hypoglycemia in men with diabetes receiving insulin or oral hypoglycemic agents, so close monitoring of blood sugars is advisable during initiation of testosterone therapy.

A. Therapies for Male Hypogonadism

1. Testosterone topical gels—Topical testosterone is usually applied once daily in the morning after showering. One or two fingers are used to apply the gel evenly to skin, followed by hand washing. Topical testosterone should not be applied to the breast or genitals. The gel should be allowed to air-dry (about 10 minutes) before dressing. Before close contact with people, a shirt must be worn or the areas of application washed with soap and water to prevent transfer of testosterone to them. The patient should avoid swimming, showering, or washing the application area for at least 2 hours following application. Table 31–2 lists topical testosterone formulations and dosages.

The serum testosterone level should be determined about 14 days after starting therapy; if the level remains below normal or the clinical response is inadequate, the daily dose may be increased to 1.5–2 times the initial dose.

Table 31–2. Topical testosterone formulations and recommended daily doses.

Medication	Available Formulations	Recommended Daily Dose and Suggestion Application Site
Testosterone 1% gel	*Packets:* 12.5 mg/1.25 g, 25 mg/2.5 g, or 50 mg/5 g *Tubes:* 50 mg/5 g	50–100 mg
Testosterone 2% gel	*Pump:* 10 mg/0.5 g actuation	40–70 mg
Androgel 1% gel	*Packets:* 25 mg/2.5 g, 50 mg/5 g *Pump:* 12.5 mg per actuation	50–100 mg Apply to the shoulders
Androgel 1.6% gel	*Pump:* 20.25 mg per actuation	40.5–81 mg
Testim 1% gel	*Tubes:* 50 mg/5 g	50–100 mg Apply to shoulders, upper arms, or abdomen
Fortesta 2% gel	*Pump:* 10 mg per actuation	40–70 mg Apply to shoulders, upper arms, or abdomen
Testogel (not available in the United States)	*Sachet:* 50 mg/5 g	Apply to shoulders, upper arms, or abdomen
Axiron 2% solution	*Pump:* 30 mg per actuation	30–60 mg Apply to each axilla daily
Vogelxo 1% gel	*Packets or tubes:* 50 mg/5 g *Pump:* 12.5 mg/1.25 g per actuation	50–100 mg Apply to the shoulders

Serum testosterone levels vary considerably during the day after topical testosterone gel application, such that a single serum testosterone level may not accurately reflect the average serum testosterone for that individual.

2. Transdermal testosterone patches—Testosterone transdermal systems (skin patches) are applied to nongenital skin. Androderm (2 or 4 mg/day) patches may be applied at bedtime in doses of 4–8 mg; they adhere tightly to the skin and may cause skin irritation.

3. Parenteral testosterone—The dose and injection intervals are adjusted according to the patient's clinical response and serum testosterone levels drawn just before the next injection is due. A target serum testosterone level of 500 ng/dL (17.3 nmol/L) is suggested. **Testosterone cypionate** is an intramuscular testosterone formulation that is available in solutions containing 200 mg/mL. Its main advantage is low cost. The usual dose is 200 mg every 2 weeks or 300 mg every 3 weeks. It is usually injected into the gluteus medius muscle in the upper lateral buttock, alternating sides. The injection technique must include sterile precautions and draw-back prior to injection to ensure against intravenous injection, which can result in pulmonary oil embolism.

Testosterone pellets (Testopel) are a long-lasting depot testosterone formulation that is available as individual vials containing a single 75 mg implantable pellet in each vial. With sterile technique, the skin of the upper-outer buttock is anesthetized with lidocaine; using a trocar, the pellets are injected subcutaneously in doses of 150–450 mg every 3–6 months as an in-office procedure.

Testosterone undecanoate (Aveed) is a long-lasting depot testosterone formulation that is restricted to qualified health care facilities, due to the risk of anaphylaxis and pulmonary oil embolism.

4. Buccal testosterone—Testosterone buccal tablets (Striant) are placed between the upper lip and gingivae. One or two 30-mg tablets are thus retained and changed every 12 hours. They should not be chewed or swallowed. It is not available in the United States.

5. Testosterone nasal gel—Intranasal gel testosterone (Natesto) is self-administered by a metered-dose nasal pump: one pump actuation (5.5 mg) into each nostril three times daily. The nasal pump needs to be primed by inverting it and pressing the pump 10 times before it is used the first time. It should not be used concurrently with intranasal sympathomimetic decongestants. Adverse effects include nasopharyngitis, sinusitis, bronchitis, epistaxis, nasal discomfort, and headache.

6. Oral testosterone undecanoate—Three oral capsule preparations of testosterone undecanoate (Jatenzo 158 mg, 198 mg, 237 mg; Kyzatrex 100 mg, 150 mg, 200 mg; Tlando 112.5 mg) are FDA-approved for the treatment of primary and hypogonadotropic hypogonadism. The recommended starting doses are Jatenzo, 237 mg twice daily; Kyzatrex, 200 mg twice daily; and Tlando, 225 mg twice daily, each taken with food. Dose adjustments are made after 7 days according to clinical response and serum testosterone levels obtained 3–9 hours (varies with each formulation) after oral dose. Side effects are those of nonoral testosterone with additional side effects including an increase in systolic blood pressure (average 4 mm Hg) with risk of adverse cardiovascular events, polycythemia, and GI intolerance.

7. Clomiphene citrate—Men with functional hypogonadotropic hypogonadism usually respond well to clomiphene citrate that is administered orally in doses that are titrated to achieve the desired clinical response with a serum testosterone level of about 500 ng/dL (17.3 nmol/L). Begin with clomiphene 25 mg on alternate days and increased to 50 mg on alternate days if necessary, with a maximum dose of 50 mg daily. Serum testosterone levels usually normalize while spermatogenesis usually improves.

8. Gonadotropins—Patients with hypogonadotropic hypogonadism may require therapy with gonadotropins, particularly to induce fertility. Men may receive hCG 2000 U subcutaneously three times weekly for 6 months; if the semen analysis shows inadequate sperm, FSH 75 units subcutaneously three times weekly is added. Men often prefer long-term therapy with hCG over transdermal testosterone therapy, since hCG therapy maintains higher serum testosterone levels in the upper-half of the reference range, thereby improving masculinization and muscle strength. The dose of hCG for chronic administration is 1500 to 2000 units subcutaneously three times weekly, with adjustments according to serum testosterone determinations.

9. Weight loss—When hypogonadotropic hypogonadism is due to morbid obesity, significant weight loss often improves serum testosterone levels. The rise in serum testosterone is proportionate to the weight loss.

B. Benefits of Testosterone Replacement or Stimulation Therapy

Testosterone therapy given for the indications listed under Treatment usually benefits men with low serum testosterone and at least three manifestations of hypogonadism. Replacement testosterone therapy can improve overall mood, sense of well-being, sexual desire, and erectile function. It also improves anemia, bone density, physical vigor, and muscle strength. Testosterone replacement improves exercise endurance and stair climbing ability. Long-term testosterone replacement causes significant weight loss and a reduction in waist circumference. After 2 years of testosterone replacement, muscle mass increases about 4.5%, while fat mass decreases by about 9.1%. Appropriate testosterone replacement therapy also appears to improve longevity.

C. Risks of Testosterone Replacement or Stimulation Therapy

Testosterone therapy does not appear to increase the risk of prostate cancer or BPH above that of normal men, provided serum testosterone levels are maintained in the normal reference range. However, testosterone therapy is contraindicated in the presence of active prostate cancer. Hypogonadal men who have had a prostatectomy for low-grade prostate cancer, and who have remained in complete remission for several years, may have testosterone therapy given cautiously while monitoring serum PSA levels.

In the large double-blind placebo-controlled TRAVERSE study of transdermal testosterone replacement in hypogonadal men at high cardiac risk, there was no increase risk observed in death, major cardiovascular events, BPH, or prostate cancer. However, there was a small increased risk for PE (0.9% versus 0.5%), atrial fibrillation (3.5% versus 2.4%), and kidney injury (2.3% versus 1.5%). Another study showed a small increased fracture risk (3.5% versus 2.5%).

Erythrocytosis is more common with intramuscular injections of testosterone enanthate than with transcutaneous testosterone. Testosterone therapy tends to aggravate sleep apnea in older men, likely through CNS effects. A formal evaluation for sleep apnea is recommended for all high-risk patients with snoring, obesity, partner's report of apneic episodes, nocturnal awakening, unrefreshing sleep with daytime fatigue, or hypertension.

Testosterone therapy frequently increases acne that is usually mild and tolerated; topical antiacne therapy or a reduction in testosterone replacement dosage may be required. Increases in intraocular pressure have occurred during testosterone therapy. During the initiation of testosterone replacement therapy, gynecomastia develops in some men, which usually is mild and tends to resolve spontaneously; switching from testosterone injections to testosterone transdermal gel may help this condition.

D. Risks of Performance-Enhancing Anabolic Steroids

Performance-enhancing agents, particularly androgenic anabolic steroids, are used by up to 2% of young athletes and by 20–65% of power sport athletes. They are often used as part of a "stacking" polypharmacy that may include nandrolone decanoate, dimethandrolone, testosterone propionate, or testosterone enanthate. These androgens are usually illegal, often contaminated by toxic substances (such as arsenic), and can produce toxic hepatitis, dependence, aggression, depression, dyslipidemias, gynecomastia, acne, male pattern baldness, hepatitis, thromboembolism, and cardiomyopathy. Arsenic contamination can cause multiorgan failure and death.

Prognosis of Male Hypogonadism

If hypogonadism is due to a pituitary lesion, the prognosis is that of the primary disease (eg, tumor, necrosis). The prognosis for restoration of virility is good if testosterone is given. In one large study, cardiovascular risk was reduced in hypogonadal men over age 40 who were receiving testosterone replacement therapy to maintain serum testosterone levels within the normal reference range.

CRYPTORCHISM

Cryptorchidism is present in about 5% of full-term males at birth, but half of them have spontaneous testicular descent by age 6 months. Cryptorchism must be distinguished from retractile testes, which require no treatment.

Infertility or subfertility occurs in up to 75% of adult men with bilateral cryptorchism and in 50% of men with unilateral cryptorchism. The recommended age for orchidopexy for cryptorchid testes is 6 months. Early orchidopexy may improve fertility and reduce later malignancy risk. The risk for testicular malignancy is higher for cryptorchid testes (0.06%) and for intra-abdominal testes (5%). For intra-abdominal testes, orchiectomy after puberty is usually the best option. Adult men who have had unilateral ochidopexy in childhood experience increased rates of erectile dysfunction, infertility, anxiety, and depression.

GYNECOMASTIA

ESSENTIALS OF DIAGNOSIS

- Palpable enlargement of the male breast, often asymmetric or unilateral.
- Glandular gynecomastia: typically tender.
- Fatty gynecomastia: typically nontender.
- Must be distinguished from carcinoma or mastitis.

General Considerations

Gynecomastia is defined as the presence of palpable glandular breast tissue in males. Gynecomastia is a common condition, and its incidence is increasing in all age groups. The causes are multiple and diverse (Table 31–3). Pubertal gynecomastia develops in 60% of boys, more commonly teenagers who are overweight; the swelling usually subsides spontaneously within a year. About 20% of adult gynecomastia is caused by drug therapy. It can develop in men with HIV treated with antiretroviral therapy, especially efavirenz

Table 31–3. Causes of gynecomastia.

Physiologic causes
- Aging
- Neonatal period, puberty
- Obesity

Endocrine diseases
- Androgen resistance syndromes
- Aromatase excess syndrome (sporadic or familial)
- Diabetic lymphocytic mastitis
- Hyperprolactinemia
- Hyper- or hypothyroidism
- Klinefelter syndrome
- Male hypogonadism (primary or secondary)
- Partial 17-ketosteroid reductase deficiency

Systemic diseases
- Chronic liver disease
- CKD stage 4–5
- HIV
- Leprosy (Hansen disease)
- Neurologic disorders
- Refeeding after starvation
- Spinal cord disorders

Neoplasms
- Adrenal tumors: secretion of estrogen or estrogen precursors
- Bronchogenic carcinoma
- Breast carcinoma
- Ectopic hCG: CNS germinoma, lung, hepatocellular, gastric, renal carcinomas
- Pituitary prolactinoma
- Testicular tumors: secretion of estrogen or hCG

Drugs (partial list)
- Alcohol (ethanol)
- Alkylating chemotherapeutic agents
- 5-α reductase inhibitors (finasteride, dutasteride)
- Amiodarone
- Anabolic steroids
- Androgens (testosterone)
- Anti-androgens (eg, flutamide, bicalutamide)
- Antipsychotics (first- and second-generation)
- Antiretrovirals
- Calcium channel blockers (rare)
- Chorionic gonadotropin
- Cimetidine
- Clomiphene
- Diazepam
- Digitalis preparations
- Domperidone
- DPP-4 inhibitors (sitagliptin)
- Estrogens (oral or topical)
- Ethionamide
- Famotidine (rare)
- Fenofibrate (rare)
- Finasteride
- GH
- GnRH analogs
- Hydroxyzine
- Isoniazid
- Ketoconazole
- Lavender and tea tree oils (topical)
- Marijuana
- Melatonin
- Methadone
- Methyldopa
- Metoclopramide
- Metronidazole
- Minocycline
- Opioids
- Phenothiazines
- Phenytoin
- Progestins
- PPIs (uncommon)
- Sulindac
- SSRIs
- Soy ingestion
- Statins (rare)
- Spironolactone (common)
- Sunitinib
- Tyrosine kinase inhibitors
- Tea tree oil (topical)
- Tricyclics

GH, growth hormone; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin.

or didanosine, and in athletes who abuse androgens and anabolic steroids. Fatty pseudogynecomastia is common among older men, particularly when there is associated weight gain. True glandular gynecomastia can be the first sign of a serious disorder in older men (Table 31–3).

Clinical Findings

A. Symptoms and Signs

The male breasts must be palpated to distinguish firm true glandular gynecomastia from softer fatty pseudogynecomastia in which only adipose tissue is felt. The breasts are best examined both seated and supine. Using the thumb and forefinger as pincers, the subareolar tissue is compared to nearby adipose tissue. Fatty tissue is usually diffuse and nontender. True glandular enlargement beneath the areola may be tender. Pubertal gynecomastia is characterized by tender discoid enlargement of breast tissue 2–3 cm in diameter beneath the areola. The following characteristics are worrisome for malignancy: asymmetry; location not immediately below the areola; unusual firmness; or nipple retraction, bleeding, or discharge. The examination must also include an assessment of masculinization, examination of the testes for size and masses, and examination of the penis for hypospadias.

B. Laboratory Findings

In the presence of true glandular gynecomastia, laboratory studies should include liver biochemical tests, serum BUN, and creatinine. Endocrine testing, including serum testosterone, free testosterone, LH, FSH, TSH, and FT_4, is obtained to determine whether primary hypogonadism (low serum testosterone, high LH), secondary hypogonadism (low serum testosterone, low or normal LH), or androgen resistance may be present. High serum testosterone levels plus high LH levels characterize partial androgen insensitivity syndrome. A serum PRL is obtained to screen for hyperprolactinemia and pituitary/hypothalamic lesions. Serum β-hCG and estradiol levels are obtained to screen for malignancy-associated gynecomastia. Detectable levels of β-hCG implicate a testicular tumor (germ cell or Sertoli cell) or other malignancy (usually lung or liver). Increased serum estradiol levels may result from testicular tumors, increased β-hCG, liver disease, obesity, adrenal tumors (rare), true hermaphroditism (rare), or aromatase gene gain-of-function mutations (rare). A karyotype for Klinefelter syndrome is obtained in men with persistent gynecomastia without obvious cause.

C. Imaging and Biopsy

Investigation of unclear cases should include bilateral mammography and a chest CT to search for bronchogenic or metastatic carcinoma. Benign mammographic findings make malignancy very unlikely. Suspicious mammographic findings require ultrasound-guided FNA and cytologic examination to distinguish gynecomastia from benign lesions (pseudogynecomastia, lipoma, posttraumatic hematoma/fat necrosis, epidermal inclusion cyst), lymphoma, and male breast cancer. Male breast cancer and gynecomastia may coexist.

Men with a high serum hCG or estradiol levels should have the test confirmed with repeat testing. Confirmed increased levels warrant a testicular ultrasound. If the testicular ultrasound is normal, high serum estradiol levels may warrant a CT of the adrenal glands; high serum hCG levels may warrant additional CT scanning to detect rare hCG-secreting carcinomas of the lung, mediastinum, liver, stomach, or kidney.

Treatment

Pubertal gynecomastia often resolves spontaneously within 1–3 years. Drug-induced gynecomastia resolves within months in most patients after the offending drug is removed. Patients with painful or persistent gynecomastia may be treated with medical therapy, usually for 9–12 months.

Selective estrogen receptor modulator (SERM) therapy is effective for true glandular gynecomastia. Raloxifene, 60 mg orally daily for 3–4 months, reduces breast volume by > 50% in about 90% of patients. Tamoxifen reduces breast volume by > 50% in about 60% of patients.

Aromatase inhibitor (AI) therapy is also reasonably effective. A starting dose of anastrozole for male gynecomastia is 0.5 mg orally three times weekly. Serum estradiol is monitored and the dose adjusted to keep the serum estradiol in the middle of the male reference range. Anastrozole reduces breast volume significantly in about 50% of adolescents over 6 months; significant size reduction can be seen within 1 month. Serum estradiol levels fall while serum testosterone levels rise. Long-term AI therapy in adolescents is not recommended because of the possibility of inducing osteoporosis and of delaying epiphyseal fusion, which could cause an increase in adult height.

Testosterone therapy for men with hypogonadism may improve or worsen preexistent gynecomastia.

Surgical correction is reserved for patients with persistent or severe gynecomastia.

Swerdloff RS et al. Gynecomastia: etiology, diagnosis, and treatment. Endotext (internet). 2023. [PMID: 25905330]

HIRSUTISM & VIRILIZATION

ESSENTIALS OF DIAGNOSIS

- Hirsutism, acne, menstrual disorders.
- Virilization: muscularity, androgenic alopecia, deepening voice, clitoromegaly.
- Rarely, a palpable pelvic tumor.
- Serum DHEAS and androstenedione elevated in adrenal disorders; variable in others.
- Serum testosterone is often elevated.

General Considerations

Hirsutism is defined as cosmetically unacceptable terminal hair growth that appears in women in a male pattern. Significant hirsutism affects about 5–10% of non-Asian women of reproductive age and over 40% of women at some point during their life. The amount of hair growth deemed unacceptable depends on a woman's ethnicity and cultural norms. Virilization is defined as the development of male physical characteristics in women, such as pronounced muscle development, deep voice, male pattern baldness, and more severe hirsutism.

Etiology

Hirsutism may be idiopathic or familial or be caused by the following disorders: polycystic ovary syndrome (PCOS), ovarian hyperthecosis, steroidogenic enzyme defects, neoplastic disorders; or rarely by medications, acromegaly, or ACTH-induced Cushing disease.

A. Idiopathic or Familial

Most women with hirsutism or androgenic alopecia have no detectable hyperandrogenism; hirsutism may be considered normal in the context of their genetic background. Such patients may have elevated serum levels of androstenediol glucuronide, a metabolite of dihydrotestosterone that is produced by skin in cosmetically unacceptable amounts.

B. Polycystic Ovary Syndrome (Hyperthecosis, Stein-Leventhal Syndrome)

PCOS is a common functional disorder of the ovaries of unknown etiology (see Chapter 21). It accounts for at least 50% of all cases of hirsutism associated with elevated serum testosterone levels.

A diagnosis of PCOS must meet three criteria: (1) androgen excess with clinical hyperandrogenism or elevated serum free or total testosterone; (2) ovarian dysfunction with oligoanovulation or polycystic ovary morphology; and (3) absence of other causes of testosterone excess or anovulation such as pregnancy, thyroid dysfunction, 21-hydroxylase deficiency, neoplastic testosterone secretion, Cushing syndrome, or hyperprolactinemia.

Affected women usually have signs of hyperandrogenism, including hirsutism, acne, or male-pattern thinning of scalp hair; this persists after natural menopause. However, women of East Asian descent are less likely to exhibit hirsutism. Most women also have elevated serum testosterone or free testosterone levels. About 70% of affected women have polycystic ovaries on pelvic ultrasound and 50% have oligomenorrhea or amenorrhea with anovulation. Of note, about 30% of women with PCOS do *not* have cystic ovaries and 25–30% of normal menstruating women *have* cystic ovaries.

Obesity and high serum insulin levels (due to insulin resistance) contribute to the syndrome in 70% of women. The serum LH:FSH ratio is often > 2.0. Both adrenal and ovarian androgen hypersecretion are commonly present.

C. 46,XX Karyotype: Congenital Adrenal Hyperplasia

Congenital adrenal steroidogenic enzyme defects result in reduced cortisol secretion with a compensatory increase in ACTH that causes adrenal hyperplasia. The most common enzyme defect in 46,XX is 21-hydroxylase deficiency, with a prevalence of about 1:18,000.

Congenital adrenal hyperplasia (CAH) can present at birth with clitoromegaly or later in puberty as hirsutism or virilization. Partial deficiency in adrenal 21-hydroxylase can present in women as hirsutism. About 2% of patients with adult-onset hirsutism have been found to have a partial defect in adrenal 21-hydroxylase. The phenotypic expression is delayed until adolescence or adulthood.

D. 46,XY Karyotype: Defects in Androgen Action or Synthesis

Phenotypically normal-appearing girls with a 46,XY karyotype can virilize to various extent at puberty. This can be caused by **partial androgen insensitivity syndrome.** Virilization at puberty can also be caused by mutations in the ***SRD5A2*** gene, resulting in **5-α-reductase** deficiency that causes a reduced conversion of testosterone to dihydrotestosterone. **Gonadal dysgenesis** (GD) refers to incomplete differentiation of the gonads. It can be caused by several different germline mutations and can cause hirsutism or virilization at puberty.

E. Neoplastic Disorders

Ovarian tumors are uncommon causes of hirsutism (0.8%) and include arrhenoblastomas, Sertoli-Leydig cell tumors, dysgerminomas, and hilar cell tumors. Adrenal carcinoma, a rare cause of Cushing syndrome and hyperandrogenism, can be quite virilizing. Pure androgen-secreting adrenal tumors occur very rarely; about 50% are malignant.

F. Rare Causes of Hirsutism and Virilization

Acromegaly and ACTH-induced Cushing syndrome are rare causes of hirsutism and virilization. Porphyria cutanea tarda can cause periorbital hair growth in addition to dermatitis in sun-exposed areas. Maternal virilization during pregnancy may result from a luteoma of pregnancy, hyperreactio luteinalis, or polycystic ovaries. In postmenopausal women, diffuse stromal Leydig cell hyperplasia is a rare cause of hyperandrogenism. Pharmacologic causes include minoxidil, cyclosporine, phenytoin, anabolic steroids, interferon, cetuximab, diazoxide, and certain progestins.

Clinical Findings

A. Symptoms and Signs

Modest androgen excess from any source increases sexual hair (chin, upper lip, abdomen, and chest) and increases sebaceous gland activity, producing acne. Menstrual irregularities, anovulation, and amenorrhea are common. If androgen excess is pronounced, defeminization (decrease in breast size, loss of feminine adipose tissue) and virilization (androgenic balding, muscularity, clitoromegaly, and deepening of the voice) occur. Virilization points to the presence of an androgen-producing neoplasm.

Hirsutism is quantitated using the Ferriman-Gallwey score; it is graded from 0 (none) to 4 (severe) in 9 areas of the body, with a maximum possible score of 36 (https://myendoconsult.com/learn/ferriman-gallwey-score/).

A pelvic examination may disclose clitoromegaly or ovarian enlargement that may be cystic or neoplastic. Hypertension may be present in Cushing syndrome, adrenal 11-hydroxylase deficiency, or cortisol resistance syndrome.

B. Laboratory Testing and Imaging

Serum androgen testing is mainly useful to screen for rare occult adrenal or ovarian neoplasms. Testing is warranted for women with moderate to severe hirsutism, mild hirsutism with menstrual disturbances, and women with worsening hirsutism despite therapy.

Serum is assayed for total testosterone and free testosterone. A serum testosterone level > 200 ng/dL (6.9 nmol/L) or free testosterone > 40 ng/dL (140 pmol/L) indicates the need for a manual pelvic examination and pelvic ultrasound. If that is negative, an adrenal CT scan is performed. A serum androstenedione level > 1000 ng/dL (34.9 nmol/L) also points to an ovarian or adrenal neoplasm.

Patients with a serum DHEAS > 700 mcg/dL (35 nmol/L) have an adrenal source of androgen. This usually is due to adrenal hyperplasia and rarely to adrenal carcinoma. Patients with any clinical signs of Cushing syndrome should receive a screening test (eg, 1-mg overnight dexamethasone suppression test) (see Chapter 29).

Screening for nonclassical “late-onset” congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency is warranted for women with (1) high serum testosterone or free testosterone levels and (2) hirsutism with normal serum testosterone levels who are at high risk for CAH due to having a family history of hirsutism or being a member of a high-risk ethnic group (eg, Ashkenazi Jews, Croatians, Iranians, Yupik Inuit). Patients with CAH usually have a baseline 17-hydroxyprogesterone level > 300 ng/dL (9.1 nmol/L). Serum levels of FSH and LH are elevated if amenorrhea is due to ovarian failure. An LH:FSH ratio > 2.0 is common in patients with PCOS. On abdominal ultrasound, about 25–30% of normal young women have polycystic ovaries, so the appearance of ovarian cysts on ultrasound is not helpful. Pelvic transvaginal ultrasound or MRI usually detects virilizing tumors of the ovary. However, small virilizing ovarian tumors may not be detectable on imaging studies; selective venous sampling for testosterone may be used for diagnosis in such patients.

Treatment

Any drugs causing hirsutism (see above) should be stopped. Any underlying medical causes of hirsutism (eg, Cushing syndrome, acromegaly) should be treated.

A. Laser and Topical Treatments

Local treatment of facial hirsutism is by shaving or depilatories, waxing, electrolysis, or bleaching. Eflornithine (Vaniqa) 13.9% topical cream retards hair growth when applied twice daily to unwanted facial hair; improvement is noted within 4–8 weeks. Eflornithine may be used during laser therapy for a more dramatic response. However, local skin irritation may occur. Hirsutism returns with discontinuation, unless it is given with laser therapy.

Laser therapy (photoepilation) can be a very effective treatment for facial hirsutism, particularly for women with dark hair and light skin. For women of color, a longer-wavelength laser such as Nd:YAG or diode laser given with skin cooling is used. In such women, laser removal of facial hair significantly improves hirsutism. Repeated laser treatments are usually required. Laser therapy is not recommended for Middle Eastern and Mediterranean women with facial hirsutism, since they have a particularly increased risk of paradoxical hypertrichosis with laser therapy.

Topical minoxidil is mildly effective for treatment of androgenic alopecia. One-half capful of 5% foam or 1 mL 2% solution is applied to the scalp twice daily.

B. Medications

Oral contraceptives are warranted as an initial therapy for women with hirsutism who are not actively pursuing pregnancy. To reduce the risk of DVT, an oral contraceptive is recommended with a low-dose of estradiol (20 mcg) and a progestin having a relatively low risk of venous thrombosis (norethindrone, norgestimate, levonorgestrel). A favored formulation for daily use contains norethindrone 1 mg with ethinyl estradiol 20 mcg. Nevertheless, such oral contraceptives confer over twofold increased risk of DVT. Also, levonorgestrel causes insulin resistance, so its use is problematic in women with polycystic ovary syndrome. Oral contraceptives that contain particularly antiandrogenic progestins such as desogestrel (Azurette, Kariva), drospirenone (Yaz, Gianvi), norgestimate (Ortho Tri-Cyclen Lo), or cyproterone acetate (Diane 35, not available in United States) more effectively reduce hirsutism and acne; however, such antiandrogenic oral contraceptives confer a fourfold risk of DVT, and their use is discouraged in high-risk patients.

Cyproterone acetate is a unique progestin that is used to treat women with hirsutism worldwide, except in the United States, where it is not FDA-approved. Cyproterone acetate blocks androgen receptors as well as 5-α-reductase activity while also suppressing testosterone levels. It is typically prescribed as an oral contraceptive in a dose of 2 mg with ethinyl estradiol 35 mcg.

Combined oral contraceptives are relatively contraindicated for women who have a personal history of or who are predisposed to thromboembolism, such as women who (1) are smokers, (2) have migraines, (3) are over age 39 years, (4) have obesity, or (5) have hypertension. Metabolic syndrome and hypertriglyceridemia are seen, particularly with antiandrogenic progestins.

Spironolactone is effective for reducing hirsutism, acne, and androgenic alopecia in women. It may be taken in doses of 100–200 mg orally daily (taken as a single dose or in two divided doses) on days 5–25 of the menstrual cycle or daily if used concomitantly with an oral contraceptive. Spironolactone is contraindicated in pregnancy, so reproductive-age women must use reliable contraception during this therapy. Hyperkalemia is an uncommon side effect, but serum potassium should be checked 1 month after beginning therapy or after dosage increases. Spironolactone should be avoided or used cautiously in women with kidney disease or who are taking an ACE inhibitor or ARB. Side effects of spironolactone include breast tenderness, menstrual irregularity, headaches, nausea, and fatigue, which may improve with continued treatment or dose reduction; paradoxical scalp hair loss has been reported at higher doses.

Flutamide and **bicalutamide** inhibit testosterone binding to androgen receptors and also suppress serum testosterone. Flutamide reduces abdominal adiposity and serum LDL cholesterol in women with PCOS. They should only be used as a last resort for women with severe hirsutism/virilization and only with very close monitoring for hepatic toxicity and strict contraceptive precautions due to risks of fetal malformations.

Finasteride inhibits 5-α-reductase, the enzyme that converts testosterone to active dihydrotestosterone in the skin. Finasteride is used off-label for its anti-androgen effects to treat women with hirsutism and transgender women. The usual dose for hirsutism is 5 mg once daily. Due to the risk of inducing pseudohermaphroditism in male fetuses if mistakenly taken during pregnancy, finasteride for hirsutism is given only with strict contraceptive precautions.

Oral minoxidil is used off-label for androgenic alopecia in women in doses of 0.25 mg to 2.5 mg daily, taken once daily or in divided doses. Side effects of oral minoxidil can include hair growth in undesirable locations

Simvastatin and **atorvastatin** can reduce hirsutism in women with PCOS. When given to women taking an oral contraceptive, these statins lead to a greater decrease in hirsutism and serum free testosterone than an oral contraceptive alone.

Women with classical congenital adrenal hyperplasia (21-hydroxylase deficiency) with hirsutism and adrenal insufficiency require **glucocorticoid and mineralocorticoid replacement**. However, women with partial “late-onset” 21-hydroxylase deficiency are not cortisol deficient and do not require glucocorticoid replacement. Glucocorticoids are ineffective in reducing hirsutism in these women. However, replacement doses of glucocorticoids (prednisone, methylprednisolone) may be indicated to normalize menses and for ovulation induction.

Crinecerfont, a corticotropin releasing factor pituitary receptor antagonist, is used for treating hirsutism and virilization in women with congenital adrenal hyperplasia (21-hydroxylase deficiency). At a dose of 100 mg twice daily, it dramatically decreases androstenedione production. Patients may experience fatigue that usually improves with time and glucocorticoid replacement optimization.

GnRH agonist therapy has been successful in treating postmenopausal women with severe ovarian hyperandrogenism when laparoscopic oophorectomy is contraindicated or declined by the patient.

C. Surgery

Androgenizing tumors of the adrenal or ovary are resected laparoscopically. Postmenopausal women with severe hyperandrogenism should undergo laparoscopic bilateral oophorectomy (if CT scan of the adrenals and ovaries is normal), since small hilar cell tumors of the ovary may not be visible on scans. Women with classic salt-wasting congenital adrenal hyperplasia and infertility or treatment-resistant hyperandrogenism may be treated with laparoscopic bilateral adrenalectomy.

Diabetes Mellitus & Hypoglycemia

Savitha Subramanian, MD
Amy Eby, MD
Umesh Masharani, MB, BS

DIABETES MELLITUS

ESSENTIALS OF DIAGNOSIS

Type 1 diabetes

- Polyuria, polydipsia, and weight loss with random plasma glucose ≥ 200 mg/dL (11.1 mmol/L).
- Plasma glucose ≥ 126 mg/dL (7.0 mmol/L) after an overnight fast, documented on more than one occasion.
- Ketonemia, ketonuria, or both.
- Islet autoantibodies frequently present.
- Generally progresses from stage 1 (autoantibodies but normal glucose tolerance) to stage 2 (autoantibodies with glucose intolerance) to stage 3 (symptomatic disease).

Prediabetes

- An intermediate stage of glucose dysregulation between normal blood glucose and development of type 2 diabetes
- Fasting plasma glucose 100–125 mg/dL (6.1–6.9 mmol/L), plasma glucose 2 hours after 75 g oral glucose 140–199 mg/dL (7.8–11 mmol/L), and/or HbA_{1c} (5.7–6.4%)
- More than 1 in 3 US adults have prediabetes.

Type 2 diabetes

- Most patients are > 40 years of age and have obesity, but onset at any age is possible
- Polyuria and polydipsia, ketonuria, and weight loss are less common at time of diagnosis
- Candidal vaginitis may be an initial manifestation, or asymptomatic
- Plasma glucose ≥ 126 mg/dL after an overnight fast on more than one occasion, and/or 2 hours after 75 g oral glucose, plasma glucose ≥ 200 mg/dL (11.1 mmol)
- HbA_{1c} ≥ 6.5%

Epidemiologic Considerations

An estimated 38.4 million persons (11.6%) in the United States have diabetes mellitus, of whom approximately 5–10% have type 1 diabetes and most others (90–95%) have type 2 diabetes. There is a global epidemic of type 2 diabetes, and the economic burden is significant. A third group designated as "other specific types" by the American Diabetes Association (ADA) (Table 32–1) numbers in the thousands (https://www.cdc.gov/diabetes/php/data-research/).

Classification & Pathogenesis

A. Type 1 Diabetes Mellitus

Type 1 diabetes is an autoimmune disorder with progressive destruction of pancreatic islet β cells resulting in endogenous insulin deficiency and hyperglycemia. In this catabolic disorder, circulating insulin is virtually absent, plasma glucagon is elevated (since not suppressed by insulin), and pancreatic β cells fail to respond to all insulinogenic stimuli. Exogenous insulin is required to reverse the catabolic state, prevent ketosis, reduce hyperglucagonemia, and decrease blood glucose.

The rate of β cell destruction is variable, being rapid in some individuals and slow in others. There are three distinct stages in the development of type 1 diabetes. Stage 1 occurs when there is β cell autoimmunity (presence of islet autoantibodies) but there is normoglycemia. Stage 2 occurs with there is abnormal glucose tolerance but patients remain asymptomatic. Stage 3 is the development of symptomatic type 1 diabetes.

Although type 1 diabetes commonly occurs in children and young adults, it can occur at any age and 50% of new cases are diagnosed in adults. Misclassification of type 1 diabetes in adults is common, and > 40% of those developing type 1 diabetes after age 30 years are initially treated for type 2 diabetes. The term *latent autoimmune diabetes of adults* (LADA) has been used to identify adults who develop immune-mediated type 1 diabetes. The rate of β cell destruction in patients with LADA is slower than in those who have a "classic" presentation of type 1 diabetes (diabetic ketoacidosis [DKA]). While there is a debate as to whether the term LADA should be used as a diagnosis, the ADA Standards of

Table 32–1. Other specific types of diabetes mellitus.

Genetic defects of pancreatic β cell function
MODY 1 (HNF-4α); rare
MODY 2 (glucokinase); less rare
MODY 3 (HNF-1α); accounts for two-thirds of all MODY
MODY 4 (PDX1); very rare
MODY 5 (HNF-1β); very rare
MODY 6 (neuroD1); very rare
MODY 7 (KLF11); very rare
MODY 8 (CEL); very rare
MODY 9 (PAX4); very rare
MODY 10 (INS); very rare
MODY 11 (BLK); very rare
MODY 12 (ABCC8); very rare
MODY 13 (KCNJ11); very rare
MODY 14 (APPL1); very rare
Mitochondrial DNA
Wolfram syndrome
Genetic defects in insulin action
Type A insulin resistance
Leprechaunism
Rabson-Mendenhall syndrome
Lipoatrophic diabetes
Diseases of the exocrine pancreas
Endocrinopathies
Drug- or chemical-induced diabetes
Other genetic syndromes (Down, Klinefelter, Turner, others) sometimes associated with diabetes

HNF, hepatic nuclear factor; MODY, maturity-onset diabetes of the young; PDX1, pancreatic duodenal homeobox 1.

Care suggests that for the purpose of classification, any form of diabetes mediated by autoimmune β cell destruction should be classified as type 1 diabetes. Therefore, the use of the term LADA in adults who may have progressive autoimmune β cell destruction is acceptable since it can increase clinicians' diagnostic awareness and accelerate appropriate insulin initiation to prevent diabetic ketoacidosis. Some individuals may retain enough β cell function to avoid ketosis, but as their β cell mass diminishes, the need for insulin therapy develops. Islet cell antibody surveys among persons of northern European descent indicate that up to 15% of patients with "type 2" diabetes may have LADA.

Many patients with type 1 diabetes mellitus have circulating antibodies to islet cells (ICA), glutamic acid decarboxylase 65 (GAD65), insulin (IAA), tyrosine phosphatase IA2 (ICA-512), and zinc transporter 8 (ZnT8) at the time the diagnosis is made (Table 32–2); screening with these autoimmune markers may identify about 98% of patients who have an autoimmune basis for their β cell loss. These antibodies also facilitate screening of siblings of affected children and adults with atypical features of type 2 diabetes mellitus. Up to 10% of patients with new-onset type 1 diabetes have no detectable islet autoantibodies; therefore, the absence of autoantibodies does not exclude type 1 diabetes. Antibody levels also decline with increasing duration of disease.

Table 32–2. Diagnostic sensitivity and specificity of autoimmune markers in patients with newly diagnosed type 1 diabetes mellitus.

	Sensitivity	Specificity
Islet cell cytoplasmic antigen (ICA)	44–100%	96%
Glutamic acid decarboxylase (GAD65)	70–90%	99%
Insulin (IAA)	40–70%	99%
Tyrosine phosphatase (IA-2, ICA 512)	50–70%	99%
Zinc transporter 8 (ZnT8)	50–70%	99%

Patients with type 1 diabetes who do not have evidence of pancreatic β cell autoimmunity do have insulinopenia and can develop ketoacidosis. This subgroup of patients is classified as having "idiopathic type 1 diabetes." Although only a minority of patients with type 1 diabetes fall into this group, most of these individuals are of Asian or sub-Saharan African origin. About 4% of West Africans with ketosis-prone diabetes are homozygous for a sub-Saharan African ancestry-specific allele in *PAX-4* (*Arg133Trp*)—a transcription factor that is essential for the development of pancreatic islets.

Multiple genetic and unidentified factors likely play a role in the etiology of pancreatic autoimmune β cell destruction. Although the risk for developing type 1 diabetes is much higher for relatives of patients with the disease, > 85% of persons who develop type 1 diabetes do not have a first-degree relative with the disease. Most sporadic cases occur because ~ 40% of persons in the general population carry the high-risk human leukocyte antigen (HLA) alleles for diabetes. Family members of probands with diabetes are at increased lifetime risk for developing type 1 diabetes. A child whose mother has type 1 diabetes has a 2% risk of developing the disease and a 6% risk if the child's father has it. The risk in siblings is related to the number of HLA haplotypes that the sibling shares with the proband having diabetes. If one haplotype is shared, the risk is 6% and if two haplotypes are shared, the risk increases to 12–25%. The highest risk is for monozygotic twins, where the concordance rate is 25–50%. Evidence for environmental factors playing a role in the development of type 1 diabetes includes the observation that the disease is more common in Scandinavian countries and becomes progressively less frequent in countries nearer to the equator. Which environmental factor is responsible for the increased risk of type 1 diabetes is not known. Breastfeeding in the first 6 months of life appears to be protective. Improvements in public health and reduced infections (especially parasitic) may lead to immune system dysregulation and development of autoimmune disorders such as asthma and type 1 diabetes (the hygiene hypothesis).

The use of checkpoint inhibitor immunotherapies, such as nivolumab, pembrolizumab, and ipilimumab, can precipitate autoimmune disorders, including type 1 diabetes; the onset of diabetes can be rapid, with diabetic ketoacidosis at presentation. Autoantibodies against islet antigens are present in < 50% of patients; therefore individuals receiving these drugs should be carefully monitored for the development of autoimmune diabetes.

B. Prediabetes for Type 2 Diabetes

A fasting plasma glucose level of 70–99 mg/dL (3.9–5.9 mmol/L) and a glucose level < 140 mg/dL (< 7.8 mmol/L) 2 hours after a meal are considered normal. The ADA definition of prediabetes is impaired fasting glucose (fasting plasma glucose 100–125 mg/dL [6.1–6.9 mmol/L]), impaired glucose tolerance 2 hours after an oral glucose tolerance test (plasma glucose 140–199 mg/dL [7.8–11mmol/L]), and/or an elevated HbA_{1c} (5.7–6.4%). The World Health Organization (WHO) uses the term intermediate hyperglycemia, and an international expert committee convened by the ADA calls prediabetes a high-risk state of developing diabetes. WHO criteria for intermediate hyperglycemia include impaired fasting glucose (fasting plasma glucose 110–125 mg/dL [6.1–6.9 mmol/L]) and impaired glucose tolerance (plasma glucose 140–200 mg/dL [7.8–11.0 mmol/L]) 2 hours after ingestion of 75 g of oral glucose, or a combination of the two.

Risk factors for prediabetes include overweight or obesity, older age, lifestyle factors, and genetic predisposition. Microvascular complications, including retinopathy, neuropathy, and nephropathy, can occur with prediabetes. Prediabetes is established as a risk factor for the development of atherosclerotic cardiovascular disease. It is estimated that in 2021, 97.6 million adults in the United States or 37.7% of the population age 18 and older had prediabetes. Annually, 5–15% of US adults progress from prediabetes to diabetes and a similar number each year revert to normoglycemia (https://www.cdc.gov/diabetes/php/data-research/.

C. Type 2 Diabetes Mellitus

Type 2 diabetes is defined by several characteristic abnormalities including resistance to the action of insulin in peripheral tissues (muscle, liver, and fat), defective β cell insulin secretion, decreased skeletal muscle glucose uptake, and increased production of glucose by the liver. β Cell function is not completely lost and is usually sufficient to prevent ketoacidosis but is inadequate to prevent hyperglycemia. This form of diabetes used to occur predominantly in adults, but it is now more frequently encountered in children and adolescents. The clinical presentation of type 2 diabetes is heterogeneous, with widely variable age at onset, severity of the condition, and degree of obesity.

Genetic and environmental factors combine to cause both the β cell loss and the insulin resistance. Most epidemiologic data indicate strong genetic influences, since in monozygotic twins > 40 years of age, concordance develops in > 70% of cases within a year whenever type 2 diabetes develops in one twin. Genome-wide association studies have identified > 700 risk variants and putative regulator mechanisms for type 2 diabetes. Several environmental factors may play a crucial role in the development of the type 2 diabetes. These include excessive caloric intake leading to obesity and a sedentary lifestyle, medications that cause metabolic abnormalities, and disruption of the gut microbiome and circadian rhythm.

Obesity is the most important environmental factor causing insulin resistance. The degree and prevalence of obesity with type 2 diabetes vary among different racial groups. In patients with type 2 diabetes, obesity or overweight is apparent in just 50% of Chinese and Japanese patients, 80% of North American or European patients, 50–80% of African patients, and nearly 100% of patients who are Pima Indians or Pacific Islanders from Nauru or Samoa.

Central or visceral obesity, due to accumulation of fat in the omental and mesenteric regions, is strongly linked to insulin resistance; subcutaneous abdominal fat is less associated with insulin insensitivity and may be protective against insulin resistance. *Metabolic obesity* is a term used to describe increased visceral fat in patients with type 2 diabetes without overt obesity.

D. Other Specific Types of Diabetes Mellitus

1. Maturity-onset diabetes of the young (MODY)—This subgroup of monogenic disorders is characterized by non–insulin-requiring diabetes with autosomal dominant inheritance and an age at onset of 25 years or younger. MODY is characterized by impaired glucose-induced secretion of insulin and the absence of obesity. Six types of MODY account for > 80% of cases, but at least 14 have been described (Table 32–1). Patients younger than 30 years with a negative autoantibody screen and endogenous insulin production (urinary C-peptide/creatinine ratio of 0.2 nmol/mmol or higher) are candidates for genetic screening for MODY.

2. Diabetes mellitus associated with a mutation of mitochondrial DNA—Diabetes due to mutations of mitochondrial DNA occurs in < 2% of patients with diabetes. Diabetes usually develops in these patients in their late 30s, and characteristically, they also have hearing loss (maternally inherited diabetes and deafness [MIDD]). In some patients, the β cell failure can be rapidly progressive and patients require insulin soon after diagnosis. Other patients can be managed by diet or oral agents for a while but most eventually require insulin. Patients with MIDD are not usually overweight; they resemble patients with type 1 diabetes mellitus but without evidence for autoimmunity.

3. Wolfram syndrome—Wolfram syndrome is an autosomal recessive neurodegenerative disorder first evident in childhood. It consists of diabetes insipidus, diabetes mellitus, optic atrophy, and deafness, hence the acronym DIDMOAD. Cranial diabetes insipidus and sensorineural deafness develop during the second decade in 60–75% of patients. Ureterohydronephrosis, neurogenic bladder, cerebellar ataxia, peripheral neuropathy, and psychiatric illness develop later in many patients.

4. Autosomal recessive syndromes—Homozygous mutations in a number of pancreatic transcription factors, such as *NEUROG3, PTF1A, RFX6*, and *GLI-similar 3 (GLIS3)*, cause neonatal or childhood diabetes. Patients with mutation in the *EIF2AK3* gene have neonatal diabetes, epiphyseal dysplasia, developmental delay, and liver and kidney dysfunction (Wolcott-Rallison syndrome).

5. Diabetes mellitus secondary to other causes—Endocrine tumors secreting growth hormone, glucocorticoids, catecholamines, glucagon, or somatostatin can cause glucose intolerance (Table 32–3). In the first four of these situations, peripheral responsiveness to insulin is impaired. With excess of glucocorticoids, catecholamines, or glucagon, increased hepatic output of glucose is a contributory

Table 32–3. Secondary causes of hyperglycemia.

Hyperglycemia due to tissue insensitivity to insulin
Medications (corticosteroids, sympathomimetic drugs, niacin, alpelisib, sirolimus)
Hormonal tumors (acromegaly, Cushing syndrome, glucagonoma, pheochromocytoma)
Liver disease (cirrhosis, hemochromatosis)
Muscle disorders (myotonic dystrophy)
Adipose tissue disorders (lipodystrophy, truncal obesity)
Hyperglycemia due to reduced insulin secretion
Medications (thiazide diuretics, β-blockers, phenytoin, pentamidine, calcineurin inhibitors, atypical antipsychotics)
Hormonal tumors (somatostatinoma, pheochromocytoma)
Pancreatic disorders (pancreatitis, hemosiderosis, hemochromatosis)

factor; in the case of catecholamines, decreased insulin release is an additional factor in producing carbohydrate intolerance, and with somatostatin, inhibition of insulin secretion is the major factor. Diabetes mainly occurs in individuals with underlying defects in insulin secretion, and hyperglycemia typically resolves when the hormone excess is resolved.

High-titer anti-insulin receptor antibodies that inhibit insulin binding cause a clinical syndrome characterized by severe insulin resistance, glucose intolerance or diabetes mellitus, and acanthosis nigricans. These patients usually have other autoimmune disorders.

Many medications are associated with the development of carbohydrate intolerance or diabetes by decreasing insulin secretion, increasing insulin resistance, or both (Table 32–3). The calcineurin inhibitors cyclosporine and tacrolimus impair insulin secretion; sirolimus increases insulin resistance. These agents contribute to the development of new-onset diabetes after solid-organ transplantation. Corticosteroids increase insulin resistance but may also impair β cell function; in a case-control study and a large population cohort study, oral corticosteroids doubled the risk for development of diabetes. Thiazide diuretics and β-blockers modestly increase the risk for diabetes. Treating hypokalemia due to thiazides may reverse the hyperglycemia. Atypical antipsychotics, particularly olanzapine and clozapine, are associated with increased risk of glucose intolerance; risperidone and quetiapine are associated with an intermediate risk. These drugs cause weight gain and insulin resistance but may also impair β cell function; an increased rate of DKA has been reported. Alpelisib is a phosphatidylinositol-3-kinase (PI3K) inhibitor, and capivasertib is an inhibitor of AKT isoforms. Both these agents are used in combination with fulvestrant for hormone receptor–positive, HER2-negative, *PIK3CA*-mutated breast cancer. PI3K/AKT are components of the insulin signaling pathway, and hyperglycemia is a common on-target side effect of alpelisib and capivasertib therapies.

A single episode of severe acute pancreatitis, chronic pancreatitis, or subtotal pancreatectomy (resected volume > 40%) reduces the number of functioning β cells. Insulin deficiency can result similar to type 1 diabetes; concomitant reduction in pancreatic α cells may also reduce glucagon secretion so that relatively lower doses of insulin replacement are needed.

Diabetes Prevention

A. Prevention of Type 1 Diabetes

At the time of diagnosis of type 1 diabetes, residual β cell pancreatic function remains. This explains why soon after diagnosis and following the initiation of insulin therapy, the diabetes goes into partial clinical remission and little or no insulin is required ("honeymoon effect"). The honeymoon period may reflect temporary slowing or recovery of β cell loss. The incidence and duration of clinical remission varies, and eventually most patients lose all β cell function and develop worsening glucose control. Immune therapies targeting the disease mechanism to prolong this partial clinical remission are used to prevent or delay the loss of functional β cell mass. The CD3 complex present on the T cell modifies CD8-positive T cells that mediate β cell death and preserve regulatory T cells. Teplizumab is a humanized monoclonal antibody against the CD3 molecule on T cells. When teplizumab was administered to patients with new-onset type 1 diabetes, it did not restore glycemic control despite C peptide preservation. However, in a phase 2 study of early intervention in nondiabetic relatives of patients with type 1 diabetes (note that these relatives were at high risk for the development of diabetes since they had two or more diabetes-related autoantibodies and glucose intolerance), a single course of teplizumab delayed progression to clinical type 1 diabetes by about 2 years. Teplizumab is thus FDA-approved for use in individuals 8 years and older at high risk for type 1 diabetes (two positive β cell autoantibodies [Table 32–2] and impaired glucose tolerance) to delay its onset. Common adverse reactions include transient decreases in white cell and lymphocyte counts, rash, and headache.

Greenbaum C et al. Evolving concepts in pathophysiology, screening, and prevention of type 1 diabetes: report of diabetes mellitus interagency coordinating committee workshop. Diabetes. 2024;73:1780. [PMID: 39167668]

B. Prevention of Type 2 Diabetes

Several large RCTs have demonstrated that lifestyle intervention with a decreased-calorie meal plan is highly effective in preventing or delaying the onset of type 2 diabetes and decreasing cardiometabolic risk. The Diabetes Prevention Program offers the strongest evidence for diabetes prevention; it studied whether lifestyle intervention or metformin could prevent the onset of type 2 diabetes in overweight men and women with impaired glucose tolerance. Intervention with a low-fat diet and 150 minutes of moderate exercise (such as a brisk walk) per week reduced the risk of incident diabetes by 58% over 3 years. Participants who took metformin 850 mg twice daily reduced their risk of developing type 2 diabetes by 31%, but this intervention was ineffective in those with a lesser degree of obesity or who were older. Of the persons in the Diabetes Prevention Program, 88% continued follow-up in the Diabetes Prevention Program Outcome Study. At 15 years of follow-up, the cumulative incidence of diabetes was 55% in the lifestyle group and 62% in the control group. Results in 2024 from the SURMOUNT-1 trial demonstrated that a 3-year treatment with tirzepatide at 5-mg, 10-mg, and 15-mg doses reduced the risk of developing type 2 diabetes by 94% in individuals with prediabetes and obesity or overweight. Participants who took tirzepatide had weight reduction of up to 20% that was sustained over 3 years, and the risk of progression to type 2 diabetes was markedly lower compared with placebo. No medication is yet approved by the FDA, though, to prevent the development of type 2 diabetes.

Clinical Findings

A. Distinguishing the Different Types of Diabetes

Type 2 diabetes accounts for 90–95% of all diagnosed diabetes. At the time of diagnosis, though, it is important to differentiate between type 1 and type 2 diabetes or other specific types such as MODY to personalize therapy. Identification of features that suggest end-organ insulin insensitivity, such as visceral obesity, acanthosis nigricans, or both, may help diagnose type 2 diabetes. The presence of obesity no longer characterizes only type 2 diabetes. In the general population, including persons with type 1 diabetes, sedentary lifestyles and increased consumption of processed foods, refined sugars, and saturated fat have resulted in increased obesity. It is important to assess for a family history of diabetes, including the age at onset, association with obesity, the need for insulin, and whether there were complications. Measurement of GAD65, IAA, ICA 512, and zinc transporter 8 antibodies can help distinguish between type 1 and type 2 diabetes (Table 32–2). Many patients with newly diagnosed type 1 diabetes still have significant endogenous insulin production, and therefore measuring C-peptide levels does not reliably distinguish between type 1 and type 2 diabetes.

B. Symptoms and Signs

1. Type 1 diabetes—The hallmark symptom complex of type 1 diabetes is polyuria and polydipsia from hyperosmolality and hyperketonemia from the accumulation of circulating glucose and fatty acids. When absolute insulin deficiency is of acute onset, there is abrupt increase in urination, thirst, blurred vision, weight loss, paresthesias, and altered level of consciousness. Ketoacidosis exacerbates the dehydration and hyperosmolality by producing anorexia and nausea and vomiting, interfering with oral fluid replacement. Symptoms occur a few weeks before diagnosis. Type 1 diabetes can develop in any decade of life; up to 50% of all new cases occur in adults. Adults may present more variably and without the classic symptom complex that occurs in children and young persons,

A. Increased urination and thirst—These symptoms are consequences of osmotic diuresis secondary to sustained hyperglycemia. The diuresis results in a loss of glucose as well as free water and electrolytes in the urine.

B. Blurred vision—As the lenses are exposed to hyperosmolar fluids, blurred vision often develops.

C. Weight loss—Despite usual or increased appetite, weight loss is a common feature of type 1 diabetes when it develops subacutely. The weight loss is initially due to depletion of water, glycogen, and triglycerides; thereafter, reduced muscle mass occurs as amino acids are diverted to form glucose and ketone bodies. Loss of subcutaneous fat and muscle wasting are features of more slowly developing insulin deficiency. Lowered plasma volume produces symptoms of postural hypotension, which is a serious prognostic sign. Total body potassium loss and the general catabolism of muscle protein contribute to the weakness.

D. Level of consciousness—The patient's level of consciousness can vary depending on the degree of hyperosmolality. When insulin deficiency develops relatively slowly and sufficient water intake is maintained, patients remain relatively alert and physical findings may be minimal. When vomiting occurs in response to worsening ketoacidosis, dehydration progresses and compensatory mechanisms become inadequate to keep serum osmolality below 320–330 mOsm/L. Stupor or even coma may occur when the serum osmolality exceeds 320–330 mOsm/L. The fruity breath odor of acetone further suggests the diagnosis of DKA.

2. Type 2 diabetes—While increased urination and thirst may be presenting symptoms in some patients with type 2 diabetes, many patients have an insidious onset and are asymptomatic, with hyperglycemia noted during routine laboratory studies. Occasionally, when the disease has been occult for some time, patients may have evidence of neuropathic or cardiovascular complications at the time of presentation. Hyperglycemic hyperosmolar coma can also be present when the serum osmolality exceeds 320–330 mOsm/L; in these cases, patients are profoundly dehydrated, hypotensive, lethargic, or comatose but without the Kussmaul respirations of ketoacidosis. When relative insulin deficiency is profound, ketoacidosis can develop.

A. Skin manifestations—Common skin infections occur, such as hordeola, furuncles, folliculitis, carbuncles, and paronychia. Generalized pruritus and symptoms of vaginitis are frequently the initial complaints of women. Diabetes should be suspected in women with chronic candidal vulvovaginitis and in men with balanoposthitis (inflammation of the foreskin and glans in uncircumcised men).

Other skin findings include acanthosis nigricans, which is associated with significant insulin resistance. The skin in the axilla, groin, and back of neck is hyperpigmented and

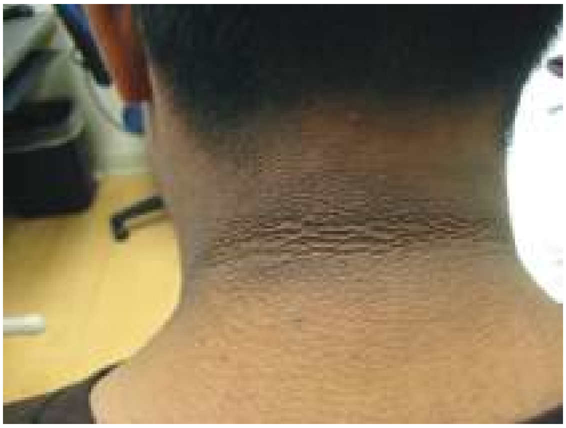

Figure 32–1. Acanthosis nigricans of the nape of the neck, with typical dark and velvety appearance. (Used, with permission, from Umesh Masharani, MB, BS, MRCP [UK].)

hyperkeratotic (Figure 32–1). Some patients with suboptimally managed diabetes develop multifactorial chylomicronemia (plasma triglycerides > 2000 mg/dL) with eruptive xanthomas on the flexor surface of the limbs and on the buttocks, lipemia retinalis, and a significantly increased risk of developing acute pancreatitis.

B. Body habitus—Patients who develop type 2 diabetes are often overweight or obese. Even those who are not significantly obese often have characteristic localization of fat deposits on the upper segment of the body (especially the abdomen, chest, neck, and face) and relatively less fat on the appendages, which may be quite muscular. This centripetal fat distribution is characterized by a high waist circumference; a waist circumference larger than 40 inches (102 cm) in men and 35 inches (88 cm) in women is associated with an increased risk of diabetes. Hypertension is often present in patients with diabetes and obesity.

C. Obstetrical complications—Type 2 diabetes should be considered in patients who have delivered babies larger than 9 lb (4.1 kg) or have had polyhydramnios, preeclampsia, or unexplained fetal losses.

C. Laboratory Findings and Diagnostic Tests

Diagnostic criteria are the same for all types of diabetes. Abnormal tests of glycemia must be present on two different occasions in the absence of symptoms. HbA_{1c} should be obtained initially and then every 3–6 months. Laboratory evaluation at initial and subsequent annual evaluations includes measurement of lipid panel, liver function tests, urine albumin/creatinine ratio, serum potassium, serum creatinine and eGFR, CBC, and vitamin B12 (when on metformin). TSH should be measured annually in individuals with type 1 diabetes.

1. Plasma or serum glucose—The glucose concentration is 10–15% higher in plasma or serum than in whole blood because structural components of blood cells are absent. A plasma glucose level ≥ 126 mg/dL (7 mmol/L) on more than one occasion after at least 8 hours of fasting is diagnostic of diabetes mellitus (Table 32–4).

Table 32–4. Criteria for the diagnosis of diabetes.

	Normal Glucose Tolerance[1]	Prediabetes or Impaired Glucose Tolerance[1]	Diabetes Mellitus[2]
Fasting plasma glucose mg/dL (mmol/L)	< 100 (5.6)	100–125 (5.6–6.9)	≥ 126 (7.0)
Plasma glucose mg/dL (mmol/L) 2 hours after glucose load	< 140 (7.8)	≥ 140–199 (7.8–11.0)	≥ 200 (11.1)
HbA_{1c} (%)	< 5.7	5.7–6.4	≥ 6.5

[1] See text for the oral glucose tolerance test protocol.

[2] A fasting plasma glucose ≥ 126 mg/dL (7.0 mmol) is diagnostic of diabetes if confirmed by *repeat testing*. A fasting plasma glucose ≥ 126 mg/dL (7.0 mmol) and HbA_{1c} ≥ 6.5% on the *same sample* also is diagnostic of diabetes.

2. Glycated hemoglobin (hemoglobin A_{1c})—Hemoglobin becomes spontaneously glycated when glucose enters the erythrocyte through the glucose transporter 1 (GLUT1). HbA_{1c} reflects glucose bound to hemoglobin within RBCs. Since the average RBC life span is about 120 days, the HbA_{1c} is a weighted average of recent blood glucose exposure during the preceding 8–12 weeks, providing an indirect method of assessing mean glucose. HbA_{1c} is a primary technique to diagnose diabetes and assess management. However, there is substantial inter- and intra-individual variability in HbA_{1c}, and caution should be exercised in estimating average glucose levels from measured HbA_{1c}. For example, for HbA_{1c} values between 6.9% and 7.1%, the glucose levels can range from 125 mg/dL to 205 mg/dL (6.9–11.4 mmol/L).

In 2010, the ADA established HbA_{1c} ≥ 6.5% as a diagnostic criterion for diabetes (Table 32–4). A cutoff value of 6.5% (48 mmol/mol) was chosen because the risk for retinopathy increases substantially above this value. The advantages of using the HbA_{1c} over fasting plasma glucose and the oral glucose tolerance test to diagnose and treat diabetes include stability of the assay and convenience (fasting is not needed) with fewer day-to-day changes due to stress, illness, or nutritional status.

Several factors can interfere with assays and affect the accuracy of HbA_{1c}. In patients with hemoglobin variants such as high levels of hemoglobin F, immunoassays give falsely low values of HbA_{1c}. The National Glycohemoglobin Standardization Program website (https://ngsp.org) provides information on how hemoglobin variants and traits impact results of commonly used HbA_{1c} assays.

HbA_{1c} may not be a suitable diagnostic test when factors affecting hemoglobin concentration or RBC turnover are present. Any condition that decreases erythrocyte survival or mean erythrocyte age (eg, recovery from acute blood loss, hemolytic anemia) will falsely lower HbA_{1c}, irrespective of the assay method used. Intravenous iron and erythropoietin therapy for treatment of anemia in CKD falsely lower HbA_{1c} levels. Alternative methods of assessing glycemia such as fructosamine (see below) should be considered in these situations. Vitamins C and E may falsely lower test results, possibly by inhibiting glycation of hemoglobin. Conditions that increase erythrocyte survival such as splenectomy for hereditary spherocytosis will falsely raise HbA_{1c} levels. Iron-deficiency anemia also is associated with higher HbA_{1c} levels.

3. Oral glucose tolerance test—In an asymptomatic nonpregnant adult in whom diabetes is suspected, a standardized oral glucose tolerance test can diagnose diabetes. This test can identify individuals with diabetes whose diagnoses might otherwise be missed, such as those with posttransplant diabetes or cystic fibrosis–related diabetes. In order to optimize insulin secretion and effectiveness, a minimum of 150–200 g of carbohydrate daily should be included in the diet for 3 days before the test. The patient should eat nothing after midnight before the test day. The test is performed in the morning because of diurnal variation in oral glucose tolerance; patients should not smoke or be active during the test. On the morning of the test, patients consume 75 g of glucose in 300 mL of water within 5 minutes. Blood samples for plasma glucose are obtained at 0 and 120 minutes after ingestion of glucose. A fasting value ≥ 126 mg/dL (7 mmol/L) or a 2-hour value > 200 mg/dL (11.1 mmol/L) is diagnostic of diabetes mellitus (Table 32–4). Patients with a 2-hour value of 140–199 mg/dL (7.8–11.1 mmol/L) have impaired glucose tolerance. False-positive results may occur in patients who are malnourished, are bedridden, or have an infection or severe emotional stress.

4. Urine glucose—A convenient method to detect glucosuria is the paper strip impregnated with glucose oxidase and a chromogen system (Clinistix, Diastix), which is sensitive to as little as 100 mg/dL (5.5 mmol) glucose in urine. A normal renal threshold for glucose as well as reliable bladder emptying are essential for interpretation.

Nondiabetic glycosuria (renal glycosuria) is a benign asymptomatic condition wherein glucose appears in the urine despite a normal amount of glucose in the blood, either basally or during a glucose tolerance test. Its cause may vary from mutations in the *SGLT2* gene coding for sodium-glucose transporter 2 (familial renal glycosuria) to one associated with dysfunction of the proximal renal tubule (Fanconi syndrome, CKD), or it may merely be a consequence of the increased load of glucose presented to the tubules by the elevated GFR during pregnancy. As many as 50% of pregnant patients typically have demonstrable sugar in the urine, especially during the third and fourth months. This sugar is practically always glucose except during the late weeks of pregnancy, when lactose may be present.

5. Urine and blood ketones—Qualitative detection of ketone bodies can be accomplished by nitroprusside tests (Acetest or Ketostix). Although these tests do not detect β-hydroxybutyric acid, which lacks a ketone group, the semiquantitative estimation of ketonuria thus obtained is nonetheless usually adequate for clinical purposes. Many laboratories measure β-hydroxybutyric acid, and there are meters available (Precision Xtra; Nova Max Plus) for patient use that measures β-hydroxybutyric acid levels in capillary glucose samples. β-Hydroxybutyrate levels > 0.6 mmol/L require evaluation. Patients with levels > 3.0 mmol/L, equivalent to very large urinary ketones, require hospitalization.

6. Glycated proteins—Serum fructosamine is formed by nonenzymatic glycosylation of several serum proteins (90% albumin) when exposed to glucose and turned into ketamines. Since serum albumin has a much shorter half-life than hemoglobin (14–20 days), serum fructosamine generally reflects the average glucose for the preceding 2–3 weeks. The glycation rate of proteins is not affected by RBC lifespan or hemoglobin variants; therefore fructosamine can be used in conditions when HbA_{1c} may not be a reliable marker, such as in the presence of abnormal hemoglobins or hemolytic states or when an earlier response to treatment is required, or in pregnancy. Conditions that reduce serum albumin (eg, nephrotic state, protein-losing enteropathy, or severe liver disease) will lower the serum fructosamine. Normal values vary in relation to the serum albumin concentration and are 200–285 mcmol/L when the serum albumin level is 5 g/dL. HbA_{1c} values and serum fructosamine are highly correlated. Serum fructosamine levels of 300, 367, and 430 mcmol/L approximate to HbA_{1c} values of 7%, 8%, and 9%, respectively. Limitations to the use of fructosamine include uncertainty about the frequency of measurements, with lack of standardization and established clinical cut points. Similarly, **glycated albumin** measures only the glycosylated form of albumin with the same advantages and disadvantages as serum fructosamine measurements. The reference range for glycated albumin is 11.9–15.8%.

7. Lipids—Lipid abnormalities are often present in individuals with diabetes. When type 1 diabetes is suboptimally managed, hypertriglyceridemia develops from the absolute insulin deficiency. Once type 1 diabetes is optimally managed or hyperglycemia is corrected, often there is no underlying lipid abnormality. In type 2 diabetes, a distinct "diabetic dyslipidemia" is present and is characteristic of underlying insulin resistance. Dyslipidemia of type 2 diabetes is typified by high serum triglycerides (300–400 mg/dL [3.4–4.5 mmol/L]), low HDL cholesterol (< 30 mg/dL [0.8 mmol/L]), and a qualitative change in LDL particles, resulting in smaller dense particles that carry higher amounts of free cholesterol. These small dense LDL particles are more susceptible to oxidation, rendering them atherogenic. These lipid abnormalities can exist even with good glycemic management. Lifestyle adjustments including healthy eating patterns with decreased consumption of sugar-sweetened beverages, refined carbohydrates and alcohol, and regular physical activity all have a beneficial impact on diabetic dyslipidemia. Primary disorders of lipid metabolism may coexist with diabetes; therefore persistence of lipid abnormalities after weight reduction and improvement in blood glucose should prompt a diagnostic workup and possible pharmacotherapy of the lipid disorder (see Chapter 33).

8. Glucose monitoring systems—Diabetes technology is a term that encompasses all devices, hardware, and software that individuals with diabetes use to aid self-management. Diabetes technology includes insulin administration devices, blood glucose monitoring (BGM) systems, and continuous glucose monitoring systems. Diabetes devices should be offered to individuals based on individual needs, preferences, and skill level; appropriate training and education should be provided for effective use on an ongoing basis.

A. Self-monitoring glucose systems—Capillary blood glucose monitoring (BGM) using a glucose meter is an important aspect of diabetes management, especially for individuals on insulin. BGM is a tool for monitoring responses to nutrition, physical activity, and response to therapy and to avoid hypoglycemia. Glucose meters use an enzymatic reaction with either glucose oxidase or glucose dehydrogenase. Many blood glucose meters are available, and accuracy rates are mostly equivalent, but they vary with regard to speed, convenience, size of blood samples required, reporting capability, and cost. Several brands are available, including LifeScan (OneTouch), Bayer Corporation (Contour), Roche Diagnostics (Accu-Chek), and Abbott Laboratories (Precision, FreeStyle). Blood glucose meters range from $20 to $80 each. Test strips remain a major expense, costing about $0.25 to $1.50 apiece. The meters also come with a lancet device and disposable 26- to 33-gauge lancets. Most meters can store from 100 to 1000 glucose values, and stored data can be downloaded onto a computer or smartphone. Some glucose meters have integrated speech that can read glucose values aloud to benefit individuals with visual impairment.

BGM systems have limitations to their use. Testing strips have limited lifespans, and improper storage (high temperature, open vial) can affect their accuracy. Patients with diabetes should be advised against using expired strips and purchasing second-hand test strips. All meters have a temperature range for accurate function, as the glucose reaction is temperature sensitive. Increases or decreases in hematocrit can affect measured glucose values. Meters and test strips are calibrated over the glucose concentrations ranging from 60 mg/dL (3.3 mmol/L) to 160 mg/dL (8.9 mmol/L), and the accuracy is not as good for higher and lower glucose levels. When the glucose is < 60 mg/dL (3.3 mmol/L), the difference between the meter and the laboratory value may be as much as 20%. Glucose oxidase–based meters underestimate glucose levels in the presence of high oxygen tension (for example, in the critically ill receiving supplemental oxygen); under these circumstances, a glucose dehydrogenase–based system may be preferable as it is not affected by oxygen tension. Glucose dehydrogenase–based systems may report falsely high glucose levels in patients who are receiving parenteral products containing nonglucose sugars such as maltose, galactose, or xylose or their metabolites. Impaired circulation to the fingers (for example, in patients with Raynaud disease) will artificially lower fingerstick glucose measurements (pseudohypoglycemia).

Despite improved accuracy and precision of BGM, it remains a static measure of glucose without information on patterns. BGM has been replaced by continuous glucose monitoring in many regions.

B. Continuous glucose monitoring (CGM) systems—CGM systems measure glucose concentrations in the interstitial fluid, which correlate with plasma glucose levels. CGM devices are either owned by the user (personal CGM device) or owned by clinical practices (professional CGM devices). Two types of personal CGM devices are available. The first type, "real-time CGM" (Dexcom G6, Dexcom G7, and Abbott Freestyle Libre 3 plus), sends a continuous stream of glucose data to a receiver, mobile application on a smartphone or smartwatch, or insulin pump. The second type, "intermittently scanned CGM" (Abbott Freestyle Libre 2 plus), requires the user to scan the sensor using a reader device or smartphone. CGM systems require the user to insert a sensor (small filament) into the subcutaneous space. This sensor measures glucose concentrations continuously in the interstitial fluid for 7–15 days. A surgically implanted glucose sensor (Senseonics Eversense) also is available and monitors glucose for 365 days. CGM systems have alerts and alarms that inform the user of rapidly rising or falling glucose values. Family members also can remotely monitor glycemia and be alerted as needed. These CGM systems require a prescription. Direct-to-consumer CGM systems without alarm features are available (Abbott Lingo and Dexcom Stelo). Several RCTs using real-time CGM have demonstrated improvement in HbA_{1c} and reduction in hypoglycemia when worn consistently. Retrospective review of CGM reports can guide therapeutic decision-making for the provider and the patient; glucose data can offer the user insight on food choices, insulin dosing, and changes in physical activity. Report of the collected CGM data, called the ambulatory glucose profile, shows various metrics used for data interpretation. The percentage of "time in range" (glucose levels 70–180 mg/day [3.9–10 mmol/L]), glucose levels that are low or high, and their variability can be assessed. There is a strong correlation between glucose levels that are 70% "time in range" and an HbA_{1c} of ~ 7%. Sensor measurement errors can occur due to faulty placement, defective sensors, or pressure on the sensor location. CGM is the standard for monitoring glucose in most adults with type 1 diabetes. Current recommendations are to offer personal CGM systems to all individuals with diabetes on insulin therapy.

Ajjan RA et al. Continuous glucose monitoring for the routine care of type 2 diabetes mellitus. Nat Rev Endocrinol. 2024;20:426. [PMID: 38589493]

Treatment

Foundational aspects of the management of individuals with diabetes include building positive health behaviors and maintaining psychosocial wellbeing. To achieve this, diabetes self-management education and support (DSMES), medical nutrition therapy (MNT), routine physical activity, adequate-quality sleep, support for cessation of tobacco products and vaping, counseling on health behaviors, and psychosocial care are vital. Individuals living with diabetes should receive person-centered collaborative care that involves shared decision-making in the treatment plan and facilitated access to medical, technological, psychosocial, and behavioral health resources and support.

A. Diabetes Self-Management Education and Support

The main goal of DSMES is to empower individuals with diabetes by providing them with tools to make informed self-management decisions. It is recommended that all persons with diabetes participate in DSMES to facilitate informed decision-making, self-care behaviors, problem-solving, and active collaboration with the health care team. These services should be culturally appropriate and responsive to individual preferences, needs, and values and are commonly offered in group or individual settings.

B. Medical Nutrition Therapy (MNT)

Nutrition therapy plays an integral role in diabetes management, and each person with diabetes should actively engage in education, self-management, and treatment planning with the health care team. There has been a vast change in how individuals with diabetes are counselled on nutrition, moving away from emphasizing macronutrients (carbohydrates, proteins, and fats), and micronutrients (vitamins and minerals) and instead focusing on foods. P are encouraged to think about eating patterns, also known as dietary patterns or food patterns, or the totality of the foods and beverages they consume. Promoting consumption of nutrient-dense food choices, such as foods high in micronutrients while being relatively low in calories (eg, vegetables, fruits, and legumes), is useful because of the simple fact that people eat food, not nutrients, and nutrition recommendations need to be applicable to what patients actually eat. MNT, when delivered by a registered dietitian, is highly beneficial to persons living with diabetes. MNT is associated with HbA_{1c} reduction of 1.0–1.9% for persons with type 1 diabetes and 0.3–2.0% for those with type 2 diabetes. There is no one-size-fits-all eating pattern for individuals with diabetes, and participation in collaboratively developing an individualized meal plan should be highly encouraged. Eating patterns should emphasize inclusion of nonstarchy vegetables, whole fruits, legumes, lean proteins, whole grains, nuts and seeds, and low-fat dairy or nondairy alternatives while minimizing consumption of red meat, sugar-sweetened beverages, sweets, refined grains, and processed and ultra-processed foods for individuals with prediabetes and diabetes. A Mediterranean-style eating pattern (a diet supplemented with walnuts, almonds, hazelnuts, and olive oil) has been shown to improve glycemic control and lower combined endpoints for cardiovascular events and stroke. Use of supplements or herbs is not recommended. Alcohol consumption can result in hypoglycemia and/or delayed hypoglycemia (particularly for those using insulin or insulin secretagogue therapies), weight gain, and hyperglycemia (when consumed in excessive amounts). Persons with diabetes should be educated about the risks of alcohol consumption and encouraged to monitor glucose frequently before and after drinking alcohol.

C. Weight Management

One of the primary modes of therapy for patients with obesity and type 2 diabetes is weight reduction. Normalization of glycemia can be achieved by weight loss resulting in improved tissue sensitivity to insulin. A combination of caloric restriction, increased exercise, and behavioral modification is required if a weight reduction program is to be successful. Understanding the risks associated with the diagnosis of diabetes may motivate the patient to lose weight.

Liraglutide 3 mg subcutaneously daily (Saxenda), semaglutide 2.4 mg subcutaneously weekly (Wegovy), and tirzepatide 2.5 to 15 mg subcutaneously weekly (Zepbound) are approved for weight loss in persons with or without diabetes along with diet and exercise. In a 68-week study in adults without diabetes, patients taking semaglutide lost 14.9% of their initial body weight compared with 2.4% body weight loss in patients taking placebo. In a 72-week study, patients taking tirzepatide 15 mg lost about 21% of their initial body weight compared to 3.1 % with placebo. Common adverse reactions include nausea, vomiting, and diarrhea. Serious side effects include pancreatitis. The medication should not be used in patients with MEN 2 or personal or family history of medullary thyroid cancer.

Other medical options for weight loss include orlistat, phentermine/topiramate, and naltrexone/extended-release bupropion (see Chapter 34).

Bariatric surgery (Roux-en-Y, gastric banding, gastric sleeve, biliopancreatic diversion/duodenal switch) typically results in substantial weight loss and improvement in glucose levels. A meta-analysis examining the impact of bariatric surgery on patients with diabetes and BMI ≥ 40 noted that 82% of patients had resolution of clinical and laboratory manifestations of diabetes in the first 2 years after surgery and 62% remained free of diabetes > 2 years after surgery. The improvement was most marked in the procedure that caused the greatest weight loss (biliopancreatic diversion/duodenal switch). There was, however, a high attrition of patients available for follow-up, and there was little information about how results vary by ethnicity. Weight regain does occur after bariatric surgery, and it can be expected that 20–25% of the lost weight will be regained over 10 years. The impact of this weight gain on diabetes recurrence depends principally on the degree of β cell dysfunction.

Patients with type 2 diabetes without obesity frequently have increased visceral adiposity—the so-called metabolic obesity in those with normal body weight. There is less emphasis on weight loss, but exercise remains an important aspect of treatment.

D. Medications for Treating Hyperglycemia

The medications for treating type 2 diabetes are listed in Table 32–5.

Table 32–5. Medications for treatment of type 2 diabetes mellitus (oral doses unless otherwise noted).

Drug	Tablet Size	Daily Dose	Duration of Action
Biguanides			
Metformin (Glucophage)	500, 625, 750, 850, and 1000 mg	500–1000 mg twice daily If eGFR is 30–45 mL/min/1.73 m^2, do not start metformin; if already taking metformin, dose is < 1000 mg daily ***Avoid*** if eGFR < 30 mL/min/1.73 m^2	4 hours
Metformin extended release, 24 hour (Glucophage XL)	500, 750, and 1000 mg	500–2000 mg once daily ***Avoid*** if eGFR < 30 mL/min/1.73 m^2	Up to 24 hours
Thiazolidinediones			
Pioglitazone (Actos)	15, 30, and 45 mg	15–45 mg daily	Up to 24 hours
Rosiglitazone (Avandia)	2, 4, and 8 mg	4–8 mg daily (can be divided)	Up to 24 hours
α-Glucosidase Inhibitors			
Acarbose (Precose)	25, 50, and 100 mg	25–100 mg three times daily just before meals *Maximal dose*: ≤ 60 kg: 50 mg three times daily; > 60 kg: 100 mg three times daily	4 hours
Miglitol (Glyset)	25, 50, and 100 mg	25–100 mg three times daily just before meals	4 hours
Voglibose (not available in United States)	0.2 and 0.3 mg	0.2–0.3 mg three times daily just before meals	4 hours
Sulfonylureas			
Acetohexamide (Dymelor) (not available in United States)	250 and 500 mg	250–1000 mg as single dose; 1500 mg in two divided doses *Maximal dose*: 1500 mg/day	12–24 hours
Chlorpropamide (Diabinese) (not available in United States)	100 and 250 mg	100–500 mg as single dose *Maximal dose*: 750 mg/day	24–72 hours
Gliclazide (not available in United States)	80 mg	40–80 mg as single dose; 160–320 mg divided dose *Maximal dose*: 320 mg/day	12 hours
Glimepiride (Amaryl)	1, 2, 3, and 4 mg	*Usual dose:* 1–4 mg once daily *Maximal dose:* 8 mg once daily ***Avoid*** if eGFR < 15 mL/min/1.73 m^2	Up to 24 hours
Glipizide, immediate release (Glucotrol, immediate release)	5 and 10 mg	*Usual dose:* 2.5–10 mg once daily 30 minutes before meals *Maximal dose:* 10 mg twice daily 2.5 mg once daily if eGFR < 30 mL/min/1.73 m^2 ***Avoid*** if eGFR < 10 mL/min/1.73 m^2	6–12 hours
Glipizide, extended release (Glucotrol XL)	2.5, 5, and 10 mg	*Usual dose:* 2.5–10 mg once daily *Maximal dose:* 20 mg once daily 2.5 mg once daily if eGFR < 30 mL/min/1.73 m^2 ***Avoid*** if eGFR < 10 mL/min/1.73 m^2	Up to 24 hours
Glyburide			
(Micronase, Diabeta, conventional tablets) (not available in United States)	1.25, 2.5, and 5 mg	1.25–20 mg as single dose or in two divided doses *Maximal dose:* 20 mg/day ***Avoid*** if eGFR < 60 mL/min/1.73 m^2	Up to 24 hours
(Glynase PresTab, micronized tablets)	1.25, 1.5, 2.5, 3, 5, and 6 mg	1.5–12 mg as single dose or in two divided doses *Maximal dose:* 12 mg/day ***Avoid*** if eGFR < 60 mL/min/1.73 m^2	Up to 24 hours
Tolazamide (Tolinase)	100, 250, and 500 mg	100–500 mg as single dose; > 500 mg in two divided doses *Maximal dose:* 1000 mg/day	Up to 24 hours
Tolbutamide (Orinase (not available in United States))	250 and 500 mg	250–3000 mg in two or three divided doses *Maximal dose:* 3000 mg/day	6–24 hours

(*continued*)

Table 32–5. Medications for treatment of type 2 diabetes mellitus (oral doses unless otherwise noted). (continued)

Drug	Tablet Size	Daily Dose	Duration of Action
Meglitinide Analogs			
Mitiglinide (available in Japan)	5 and 10 mg	5 or 10 mg three times daily before meals	2 hours
Repaglinide (Prandin)	0.5, 1, and 2 mg	*Usual dose:* 0.5 to 4 mg three times daily 15 minutes before meals *Maximal dose:* 16 mg daily	3 hours
D-Phenylalanine Derivative			
Nateglinide (Starlix)	60 and 120 mg	60 or 120 mg three times daily before meals *Maximal dose:* 360 mg/day 60 mg three times daily if eGFR $<$ 30 mL/min/1.73 m^2	4 hours
DPP-4 Inhibitors			
Alogliptin (Nesina)	6.25, 12.5, and 25 mg	25 mg once daily if eGFR $\geq$ 60 mL/min/1.73 m^2 12.5 mg daily if eGFR 30–59 mL/min/1.73 m^2 6.25 mg daily if eGFR $<$ 30 mL/min/1.73 m^2	24 hours
Linagliptin (Tradjenta)	5 mg	5 mg daily	24 hours
Sitagliptin (Januvia)	25, 50, and 100 mg	100 mg once daily if eGFR $>$ 45 mL/min/1.73 m^2 50 mg once daily if eGFR 30–45 mL/min/1.73 m^2 25 mg once daily if eGFR $<$ 30 mL/min/1.73 m^2	24 hours
Vildagliptin (Galvus) (not available in United States)	50 mg	50 mg once or twice daily ***Avoid*** if eGFR $\leq$ 60 mL/min/1.73 m^2 or AST/ALT three times upper limit of normal	24 hours
GLP-1 Receptor Agonists			
Dulaglutide (Trulicity)	0.75-, 1.5-, 3.0-, 4.5-mg single-dose pens or prefilled syringe	*Usual dose:* 1.5–3.0 mg subcutaneously once weekly *Maximal dose:* 4.5 mg subcutaneously once weekly	1 week
Liraglutide (Victoza)	Prefilled, multidose pens delivering 0.6, 1.2, or 1.8 mg	*Initial dose:* 0.6 mg subcutaneously once daily. Increase to 1.2 mg after a week if tolerated. *Maximal dose:* 1.8 mg subcutaneously once daily.	24 hours
Semaglutide (Ozempic, Rybelsus)	Prefilled multidose pens delivering 0.25, 0.5, 1, or 2 mg	*Initial dose:* 0.25 mg weekly for 1 month and increase to 0.5 mg weekly. Increase dose to 1 mg weekly or 2 mg weekly for additional glucose lowering and/or weight loss as needed (a 2.4-mg weekly dose is approved for weight loss).	1 week
	1-, 3-, 7-, and 14-mg tablets	*Initial dose:* 3 mg for 1 month and then increase to 7 mg. Take fasting daily with water and wait 30 minutes to eat. *Maximal dose:* 14 mg daily.	Daily
Dual GIP/GLP-1 Receptor Agonists			
Tirzepatide (Mounjaro)	Single-dose vial or pen: 2.5, 5, 7.5, 10, 12.5, and 15 mg	*Initial dose*: 2.5 mg weekly for 1 month and increase to 5 mg weekly. Increase dose by 2.5 mg weekly at 1-month intervals for additional glucose lowering and/or weight loss as needed. *Maximal dose*: 15 mg weekly.	1 week
SGLT-2 Inhibitors			
Bexagliflozin (Brenzavvy)	20 mg	20 mg once daily ***Avoid*** if eGFR $<$ 30 mL/min/1.73 m^2 for glycemic control	24 hours
Canagliflozin (Invokana)	100 and 300 mg	100–300 mg daily if eGFR $>$ 60 mL/min/1.73 m^2 100 mg daily if eGFR is 30–60 mL/min/1.73 m^2 ***Avoid*** if eGFR $<$ 30 mL/min/1.73 m^2.	24 hours

(*continued*)

Table 32–5. Medications for treatment of type 2 diabetes mellitus (oral doses unless otherwise noted). (continued)

Drug	Tablet Size	Daily Dose	Duration of Action
Dapagliflozin (Farxiga)	5 and 10 mg	5–10 mg daily ***Avoid*** if eGFR < 45 mL/min/1.73 m^2 for glycemic control	24 hours
Empagliflozin (Jardiance)	10 and 25 mg	*Usual dose:* 10 mg daily *Maximal dose:* 25 mg ***Avoid*** if eGFR < 30 mL/min/1.73 m^2 for glycemic control	24 hours
Ertugliflozin (Steglatro)	5 and 15 mg	*Usual dose:* 5 mg daily *Maximal dose:* 15 mg ***Avoid*** if eGFR < 45 mL/min/1.73 m^2 for glycemic control	24 hours
Other			
Pramlintide (Symlin)		For insulin-treated type 2 diabetes, start at 60 mcg subcutaneously three times daily. Increase to 120 mcg three times daily if no nausea for 3–7 days. Give immediately before meal.	2 hours
	SymlinPen 60 or SymlinPen 120	For type 1 diabetes, start at 15 mcg three times daily and increase by increments of 15 mcg to a maximum of 60 mcg three times daily, as tolerated. To avoid hypoglycemia, lower insulin dose by 50% on initiation of therapy.	

1. Medications that primarily lower glucose levels by their actions on the liver, muscle, and adipose tissue

A. Metformin—Metformin is a first-line therapy for patients with type 2 diabetes—especially in patients without established cardiovascular or kidney disease, in which case other agents may be preferred. It can be used alone or in conjunction with other oral agents or insulin in the treatment of patients with type 2 diabetes. It is ineffective in patients with type 1 diabetes. The major site of action of metformin is the liver, where it decreases hepatic gluconeogenesis and hepatic insulin resistance, resulting in decreased hyperglycemia. Metformin has a half-life of 1.5–3 hours and is not bound to plasma proteins or metabolized. It is excreted unchanged by the kidneys. Hypoglycemia does not occur with therapeutic doses of metformin.

The maximum dosage of metformin is 2550 mg, although little benefit is seen above a total dose of 2000 mg. Metformin is available in immediate release (IR) and extended release (ER) formulations. When initiating metformin, it is important to start with a low dose and increase the dosage gradually; it should be taken with food to reduce gastrointestinal side effects. Nausea, vomiting, abdominal cramps, and diarrhea occur in up to 20% of patients. Up to 48% of patients initiated on metformin may discontinue treatment. The ER formulation has fewer gastrointestinal side effects and may result in better adherence. A common schedule is one 500-mg tablet three times a day (IR formulation) with meals or one 850- or 1000-mg tablet twice daily at breakfast and dinner. Up to 2000 mg of the ER preparation can be taken once a day.

Safety Concerns: GI side effects are dose-related, tend to occur at onset of therapy, and often are transient. However, discontinuation of metformin may be required in some individuals due to persistent gastrointestinal discomfort. An eGFR should be obtained in all individuals before initiating metformin. The dose of metformin should be reduced to 50% of maximal dose (1000 mg daily) in patients with eGFRs between 30 and 45 mL/min/1.73 m^2 and in older adults who are at higher risk for AKI from reduced renal functional reserve. Metformin is contraindicated and should be discontinued if the eGFR drops below 30 mL/min/1.73 m^2. Patients with liver failure, excessive alcohol intake, or hypotension should not receive this medication because of the risk of lactic acidosis.

Metformin-induced liver injury with cholestasis is rare but has been described. Metformin interferes with the calcium-dependent absorption of vitamin B_{12}–intrinsic complex in the terminal ileum; thus vitamin B_{12} deficiency can occur. *Measurements of vitamin B_{12} levels is advisable every few years during therapy*, especially in patients with peripheral neuropathy (which may be erroneously attributed to diabetic neuropathy) or if macrocytosis develops. Increased intake of dietary calcium may prevent metformin-induced B_{12} malabsorption.

Lactic acidosis has been reported as a side effect of metformin but is rare (incidence of < 10/10,000 patient-years). Almost all reported cases have involved patients with associated risk factors (sepsis, hypoxia, dehydration, heart failure, liver or kidney dysfunction, and alcohol use disorder). AKI can occur rarely in patients taking metformin who receive radiocontrast agents. Metformin therapy should be temporarily halted on the day of radiocontrast administration in patients with eGFR 30–60 mL/min/1.73 m^2 and restarted 48 hours later, after confirmation that kidney function has not deteriorated.

B. Thiazolidinediones (TZDS)—The thiazolidinediones (rosiglitazone and pioglitazone) improve insulin sensitivity and lower glucose levels by causing a favorable expansion of the subcutaneous adipose depot. Rosiglitazone, however, is no longer widely used worldwide.

TZDs are effective as monotherapy and in combination with sulfonylureas or metformin or insulin, lowering HbA_{1c} by 1–2%. When used in combination with insulin, they can result in a 30–50% reduction in insulin dosage, and some patients can come off of insulin completely. Pioglitazone is available as a generic agent and is inexpensive; the oral dosage is 15–45 mg daily and can be taken with or without food. These agents do not cause hypoglycemia when used as monotherapy or in combination with other agents.

Pioglitazone potently enhances insulin sensitivity by its action on adipose tissue, liver, and skeletal muscle, and it effectively decreases plasma glucose and HbA_{1c} levels. Pioglitazone also preserves β cell function. Beyond glucose-lowering, pioglitazone can lower blood pressure and has favorable effects on plasma lipids. There is reduction in triglycerides (9%) and increase in HDL-C (15%) without significant changes in total and LDL-cholesterol. Multiple studies have demonstrated that pioglitazone reduces hepatic fat content and reverses hepatic fibrosis. Pioglitazone can decrease urinary albumin and protein excretion in type 2 diabetes; there are no studies in patients with low eGFR. Pioglitazone is metabolized by CYP 2C8 and CYP 3A4.

Safety concerns: Weight gain is common with pioglitazone therapy (1–4 kg over a year [2–5% body weight]). Interestingly, the greater the weight gain, the greater the decline in HbA_{1c} and improvement in insulin sensitivity. Weight gain can be minimized by not exceeding a dose of 30 mg/day (a dose that accounts for 80% of maximal glucose lowering). Using pioglitazone in combination with metformin can limit weight gain. Combination therapy with an SGLT-2 inhibitor or with a GLP-1 receptor agonist reduces weight gain and fluid retention (see below).

(1) Cardiovascular benefit—A large body of evidence from observational RCTs and mechanistic studies suggests that pioglitazone decreases recurrent cardiovascular events in individuals with and without diabetes.

(2) Fluid retention and heart failure—Edema occurs in about 5–10% of patients treated with pioglitazone and is dose related. The edema occurs more frequently (10–15%) in patients receiving concomitant sulfonylurea or insulin therapy and may result in heart failure. Edema results from peripheral vasodilation and renal sodium retention. Pioglitazone is contraindicated in patients with type 2 diabetes with New York Heart Association Class III and IV heart failure. It should also not be used if edema is present on clinical examination. Patients should be instructed to report new-onset edema or shortness of breath. Salt and water retention respond best to diuretics that act in the distal tubule such as spironolactone, triamterene, and amiloride. If more than trace edema is present, dietary sodium restriction should be advised, the dose of pioglitazone should be decreased, and treatment should be initiated with a distally acting diuretic.

(3) Bone fractures—An increase in bone fractures has been reported in individuals with type 2 diabetes treated with TZDs. The fractures appear to occur more commonly in postmenopausal women in the distal long bones of the hands and feet and are secondary to trauma. Decrease in lumbar spine bone density also can occur. Fractures are uncommon in premenopausal women and men. Pioglitazone should be used cautiously or avoided in individuals at high risk for fracture, including postmenopausal women with osteoporosis or those with prior fractures.

(4) Bladder cancer—Clinical studies have reported conflicting results regarding an association of bladder cancer with pioglitazone use. A 10-year observational cohort study of patients taking pioglitazone failed to find an association with bladder cancer. A large multipopulation pooled analysis (1.01 million persons over 5.9 million person-years) also failed to find an association between cumulative TZD exposure and incidence of bladder cancer. Another population-based study, however, generating 689,616 person-years of follow-up, did find that pioglitazone was associated with an increased risk of bladder cancer. Thus, the FDA still cautions about bladder cancer risk and recommends avoiding use of pioglitazone in patients with type 2 diabetes and active bladder cancer or history of bladder cancer.

2. Medications that primarily stimulate insulin secretion by binding to the sulfonylurea receptor on the β cell

A. Sulfonylureas—The primary mechanism of action of the sulfonylureas is to stimulate insulin release from pancreatic β cells; they are used in type 2 diabetes. Sulfonylureas are metabolized by the liver, and apart from acetohexamide, whose metabolite is more active than the parent compound, the metabolites of all the other sulfonylureas are weakly active or inactive. The metabolites are excreted by the kidney and, in the case of the second-generation sulfonylureas, partly excreted in the bile.

Safety Concerns: Hypoglycemia is a common adverse reaction with the sulfonylureas. Weight gain also is common, especially in the first year of use. The mechanisms of the weight gain include improved glucose control and increased food intake in response to hypoglycemia. Idiosyncratic reactions are rare, with skin rashes or hematologic toxicity (leukopenia, thrombocytopenia) occurring in < 0.1% of users.

(1) First-generation oral sulfonylureas (tolazamide, acetohexamide, chlorpropamide)—The use of these first-generation agents has been generally supplanted by newer generation oral sulfonylureas. Chlorpropamide has a prolonged biologic effect, and severe hypoglycemia can occur especially in older adults as their renal clearance declines with aging. Its other side effects include alcohol-induced flushing and hyponatremia due to increased vasopressin secretion and action.

(2) Second-generation sulfonylureas (glyburide, glipizide, gliclazide, glimepiride)—These medications should be used with caution and at lower doses in the elderly and in those with liver and kidney disease, due to higher risk of hypoglycemia.

Glyburide is usually started at an oral dose of 2.5 mg/day. The average maintenance dose is 5–10 mg/day given as a single morning dose; maintenance doses higher than 20 mg/day are not recommended. Glyburide is metabolized in the liver, and the metabolic products have hypoglycemic activity. This can cause prolonged hypoglycemia, and glyburide should not be used in older patients or in patients with liver failure or CKD. Flushing has rarely been reported after ethanol ingestion.

Glipizide is usually begun at an oral dose of 5 mg/day, with up to 15 mg/day given as a single daily dose before breakfast. When higher daily doses are required, they should be divided and given before meals. The maximum recommended dose is 40 mg/day, although doses above 10–15 mg probably provide little additional benefit. For maximum effect in reducing postprandial hyperglycemia, glipizide should be ingested 30 minutes before meals, since rapid absorption is delayed when the medication is taken with food. Glipizide therapy should not be used in patients with liver failure. Because of its lower potency and shorter duration of action, it is preferable to glyburide in older patients and for those patients with kidney disease. Glucotrol XL provides extended release of glipizide during transit through the GI tract with greater effectiveness in lowering prebreakfast hyperglycemia than the shorter-duration immediate-release standard glipizide tablets. However, this formulation has not shown any demonstrable therapeutic advantages over glyburide.

Gliclazide (not available in the United States) is an intermediate-duration sulfonylurea with a duration of action of about 12 hours. See Table 32–5 for dosing options. The medication is metabolized by the liver; the metabolites and conjugates have no hypoglycemic effect. An extended-release preparation is available.

Glimepiride has a long duration of effect with a half-life of 5 hours allowing once- or twice-daily dosing. Glimepiride achieves blood glucose lowering with the lowest dose of any sulfonylurea compound. A single daily dose of 1 mg/day has been shown to be effective, and the maximal recommended dose is 8 mg. It is completely metabolized by the liver to relatively inactive metabolic products.

B. MEGLITINIDE ANALOGS—Repaglinide is an insulin secretagogue structurally similar to glyburide but lacks the sulfonic acid–urea moiety. It is rapidly absorbed from the intestine and then undergoes complete metabolism in the liver to inactive biliary products, giving it a very short plasma half-life of < 1 hour. The medication therefore causes a brief but rapid pulse of insulin. The starting dose is 0.5 mg three times a day 15 minutes before each meal. The maximum dose is 4 mg with each meal. Metabolism is by cytochrome P450 3A4 isoenzyme, and other medications that induce or inhibit this isoenzyme may increase or inhibit the metabolism of repaglinide. Like the sulfonylureas, repaglinide can be used in combination with metformin. Hypoglycemia is the main side effect. Like the sulfonylureas, repaglinide causes weight gain. Repaglinide may be useful in patients for whom nocturnal hypoglycemia needs to be avoided, in kidney impairment, or in older adults.

3. Medications that affect absorption of glucose—α-Glucosidase inhibitors competitively inhibit the α-glucosidase enzymes in the gut that digest dietary starch and sucrose. Two of these medications—acarbose and miglitol—are available for clinical use in the United States. Voglibose, another α-glucosidase inhibitor, is available in Japan, Korea, and India. Both acarbose and miglitol delay the absorption of carbohydrate and lower postprandial glycemic excursion. To maximize tolerance, the starting dose of these medications should be low (eg, one-fourth of the maximum dose), taken just once daily, with dose and frequency slowly increased over a period of weeks or months.

A. ACARBOSE—In patients with diabetes, acarbose reduces postprandial hyperglycemia by 30–50%, and its overall effect is to lower the HbA_{1c} by 0.5–1%. The recommended starting dose of acarbose is 50 mg orally twice daily, gradually increasing to 100 mg three times daily. For maximal benefit on postprandial hyperglycemia, acarbose should be given with the first mouthful of food.

Safety Concerns: The principal adverse effect that limits its use is flatulence, which occurs in 20–30% of individuals. In 3% of cases, troublesome diarrhea occurs. The GI discomfort tends to discourage excessive carbohydrate consumption and promotes improved adherence of patients with type 2 diabetes to their diet prescriptions. When acarbose is given alone, hypoglycemia does not occur. However, if acarbose is combined with insulin or sulfonylureas, it might increase the risk of hypoglycemia from the latter two agents. A slight rise in hepatic aminotransferases has been noted in clinical trials with acarbose (5% vs 2% in placebo controls, and particularly with doses > 300 mg/day). The levels generally return to normal on stopping the medication.

B. MIGLITOL—Miglitol is similar to acarbose in terms of its clinical effects. It is indicated for use in diet- or sulfonylurea-treated patients with type 2 diabetes. GI side effects occur as with acarbose. The medication is not metabolized and is excreted unchanged by the kidney. Miglitol should not be used in ESKD, when its clearance is affected.

4. Incretins—Oral glucose provokes a threefold to fourfold higher insulin response than an equivalent dose of glucose given intravenously. This is due to the release of gut hormones, principally GLP-1 and glucose-dependent insulinotropic polypeptide (GIP), that amplify the glucose-induced insulin release. This "incretin effect" of GLP-1 secretion (but not GIP secretion) is reduced in patients with type 2 diabetes; when GLP-1 is infused in patients with type 2 diabetes, it stimulates insulin secretion and lowers glucose levels. GLP-1, unlike the sulfonylureas, has only a modest insulin stimulatory effect at normoglycemic concentrations. This means that GLP-1 has a lower risk for hypoglycemia than the sulfonylureas.

In addition to its insulin stimulatory effect, GLP-1 has a number of other pancreatic and extrapancreatic effects. It suppresses glucagon secretion and so may ameliorate the hyperglucagonemia that is present in patients with diabetes and improve postprandial hyperglycemia. GLP-1 acts on the stomach, delaying gastric emptying; the importance of this effect on glucose lowering is illustrated by the observation that antagonizing the *deceleration* of gastric emptying markedly reduces the glucose-lowering effect of GLP-1. GLP-1 receptors are present in the CNS and may play a role in the anorectic effect of the drugs. Patients with type 2 diabetes undergoing GLP-1 infusion are less hungry; it is unclear whether this is mainly due to a deceleration of gastric emptying or whether there is a CNS effect as well.

The half-life of GLP-1 is only 1–2 minutes. It is rapidly proteolyzed by dipeptidyl peptidase 4 (DPP-4) and other enzymes, and cleared quickly by the kidney. The native peptide, therefore, cannot be used therapeutically; thus current treatment targets the GLP-1 and GIP receptor.

A. DPP-4 INHIBITORS—Inhibition of the enzyme DPP-4 prolongs the action of endogenously released, intact, biologically active GLP-1 and GIP. DPP-4 inhibitors are therefore incretin enhancers since they increase the levels of GLP-1 and GIP, which then increase β cell insulin secretion in the pancreas, thereby reducing postprandial and fasting hyperglycemia. Three oral DPP-4 inhibitors, alogliptin, linagliptin, and sitagliptin, are available in the United States for the treatment of type 2 diabetes. Vildagliptin is available in Europe. Other DPP-4 inhibitors—gemigliptin, anagliptin, teneligliptin, trelagliptin, omarigliptin, evogliptin, and gosogliptin—are approved outside of the United States and European Union. DPP4 inhibitors as a class decrease HbA_{1c} by 0.6–0.8% and are generally well-tolerated oral agents. They do not cause weight gain, weight loss, or hypoglycemia. These agents should not be used in combination with the GLP-1 receptor agonists. All DPP-4 inhibitors are noninferior to placebo in cardiovascular outcomes trials and are safe to use in patients with known atherosclerotic CVD, but they do not have any demonstrable benefits on CVD. There is no impact on liver fat accumulation.

Sitagliptin is dosed at 100 mg once daily, but since it is cleared by the kidneys, the dose is reduced to 50 mg daily if eGFR is 30–50 mL/min/1.73 m^2 and to 25 mg for eGFR < 30 mL/min/1.73 m^2. Alogliptin dosed at 25 mg orally daily; a 12.5-mg dose is used in patients with eGFR of 30–60 mL/min/1.73 m^2, and 6.25 mg for clearance < 30 mL/min/1.73 m^2. The linagliptin dose is 5 mg orally daily, and since it is primarily excreted unmetabolized via the bile, no dose adjustment is needed in patients with kidney disease. The dose of vildagliptin (available outside of the United States) is 50 mg once or twice daily.

Safety Concerns: A predisposition to nasopharyngitis or upper respiratory tract infection is observed in clinical trials. Rare hypersensitivity reactions, including anaphylaxis, angioedema, and exfoliative skin conditions (such as Stevens-Johnson syndrome) and bullous pemphigoid, have been reported. There does not appear to be a clear pancreatitis or pancreatic cancer signal with these agents. Rare cases of hepatic dysfunction, including hepatitis, have been reported with the use of vildagliptin; liver biochemical testing is recommended quarterly during the first year of use and periodically thereafter. Vildagliptin is also associated with increased left ventricular volume but no increase in HF. In a large postmarketing study, alogliptin was associated with a slightly increased rate of HF. In addition, the FDA has issued a warning that the DPP-4 inhibitors can occasionally cause joint pains that resolve after stopping the drug. Overall, DPP-4 inhibitors are safe to use, especially in older individuals and in those with comorbid conditions or kidney impairment.

B. GLP-1 RECEPTOR AGONISTS—The GLP-1 receptor agonists liraglutide, dulaglutide, semaglutide, and lixisenatide (only in combination pen in the United States) are available for treatment of diabetes. (Production of exenatide was discontinued in 2024.) Liraglutide, dulaglutide, and semaglutide are also approved for weight loss and for reducing the risk of major cardiovascular events and stroke in patients with obesity or overweight and established cardiovascular disease. The decrease in major cardiovascular events is due to a combination of not only glucose lowering and weight reduction, but also lipid profile improvement, endothelial anti-inflammatory effects, reduction in plaque formation, and neurohormonal regulation. Tirzepatide, a dual GLP-1 and GIP receptor agonist, is approved for treatment of diabetes and for treatment of obesity and sleep apnea in patients with obesity. Cardiovascular and kidney benefits of tirzepatide remain under investigation.

Liraglutide is a soluble fatty acid acylated GLP-1 analog. It has a half-life of approximately 12 hours, allowing the medication to be injected once a day from a multidose pen. Dosing is initiated at 0.6 mg daily; it is increased after 1 week to 1.2 mg daily, and then to 1.8 mg daily after 4 weeks if needed for glucose control and if tolerated. In clinical trials lasting 26 and 52 weeks, adding liraglutide to the therapeutic regimen (metformin, sulfonylurea, thiazolidinedione) of patients with type 2 diabetes further lowered the HbA_{1c} value. HbA_{1c} decline was in the range of 0.6% to 1.5%. The patients had sustained weight loss of 1–6 pounds. Liraglutide at a dose of 3 mg daily has been approved for weight loss.

In a postmarketing multinational study of 9340 patients with type 2 diabetes with known CVD, the addition of liraglutide was associated with a lower primary composite outcome of death from cardiovascular causes, nonfatal MI, or nonfatal stroke (hazard ratio 0.87, $P = 0.01$). Patients taking liraglutide had lower HbA_{1c} levels, weight loss of 2.3 kg, lower systolic blood pressure, and fewer episodes of severe hypoglycemia.

Dulaglutide has a half-life of about 5 days. Dulaglutide is available in four fixed-dose, single-use pens (0.75 mg, 1.5 mg, 3.0 mg, and 4.5 mg). Dose is increased after at least 4 weeks if needed for glucose control and if tolerated. Dulaglutide monotherapy and combination therapy lowers HbA_{1c} by about 1.5–1.8% at 36 weeks. Weight loss ranges from 2 pounds to 10 pounds (at maximum dose).

Semaglutide is a synthetic analog of GLP-1 with a half-life of about 1 week. It is dispensed either subcutaneously or orally. There are three multiuse pens available for subcutaneous injection (0.25-mg or 0.5-mg dose in a starting pen, 1-mg and 2-mg pens). Dose is escalated if needed for glucose control every 4 weeks if tolerated. Semaglutide monotherapy and combination therapy lowers HbA_{1c} by 1.5–2.1%. Weight loss of up to 10 pounds at the 1-mg dose and 14 pounds at the 2-mg dose was noted in the same trial.

Oral semaglutide is taken fasting with a glass of water. The patient must then wait half an hour before eating, drinking, or taking other medicines. The recommended starting dose is 3 mg daily for the first month, with the dose increased to 7–14 mg daily as needed for glucose control if tolerated.

Lixisenatide has a half-life of 3 hours. It is available in the United States only as a combined medication with insulin glargine. Still available outside the United States, it is dispensed as two daily-injection fixed-dose pens (10 mcg and 20 mcg). HbA_{1c} lowering is in the 0.4–0.6% range, and weight loss ranges from 2 to 6 pounds. Antibodies to lixisenatide occur frequently (70%), and ~2.4% of patients with the highest antibody titers have attenuated glycemic response.

Safety Concerns: The most frequent adverse reactions of the GLP-1 receptor agonists are nausea (11–40%), vomiting (4–13%), and diarrhea (9–17%). The reactions are more frequent at higher doses. About 1–5% of participants of clinical trials withdrew because of the GI symptoms.

The GLP-1 receptor agonists have been associated with increased risk of pancreatitis. The pancreatitis was severe (hemorrhagic or necrotizing) in 6 instances, and 2 of these patients died. In the liraglutide and dulaglutide clinical trials, there were 13 and 5 cases of pancreatitis in the drug-treated groups versus 1 and 1 case in the comparator groups, respectively. This translates to about 1.4–2.2 vs 0.6–0.9 cases of pancreatitis per 1000 patient-years. *Patients taking GLP-1 receptor agonists should be advised to seek immediate medical care if they experience unexplained persistent severe abdominal pain.*

There have been rare reports of AKI in patients taking exenatide. Some of these patients had preexisting kidney disease, and others had one or more risk factors for kidney disease. A number of the patients reported nausea, vomiting, and diarrhea, and it is possible that these side effects caused volume depletion and contributed to the development of kidney injury. Liraglutide, semaglutide, and dulaglutide are metabolized by proteolysis and are preferred choices in patients with kidney failure.

GLP-1 receptor agonists stimulate C-cell neoplasia and cause medullary thyroid carcinoma in rats. Human C cells express very few GLP-1 receptors, and the relevance to human therapy is unclear. The medications, however, should not be used in patients with personal or family history of medullary thyroid carcinoma or multiple endocrine neoplasia (MEN) syndrome type 2.

An increase in diabetic retinopathy was observed in the semaglutide-treated group in one of the clinical trials, perhaps from rapid glucose lowering with the drug.

Prescribing information contains a caution about possible suicidal thoughts. Health care professionals are advised to monitor for and advise patients using GLP-1 receptor agonists to report new or worsening depression, suicidal thoughts, or any unusual changes in mood or behavior. Investigation is underway and not yet conclusive at the time of this writing.

c. Dual GIP/GLP-1 receptor agonists—Tirzepatide, a dual GIP/GLP-1 receptor agonist, is an analog of the GIP hormone. Acylation results in albumin binding, allowing for prolonged action and once-weekly dosing. The recommended starting dose is 2.5 mg injected subcutaneously weekly. The dose is increased to 5 mg weekly after 4 weeks. If additional glucose lowering is needed, the dose can be incrementally increased by 2.5 mg every 4 weeks to a maximum dose of 15 mg. Treatment with tirzepatide resulted in dose-dependent HbA_{1c} reductions of 1.9% to 2.6%. The average weight loss ranged from 6.2 kg to 12.9 kg. Tirzepatide is approved for weight loss in fixed-dose pens and vials (2.5 mg through 15 mg in 2.5-mg increments).

Beneficial effects include improved lipid profile, lowering of blood pressure, and reduction of fatty liver. Effects on major adverse cardiovascular events, HF, and CKD are under investigation. The safety profile is the same as that of the GLP-1 receptor agonists. GI side effects (nausea, vomiting, diarrhea) occur more frequently at higher doses. In clinical trials, there was a slightly higher rate of pancreatitis in the treated group who received tirzepatide compared with the placebo group (0.23 vs 0.11 patients per 100 years of exposure). Tirzepatide packaging includes a warning that its use may make oral birth control ineffective due to decrease in absorption of the medication. Clinicians should counsel patients to report any increase in depressive symptoms or suicidal thoughts, and investigation continues.

5. Sodium-glucose co-transporter 2 inhibitors—Glucose is freely filtered by the kidney glomeruli and is reabsorbed in the proximal tubules by the action of SGLTs. SGLT-2 accounts for ~ 90% of glucose reabsorption, and its inhibition causes glycosuria in persons with diabetes, lowering plasma glucose levels. The FDA-approved oral SGLT-2 inhibitors for treatment of diabetes are canagliflozin, dapagliflozin, empagliflozin, ertugliflozin, and bexagliflozin. SGLT-2 inhibitors reduce the threshold for glycosuria by 30–50% and lower HbA_{1c} by 0.5–1% when used alone or in combination with other oral agents or insulin. The efficacy is higher at higher HbA_{1c} levels, when more glucose is excreted as a result of SGLT-2 inhibition. The loss of calories results in modest weight loss of 2–5 kg. Dapagliflozin and empagliflozin reduce risk of major cardiovascular endpoints; canagliflozin, dapagliflozin, empagliflozin, and ertugliflozin reduce risk of hospitalization for HF; canagliflozin, dapagliflozin, and empagliflozin are indicated for reducing the risk of decline in GFR and progression to ESKD.

Canagliflozin is dosed at 100 mg daily, but up to 300 mg daily can be used in patients with normal kidney function. The dose of dapagliflozin is 10 mg daily but 5 mg daily is the recommended initial dose in patients with liver failure. The usual dosage of empagliflozin is 10 mg daily, but a higher dose of 25 mg daily can be used. The recommended starting dose of ertugliflozin is 5 mg, but the dose can be increased to 15 mg daily if additional glucose lowering is needed. Bexagliflozin is dosed at 20 mg daily, and for mild to moderate kidney impairment (eGFR 30–89 mL/min/1.73 m^2) no dosage adjustment is required. Bexagliflozin is not recommended for severe kidney impairment (eGFR < 30 mL/min/1.73 m^2).

Safety Concerns: SGLT-2 inhibitors are less effective at glucose lowering with advancing CKD (eGFR < 45 mL/min/1.73 m^2), as their ability to lower glucose through glucosuria is proportional to eGFR. They can cause a transient increase in creatinine after initiation, especially in patients with kidney impairment. The kidney benefit is independent of glucose effect; SGLT-2 inhibitors are recommended for kidney protection with eGFR as low as 20 mL/min/1.73 m^2 per Kidney Disease: Improving Global Outcomes (KDIGO) guidelines and can be continued until time of dialysis initiation. The study of dapagliflozin in CKD noted that the drug is safe and beneficial in patients with eGFR as low as 25 mL/min/1.73 m^2. The main side effects of this class are increased incidence of genital mycotic infections and UTIs affecting ~ 8–9% of patients. Cases of necrotizing fasciitis of the perineum (Fournier gangrene) have been reported. There have also been reports of pyelonephritis and septicemia requiring hospitalization. The glycosuria can cause intravascular volume contraction and hypotension.

One multinational study with canagliflozin (CANVAS Program) showed an increased risk of amputations, especially of the toes (hazard ratio 1.97). This finding has not been observed in other studies of this drug or with other SGLT-2 inhibitors.

Canagliflozin causes a decrease in bone mineral density at the lumbar spine and the hip. In a pooled analysis of eight clinical trials (mean duration 68 weeks), a 30% increase in fractures was observed in patients taking canagliflozin. All SGLT-2 inhibitors cause a modest increase in LDL cholesterol levels (3–8%).

DKA is a rare but serious side effect in patients with insulinopenia in type 2 diabetes, ketosis-prone diabetes, and off-label use of SGLT-2 inhibitors in patients with type 1 diabetes. Patients with insulin-requiring diabetes are taught to administer less insulin if their glucose levels are low or at risk of going low. SGLT-2 inhibitors lower glucose levels by changing the renal threshold for glucosuria; therefore, patients taking an SGLT-2 inhibitor may withhold or reduce their insulin doses while glucose levels are low to such a degree as to induce ketoacidosis. This is especially common during times of fasting and acute illness when oral intake has diminished. *All patients with diabetes who are prescribed SGLT-2 inhibitors should be educated to hold this medication when oral intake has severely decreased, to increase fluid intake during this time, to monitor for ketones, and to seek medical attention for severe symptoms and/or elevated ketones as this may represent euglycemic DKA (DKA with normal or only mildly elevated glucose levels). Patients are instructed to discontinue SGLT-2 inhibitors 3 days before any planned major surgery that will require prolonged periods with nothing by mouth.*

6. Others—Pramlintide is a synthetic analog of islet amyloid polypeptide (IAPP or amylin). Given subcutaneously before a meal, it delays gastric emptying, suppresses glucagon secretion, and decreases appetite. It is approved for use both in type 1 diabetes and in insulin-treated type 2 diabetes. In 6-month clinical studies of patients with type 1 and insulin-treated type 2 diabetes, those taking the medication had ~ 0.4% reduction in HbA_{1c} and ~ 1.7-kg weight loss compared with placebo. The HbA_{1c} reduction was sustained for 2 years, but some of the weight was regained. Hypoglycemia can occur, and it is recommended that the short-acting or premixed insulin doses be reduced by 50% when the medication is started. Since the medication slows gastric emptying, recovery from hypoglycemia can be a problem because of delay in absorption of fast-acting carbohydrates. Nausea affects 30–50% of persons but tends to improve with time. In patients with type 1 diabetes, the initial dose of pramlintide is 15 mcg before each meal and titrated up by 15-mcg increments to a maintenance dose of 30 mcg or 60 mcg before each meal. In patients with type 2 diabetes, the starting dose is 60 mcg before meals, increased to 120 mcg in 3–7 days if no significant nausea occurs.

7. Medication combinations—Various medication combinations are available in different dose sizes to allow for decrease in number of pills taken. Metformin is available in combination with glyburide, glipizide, repaglinide, pioglitazone, sitagliptin, linagliptin, alogliptin, dapagliflozin, canagliflozin, and empagliflozin. Pioglitazone is available in combination with glimepiride and alogliptin. Combinations of SGLT-2 inhibitors and DPP4 inhibitors also exist. Combinations of insulin degludec and liraglutide (Xultophy), as well as insulin glargine and lixisenatide (Soliqua), are available in the United States. These medication combinations limit the clinician's ability to optimally adjust dosage of the individual medications.

E. Insulin

Insulin is the primary treatment for individuals with type 1 diabetes. Insulin therapy is also indicated for patients with progressive type 2 diabetes with insulin deficiency when hyperglycemia does not respond to other antihyperglycemic agents.

1. Characteristics of available insulin preparations—Available insulins include human insulins—regular (R) or NPH (N) formulations—or insulin analogs. Human insulins are engineered using biotechnology and are structurally similar to endogenous human insulin. Insulin analogs are insulin molecules that are modified by genetic engineering and recombinant DNA technology. The amino acid structure of insulin is altered, and this changes certain properties of insulin—time of onset, peak, and duration of action—compared with human regular insulin. Importantly, the biologic properties and stability of the insulin molecule remain intact (Table 32–6). Six analogs of human insulin—three rapidly acting (insulin lispro, insulin aspart, insulin glulisine) and three long-acting (insulin glargine, insulin detemir, insulin degludec)—are available for clinical use. All currently available insulins are "purified" to preserve their potency so that refrigeration is recommended but not crucial. During travel, reserve supplies of insulin can be readily transported for weeks without losing potency if protected from extremes of heat or cold. All the insulins for human use worldwide are available in a concentration of 100 U/mL (U-100) and dispensed in 10-mL vials or 0.3-mL cartridges or prefilled disposable pens. Several insulins are available at higher concentrations: insulin glargine, 300 U/mL (U-300); insulin degludec, 200 U/mL (U-200); insulin lispro, 200 U/mL (U-200); and regular insulin, 500 U/mL (U-500).

2. Insulin preparations— See Table 32–7. All rapidly acting insulin analogs and the long-acting insulins are designed for subcutaneous administration; only regular insulin and insulin aspart can be given intravenously. Based on their action profiles, insulin products are categorized as follows:

A. Rapid-acting insulin analogs
B. Short-acting: regular (soluble) insulin
C. Intermediate-acting: NPH (isophane)
D. Long-acting insulin analogs, including ultra-long-acting and weekly insulins
E. Premixed insulin
F. Concentrated insulin
G. Inhaled insulin

Table 32–6. Summary of bioavailability characteristics of the insulins.

Insulin Preparations[1]	Onset of Action	Peak Action	Effective Duration
Insulins lispro,[2] aspart,[3] glulisine	5–15 minutes	1–1.5 hours	3–4 hours
Human regular	30–60 minutes	2 hours	6–8 hours
Human NPH	2–4 hours	6–7 hours	10–20 hours
Insulin glargine	0.5–1 hour	Flat	~24 hours
Insulin degludec	0.5–1.5 hours	Flat	> 42 hours
Technosphere inhaled insulin	5–15 minutes	1 hour	3 hours

[1] Insulin administered subcutaneously unless otherwise noted.
[2] Insulin lispro formulated with treprostinil and citrate (Lyumjev, lispro-aabc) has an 11-minute faster onset of action.
[3] Insulin aspart formulated with niacinamide (Fiasp) has a ~ 10-minute faster onset of action.
NPH, neutral protamine Hagedorn.

A. Rapid-acting insulins—This category includes insulin lispro, aspart, and glulisine. When injected subcutaneously, these insulins have a rapid onset of action in 15–30 minutes, peak in 30–90 minutes, and have an effective duration of 4–5 hours. They have a shorter duration of action compared with human (regular) insulin (see below) because they do not self-aggregate in solution. Clinical trials have demonstrated that the optimal time for premeal injection is 20 minutes for rapid-acting insulin. Another desirable feature of rapid-acting insulin analogs is that their duration of action remains at about 4 hours for most commonly used dosages.

Table 32–7. Insulin preparations available in the United States.[1]

Rapidly acting human insulin analogs
- Insulin lispro (Humalog, Lyumjev, Lilly; Admelog, Sanofi)
- Insulin aspart (Novolog, Fiasp, Novo Nordisk)
- Insulin glulisine (Apidra, Sanofi Aventis)

Short-acting regular insulin
- Regular insulin (Lilly, Novo Nordisk)
- Technosphere inhaled regular insulin (Afrezza)

Intermediate-acting insulins
- NPH insulin (Lilly, Novo Nordisk)

Premixed insulins
- 70% NPH/30% regular (70/30 insulin—Lilly, Novo Nordisk)
- 75% NPL/25% insulin lispro (Humalog Mix 75/25—Lilly)
- 50% NPL/50% insulin lispro (Humalog Mix 50/50—Lilly)
- 70% insulin aspart protamine/30% insulin aspart (Novolog Mix 70/30—Novo Nordisk)
- 70% insulin degludec/30% insulin aspart (Ryzodeg, Novo Nordisk)

Long-acting human insulin analogs
- Insulin glargine (Lantus [U-100], Toujeo [U-300], Sanofi Aventis; Basaglar [U-100], Lilly; Semglee, Mylan; Rezvoglar, Lilly)
- Insulin degludec (Tresiba, Novo Nordisk)

[1] All insulins available in the United States are recombinant human or human insulin analog origin. All the above insulins are dispensed at U-100 concentration. There is an additional U-500 preparation of regular insulin; U-300 preparation of insulin glargine; U-200 preparation of insulin lispro; and U-200 preparation of insulin degludec.
NPH, neutral protamine Hagedorn.

Ultra-rapid-acting insulin aspart (Fiasp) contains aspart with niacinamide (vitamin B_3) to allow for rapid absorption from the injection site and onset of action 10 minutes faster than the standard insulin aspart formulation. It can therefore be injected right before the start of a meal or within 20 minutes after the start of a meal, allowing for some flexibility of dosing. The ultra-rapid-acting formulation of insulin lispro (Lyumjev) contains treprostinil to induce local vasodilation and citrate to increase vascular permeability. Its onset of action is 11 minutes faster than the standard insulin lispro formulation and has lower 1- and 2-hour postprandial glucose excursions.

Insulin aspart has been approved for intravenous use (eg, in hyperglycemic emergencies) but does not have any advantage over intravenous regular insulin.

B. Short-acting insulin—Regular insulin is structurally similar to endogenous human insulin. It consists of dissolved zinc–insulin crystals that, when injected subcutaneously, self-aggregate and result in its effect in 30 minutes. It peaks at 2–3 hours and lasts 6–8 hours. For effective use, it needs to be injected at least 20–30 minutes before meals. Use of regular insulin is associated with an increased hypoglycemia risk due to its prolonged duration of action. Intravenous infusions of regular insulin are particularly useful in the treatment of DKA and during the perioperative management of patients with diabetes who require insulin.

C. Intermediate-acting insulins

*(1) NPH (neutral protamine Hagedorn or isophane) insulin—*NPH insulin is an intermediate-acting insulin that combines recombinant human insulin with protamine, which results in crystal formation. After subcutaneous injection, slow release of precipitated crystals of NPH insulin result in a longer duration of action compared with regular insulin. Its onset of action is 2–4 hours, with peak response in about 6–10 hours. Duration of action often ranges from 12 to 20 hours; therefore most patients require twice-daily dosing for adequate basal coverage. The action of NPH can vary within the same patient and between individuals. NPH insulin is dispensed as a turbid suspension at neutral pH with protamine in phosphate buffer.

Occasional vials of NPH insulin have tended to show unusual clumping of their contents or “frosting” of the container, with considerable loss of bioactivity. This instability is rare and occurs less frequently if NPH human insulin is refrigerated when not in use and if bottles are discarded after 1 month of use.

(2) Insulin glargine—Insulin glargine is a clear insulin that, when injected into the neutral pH environment of the subcutaneous tissue, forms microprecipitates that slowly release the insulin into the circulation. It has no pronounced peak and a duration of action of 20–24 hours in most patients, allowing for once-daily basal dosing. Occasionally, twice-daily dosing may be needed. Insulin glargine should not be mixed with any other insulin, as it is solubilized in acidic pH.

A more concentrated form of insulin glargine (U-300) also is available (see below). Although limited clinical data suggest that insulin glargine is safe in pregnancy, it is not approved for this use.

(3) Insulin degludec—Insulin degludec is an ultra-long-acting insulin analog. The half-life of insulin degludec is 25 hours. Its onset of action is in 30–90 minutes and its duration of action is at least 42 hours. Due to this long duration of action, the daily injection time of insulin degludec can be varied without compromising glycemic control or safety. This long duration of action of degludec should be considered when a patient is fasting for a procedure or when switching to a different basal insulin, since residual insulin action can last for up to 42 hours. Insulin degludec is available in two concentrations, U-100 and U-200, and dispensed in prefilled disposable pens.

(4) Insulin icodec—This basal insulin analog is given once weekly. The lysine at B29 of the insulin is conjugated to 1,20-icosanedioic acid (C20). There are three amino acid substitutions (A14E, B16H, and B25H). The C20 diacid group results in strong, reversible binding to albumin, and the amino acid substitutions attenuate insulin receptor affinity and increase resistance to degradation. It is dispensed in a disposable pen form and approved for use in Europe, Canada, Australia, China, and Japan.

D. Mixed insulin preparations—Patients sometimes mix a mealtime insulin and intermediate-acting NPH insulin, “free mixing,” to provide both basal and bolus coverage while limiting the number of daily injections. Regular insulin or rapid-acting insulin analog is drawn first from the vial followed by NPH insulin and injected immediately. Although free mixing is still practiced, premixed insulin formulations are popular in many parts of the world. These premixed insulins add to the convenience and prevent mixing errors while also achieving reasonable glucose control. Stable premixed insulins (70% NPH and 30% regular) are also beneficial to individuals with vision issues or impaired manual dexterity (Table 32–7). Premixed preparations of insulin lispro and NPH insulins are unstable; stability is achieved by replacing the NPH insulin with NPL (neutral protamine lispro). This insulin has the same duration of action as NPH insulin. Premixed combinations of NPL and insulin lispro (75% NPL/25% insulin lispro mixture [Humalog Mix 75/25] and 50% NPL/50% insulin lispro mixture [Humalog Mix 50/50]) are available for clinical use. Similarly, a 70% insulin aspart protamine/30% insulin aspart (NovoLog Mix 70/30) is available. Advantages of using insulin mixtures are that they can be given within 15 minutes of starting a meal and they are superior in controlling the postprandial glucose rise after a carbohydrate-rich meal. These benefits have not translated into improvements in HbA_{1c} levels when compared with the usual 70% NPH/30% regular mixture. Insulin glargine cannot be mixed with either regular insulin or the rapidly acting insulin analogs. Insulin degludec, however, can be mixed and is available as 70% insulin degludec/30% insulin aspart and is injected once or twice a day.

E. Concentrated insulins—Concentrated insulins are able to deliver more insulin in a lesser volume with fewer injections and less pain at the injection site compared with U-100 insulin, potentially improving adherence. When total daily dose requirements exceed 200 units daily, concentrated insulins are indicated. It is important to understand that switching from U-100 insulin to U-500 insulin should be done carefully, as they are not bioequivalent.

(1) Concentrated insulin analogs—When U-100 glargine is concentrated threefold, its duration of action is prolonged. U-300 glargine is delivered in one-third of the volume of U-100 glargine, with longer and flatter (more consistent) effects. Since a smaller volume is injected into a lesser surface area in the subcutaneous space, there is slower and gradual release of insulin monomers. U-300 glargine results in lesser hypoglycemia compared with U-100 glargine. U-200 degludec, a twofold concentrated U-100 degludec, also is available. A U-200 concentration of insulin lispro is available in a disposable prefilled pen.

(2) U-500 insulin—This fivefold concentrated regular insulin is administered two to three times a day without basal insulin. Due to its concentration, the action is prolonged and variable. For markedly insulin-resistant persons who require large doses of insulin, U-500 insulin is helpful. The U-500R formulation provides mealtime coverage while its extended duration of action provides basal insulin properties, allowing use of U-500R as insulin monotherapy when injected two to three times a day. It is available both in a vial form and as a disposable pen. A dedicated U-500 insulin syringe should be used if the vial form is dispensed. The U-500 pen allows patients to administer insulin by 5-unit increments up to a maximum of 300 units at a time. Caution should be used while prescribing U-500 insulin, as confusion may occur among clinicians, pharmacists, nurses, and patients who are unfamiliar on how to use it, due to risk of hypoglycemia.

F. Inhaled insulin—Technosphere insulin (Afrezza) is a dry-powder formulation of recombinant human regular insulin that can be inhaled. This insulin is rapidly absorbed, with peak insulin levels reached in 12–15 minutes and declining to baseline in 3 hours; the median time to maximum effect with inhaled insulin is approximately 1 hour. In contrast, the median time to maximum effect with subcutaneous insulin lispro is about 2 hours, declining to baseline in 4 hours. In clinical trials, Technosphere insulin combined with basal insulin was as effective in glucose lowering as rapid-acting insulin analogs combined with basal insulin. It is formulated as a single-use, color-coded cartridge delivering 4, 8, or 12 units immediately before the meal. The manufacturer provides a dose conversion table; patients injecting up to 4 units of rapid-acting insulin analog should use the 4-unit cartridge. Those injecting 5–8 units should use the 8-unit cartridge. If the dose is 9–12 units of rapid-acting insulin premeal, then one 4-unit cartridge and one 8-unit cartridge or one 12-unit cartridge should be used. The inhaler is about the size of a referee's whistle.

The most common adverse reaction of inhaled insulin is a cough, affecting about 27% of patients. A small decrease in pulmonary function (FEV_1) is seen in the first 3 months of use persisting over 2 years of follow-up. Inhaled insulin is contraindicated in patients who smoke cigarettes and in those with chronic lung disease, such as asthma and COPD. Spirometry should be performed to identify potential lung disease prior to initiating therapy. During clinical trials, there were two cases of lung cancer in patients who were taking inhaled insulin and none in the comparator-treated patients. All the patients in whom lung cancer developed had a history of prior cigarette smoking. Cases of lung cancer were also reported in cigarette smokers using a previously available inhaled insulin preparation (Exubera). The incidence rate in the Exubera-treated group was 0.13 per 1000 patient-years, whereas it was 0.03 per 1000 patient-years in the comparator-treated group.

3. Sites of insulin injection—Any part of the body covered by loose skin can be used, such as the abdomen, thighs, upper arms, flanks, and upper buttocks. Preparation with alcohol is not required prior to injection as long as the skin is clean. Rotation of sites is recommended to prevent development of lipohypertrophy or scarred adipose tissue that results from repeated use of a single site. Exercise can increase absorption when the injection site is adjacent to the exercised muscle. For most patients, the abdomen is the recommended region for injection because it provides adequate area in which to rotate sites. The effect of anatomic regions appears to be much less pronounced with the analog insulins.

4. Methods of insulin delivery

a. Insulin vials, syringes, and needles—Plastic disposable syringes are available in 1-mL, 0.5-mL, and 0.3-mL sizes, and the needle gauges (G) are 28, 30, and 31 G. The three lengths of needles are 6 mm, 8 mm, and 12.7 mm. Long needles are preferable in patients with obesity to reduce variability of insulin absorption.

b. Insulin pens—Insulin delivery by vial and syringe has been mostly replaced by disposable or reusable insulin pens in many parts of the world. Insulin pens are simple, convenient, and portable, offering flexibility. Insulin pens contain a cartridge containing insulin that is injected into the subcutaneous tissue through a fine, replaceable needle. Insulin pens are available as disposable pens with prefilled cartridges or reusable pens with replaceable insulin cartridges. Most available insulins on the market are available in pen form. Pen needles are available in 29, 31, and 32 gauges and 4-, 5-, 6-, 8-, and 12.7-mm lengths.

Bluetooth-connected insulin pens and pen caps are available. These smart pens are reuseable devices that are integrated into a dedicated mobile application on a smartphone. The pens contain reusable insulin cartridges and have a battery duration of 1 year. Their features include the ability to record the timing and amount of each administered insulin dose, display the last dose, make dosing recommendations based on prespecified information, and provide reminders to administer insulin. Pen caps attach to disposable, prefilled pens of long-acting or rapid-acting insulin. Both smartpens and pen caps integrate with traditional BGM or selected CGM systems. These devices also connect with software, and data can be reviewed retrospectively with the clinician.

c. Insulin pumps—Continuous subcutaneous insulin infusion (CSII) is the most precise way to mimic physiologic insulin secretion. An insulin pump is a computerized mechanical device that can automatically deliver insulin in a physiologic manner throughout the day. Individuals can accommodate changes related to eating, exercise, illness, or varying work and travel schedules by modifying insulin availability. Pumps are small battery-operated devices and house a reservoir or cartridge for insulin. Pumps can be tubed or tubeless. Pumps with tubing have an infusion set that is required for insulin delivery. A catheter or tubing connects the insulin reservoir to a needle or cannula that is inserted subcutaneously to deliver the insulin. The catheter connecting the insulin reservoir to the subcutaneous cannula can be disconnected, allowing the patient to remove the pump temporarily (eg, for bathing). The abdomen is the preferred site for such pumps because of convenience and consistent insulin absorption. The upper outer quadrant of the buttocks, upper thighs, and triceps fat pad of the arms also may be used. Patients may also choose the convenience of a tubeless pump. This pump consists of disposable "pods" that are discarded every 3 days. The pods are small, self-contained, all-in-one units with an internal insulin cartridge, insertion needle, and cannula. Insulin is infused directly from the pod through a catheter without the use of tubing based on wirelessly transmitted instructions from a smartphone or personal digital assistant. All pumps have software that can assist the patient to calculate boluses based on glucose reading and carbohydrates to be consumed. The pumps keep track of the time elapsed since the last insulin bolus, reminding patients of the elapsed time when they attempt to give additional correction bolus before the effect of the previous bolus has worn off. This reminder feature reduces the risk of overcorrecting and subsequent hypoglycemia. Sensor-augmented pumps communicate with a CGM system and can suspend insulin when glucose levels are low or are predicted to fall low. These systems are effective in reducing nocturnal hypoglycemia. Rapid-acting insulin analogs are almost always used in insulin pumps. Pump therapy can be successfully started at the time of diagnosis of type 1 diabetes or in older individuals with long-standing disease.

d. Automated insulin delivery (AID) systems—Exponential improvements in CGM technologies and refined insulin dosing pump algorithms have led to the development of AID systems that minimize insulin delivery burden. The AID system consists of three components: an insulin pump that continuously delivers rapid-acting insulin, a CGM that measures interstitial fluid glucose at frequent intervals, and a control algorithm that resides in the insulin pump, smartphone application, or handheld device and adjusts the insulin delivery. All current AID systems are referred to as "hybrid" closed loop systems that adjust basal insulin delivery in real time. Users are required to manually enter insulin boluses pre-meal and when they exercise, but insulin delivery is automated at nighttime and between meals. AID systems are preferred over non-automated pumps and multiple daily injection regimens in persons with type 1 diabetes. AID systems, regardless of the type used, improve glycemic control and quality of life, are cost effective, and decrease anxiety in persons with type 1 diabetes.

Successful use of AID systems requires proficiency at using both the insulin pump and a continuous glucose monitor. Patients should be trained on what to do if there are unexpected high and low glucose levels. Known complications of insulin pump therapy include problems with infusion sets (occlusion, kinking), skin complications such as lipohypertrophy, and pump-site infection. When insulin delivery is interrupted, ketoacidosis can occur if insulin delivery is interrupted; this must be recognized immediately.

Do-it-yourself (DIY) closed loop systems have been developed by persons with type 1 diabetes to self-adjust insulin by modifying their individually owned pumps. These systems are built using widely available open-source codes with compatible medical devices by anyone who can build their own system. DIY systems are not approved by regulatory bodies; they are patient-driven and employ "off-label" use of technology, with the patient assuming full responsibility for their use. It is important for clinicians caring for these patients to ensure the user has basic diabetes skills, including pump-site maintenance and knowledge about how to troubleshoot.

E. MECHANICAL PATCH PUMPS—Mechanical insulin delivery devices have been developed to enhance adherence to mealtime insulin dosing. V-Go (MannKind Corporation) is a wearable 24-hour patch pump designed for patients with type 2 diabetes who use a basal/bolus insulin regimen. The device delivers rapid-acting insulin continuously and is preset to deliver one of three fixed and flat basal rates (0.83 units/hour, 1.25 units/hour, or 1.67 units/hour) for 24 hours, after which it must be replaced. The V-Go also has an on-demand bolus button that delivers insulin in 2-unit increments to cover meals and lower high glucose excursions. CeQur Simplicity (CeQur Corporation) is a wearable 3-day mechanical patch device that holds 200 units of rapid-acting insulin and delivers 2 units per press of a button to cover meals and to lower high glucose excursions.

F. COMPLICATIONS OF INSULIN THERAPY

(1) Hypoglycemia—Hypoglycemia is the most common complication that occurs in patients with diabetes treated with insulin. The signs and symptoms of hypoglycemia may be divided into those resulting from stimulation of the autonomic nervous system and those from neuroglycopenia (insufficient glucose for normal CNS function). When the blood glucose falls to around 54 mg/dL (3 mmol/L), the patient starts to experience both sympathetic (tachycardia, palpitations, sweating, tremulousness) and parasympathetic (nausea, hunger) nervous system symptoms. If these autonomic symptoms are ignored and the glucose levels fall further (to around 50 mg/dL [2.8 mmol/L]), then neuroglycopenic symptoms appear, including irritability, confusion, blurred vision, tiredness, headache, and difficulty speaking. If untreated, worsening hypoglycemia can lead to loss of consciousness, seizures, or sometimes death.

(2) Hypoglycemic unawareness—Repeated episodes of hypoglycemia lead to adaptation; autonomic symptoms do not occur until the blood glucose levels are much lower and the first symptoms are often due to neuroglycopenia. This "hypoglycemia unawareness" can be reversed by keeping glucose levels at a higher range for several weeks.

Common reasons for hypoglycemia with diabetes include injecting too much insulin for the amount of ingested carbohydrates, exercise, and excessive consumption of alcoholic beverages, especially without having eaten. In patients with type 1 diabetes, hypoglycemia can occur during or even several hours after exercise; therefore glucose levels need to be monitored and food and insulin adjusted. Aggressive self-management of diabetes with repeated insulin boluses in close intervals ("insulin stacking") can result in hypoglycemia.

Impaired counterregulation resulting in hypoglycemia includes reduced glucagon and sympathoadrenal responses and cortisol deficiency. Patients with diabetes for > 5 years lose their glucagon response to hypoglycemia and lack adequate counterregulation against falling glucose levels. Once the glucagon response is lost, the sympathoadrenal responses take on added importance. Aging, autonomic neuropathy, or hypoglycemia unawareness from repeated low glucose levels further blunts the sympathoadrenal responses. In persons with type 1 diabetes mellitus who develop primary adrenal insufficiency, insulin requirements drop significantly and the insulin dose must be reduced to prevent recurrent hypoglycemia.

Complications of diabetes that increase the risk for hypoglycemia include autonomic neuropathy, gastroparesis, and ESKD. Tachycardia, palpitations, sweating, and tremulousness are important symptoms of the sympathetic nervous system to alert the individual of a falling glucose level. Failure of the sympathoadrenal responses increases the risk of hypoglycemia. In If insulin is given before a meal to patients with gastroparesis, hypoglycemia may develop because the insulin action may peak before the food is absorbed. Hypoglycemia can occur with ESKD, presumably because of decreased insulin clearance and loss of renal gluconeogenesis.

Hypoglycemia can develop in patients taking sulfonylureas, repaglinide, and nateglinide, particularly if the patient is older, has kidney or liver disease, or is taking other medications that alter the metabolism of the sulfonylureas (eg, sulfonamides or warfarin). Hypoglycemia occurs more frequently with the use of long-acting sulfonylureas than with shorter-acting agents. Hypoglycemia in insulin-treated patients is a consequence of three factors: behavioral issues, impaired counterregulatory systems, and complications of diabetes. Though not absolutely contraindicated, β-blockers must be used with caution in patients who use insulin. β-Blockers can blunt most sympathetic symptoms of hypoglycemia except sweating; therefore, β-1-selective blocking agents are preferred.

To prevent and treat insulin-induced hypoglycemia, a patient with diabetes should carry glucose tablets or juice at all times. For most episodes, ingestion of 15 g of carbohydrate is sufficient to reverse the hypoglycemia. The patient should be instructed to check the blood glucose in 15 minutes and treat again if the glucose level is still low. *A parenteral (1 mg) or nasal inhalation (3 mg) glucagon emergency kit should be provided to every patient with diabetes who is receiving insulin therapy.* Family or friends should be instructed how to inject glucagon subcutaneously or intramuscularly into the buttock, arm, or thigh or administer a nasal dose in the event that the patient is unconscious or will not ingest food. Glucagon can occasionally cause vomiting, and the unconscious patient should be turned on his or her side to protect the airway. Glucagon mobilizes glycogen from the liver, raising the blood glucose by about 36 mg/dL (2 mmol/L) in about 15 minutes. After the patient recovers consciousness, additional oral carbohydrate should be given. *Patients with diabetes receiving medications that can cause hypoglycemia should wear an identification MedicAlert bracelet or necklace or carry a card in their wallet (800-ID-ALERT, www.medicalert.org).*

Medical personnel treating severe hypoglycemia can give 50 mL of 50% glucose solution by rapid intravenous infusion. If intravenous access is not available, 1 mg of glucagon can be injected intramuscularly or 3 mg given by nasal spray.

3. Immunopathology of insulin therapy—

a. Insulin allergy—Insulin allergy, or immediate-type hypersensitivity, is a rare condition in which local or systemic urticaria is due to histamine release from tissue mast cells sensitized by adherence of anti-insulin IgE antibodies. In severe cases, anaphylaxis results. When only human insulin has been used from the onset of insulin therapy, insulin allergy is exceedingly rare. Antihistamines, corticosteroids, and even desensitization may be required, especially for systemic hypersensitivity.

b. Immune insulin resistance—A low titer of circulating IgG anti-insulin antibodies that neutralize the action of insulin to a small extent develops in most insulin-treated patients. This is rarely of clinical importance with the switch to human or highly purified pork insulins from the old animal insulins and has not been reported with the analogs.

c. Lipodystrophy—Atrophy of subcutaneous fatty tissue leading to disfiguring excavations and depressed areas may rarely occur at the site of insulin injection. This complication results from an immune reaction, and it has become rarer with the use of human and highly purified insulin preparations. Lipohypertrophy, on the other hand, is a consequence of the pharmacologic effects of insulin being injected in the same location repeatedly. Rotation of injection sites and avoiding needle reuse will prevent lipohypertrophy.

Rodriguez-Gutierrez R et al. Benefits and harms of intensive glycemic control in patients with type 2 diabetes. BMJ. 2019;367:l5887. [PMID: 31690574]

G. Transplantation

1. Pancreas transplantation—Patients undergoing simultaneous pancreas and kidney transplantation have an 83% chance of pancreatic graft survival at 1 year and 69% at 5 years. Solitary pancreatic transplantation in the absence of a need for kidney transplantation is considered only in those rare patients who do not respond to all other insulin therapeutic approaches and who have frequent severe hypoglycemia, or who have life-threatening complications related to their lack of metabolic control. Solitary pancreas transplant graft survival is 78% at 1 year and 54% at 5 years. All patients with ESKD and type 1 diabetes who are candidates for a kidney transplant are potential candidates for a pancreas transplant. Eligible candidates include those younger than 55 and those with minimal cardiovascular risk. Extensive CAD and peripheral vascular disease, as well as significant obesity (weight > 100 kg), are contraindications to transplantation.

2. Islet transplantation—Islet transplantation can be pursued in select patients with type 1 diabetes who experience severe hypoglycemia and hypoglycemia unawareness, to help restore the α cell response critical for responding to hypoglycemia. Survival of the islet grafts, limited donor supply, and need for lifelong immunosuppression are big challenges. Islet transplantation is offered in a few specialized centers around the world.

Clinical Trials About Optimum Diabetic Glucose Control

Findings of the Diabetes Control and Complications Trial (DCCT) in type 1 diabetes and of the United Kingdom Prospective Diabetes Study (UKPDS) in type 2 diabetes have confirmed the beneficial effects of improved glycemic control in both type 1 and type 2 diabetes.

A. Type 1 Diabetes

The DCCT, a long-term therapeutic study involving 1441 patients with type 1 diabetes mellitus, reported that “near” normalization of blood glucose resulted in a delay in the onset and a major slowing of the progression of established microvascular and neuropathic complications of diabetes.

The intensive treatment group had a mean HbA_{1c} of 7.2% while in the conventionally treated group, the HbA_{1c} averaged 8.9%. Over the study period, which averaged 7 years, the intensive treatment group had a ~ 60% reduction in risk for diabetic retinopathy, nephropathy, and neuropathy compared with the other group. The intensively treated group also had a nonsignificant reduction in the risk of macrovascular disease of 41% (95% CI, –10% to 68%). Intensively treated patients had a threefold greater risk of serious hypoglycemia as well as a greater tendency toward weight gain; however, there were no deaths definitely attributable to hypoglycemia in any persons in the DCCT study, and no evidence of posthypoglycemic cognitive damage was detected.

The general consensus of the ADA is that intensive insulin therapy associated with comprehensive self-management training should be standard therapy in patients with type 1 diabetes mellitus after the age of puberty. Exceptions include those with advanced chronic kidney disease and older adults since the detrimental risks of hypoglycemia outweigh the benefits of tight glycemic control in these groups.

B. Type 2 Diabetes

The UKPDS, a multicenter study, was designed to establish whether the risk of macrovascular or microvascular complications could be reduced by intensive blood glucose control with oral hypoglycemic agents or insulin and whether any particular therapy was more beneficial than the other for patients with type 2 diabetes.

Intensive treatment with sulfonylureas, metformin, combinations of those two, or insulin achieved mean HbA_{1c} levels of 7%. This level of glycemic control decreased the risk of microvascular complications (retinopathy and nephropathy) in comparison with conventional therapy (mostly diet alone), which achieved mean levels of HbA_{1c} of 7.9%. Weight gain occurred in intensively treated patients except when metformin was used as monotherapy. No adverse cardiovascular outcomes were noted regardless of the therapeutic agent. In the subgroup of patients who were overweight or had obesity, metformin therapy was more beneficial than diet alone in reducing the number of patients who experienced MIs and strokes. Hypoglycemic reactions occurred in the intensive treatment groups, but only one death from hypoglycemia was documented during 27,000 patient-years of intensive therapy.

Tight control of blood pressure (median value 144/82 mm Hg vs 154/87 mm Hg) substantially reduced the risk of microvascular disease and stroke but not MI. In fact, reducing blood pressure by this amount had substantially greater impact on microvascular outcomes than that achieved by lowering HbA_{1c} from 7.9% to 7%. An epidemiologic analysis of the UKPDS data showed that every 10–mm Hg decrease in mean systolic blood pressure was associated with 11% reduction in risk for MI. More than half of the patients needed two or more medications for adequate therapy of their hypertension, and there was no demonstrable advantage of ACE inhibitor therapy over therapy with β-blockers with regard to diabetes end points. Use of a calcium channel blocker added to both treatment groups appeared to be safe over the long term in this population with diabetes despite some controversy in the literature about its safety in patients with diabetes.

Findings from the UKPDS support that glycemic control to HbA_{1c} levels of 7% show benefit in reducing total diabetes endpoints, including a 25% reduction in microvascular disease compared with HbA_{1c} levels of 7.9%. This reassures those who have questioned whether the value of intensive therapy, so convincingly shown by the DCCT in type 1 diabetes, can safely be extrapolated to older patients with type 2 diabetes. It also argues against the concept of a "threshold" of glycemic control since in this group there was a benefit from this modest reduction of HbA_{1c} below 7.9%, whereas in the DCCT a threshold was suggested in that further benefit was less apparent at HbA_{1c} levels below 8%.

Steps in the Management of Diabetes

A. Patient Education (Self-Management Training)

Since diabetes is a lifelong disorder, education of the patient and the family is a most important obligation of the clinician who provides care. The best persons to manage a disease that is affected so markedly by daily fluctuations in environmental stress, exercise, diet, and infections are the patients themselves and their families. The "teaching curriculum" should include explanations by the clinician or nurse of the nature of diabetes and its potential acute and chronic hazards and how they can be recognized early and prevented or treated. Self-monitoring of blood glucose should be emphasized, especially in patients with diabetes who require insulin, and instructions must be given on proper testing and recording of data.

Patients taking insulin should understand the actions of basal and bolus insulins. They should be taught to determine whether the basal dose is appropriate and how to adjust the rapidly acting insulin dose for the carbohydrate content of a meal. Patients and their families and friends should be taught to recognize signs and symptoms of hypoglycemia and how to treat low glucose reactions. Strenuous exercise can precipitate hypoglycemia, and patients must therefore be taught to reduce their insulin dosage in anticipation of strenuous activity or to take supplemental carbohydrate. Injection of insulin into a site farthest away from the muscles most involved in the exercise may help ameliorate exercise-induced hypoglycemia, since insulin injected in the proximity of exercising muscle may be more rapidly mobilized. Exercise training also increases the effectiveness of insulin, and insulin doses should be adjusted accordingly. Infections can cause insulin resistance, and patients should be instructed on how to manage the hyperglycemia with supplemental rapidly acting insulin.

Advice on personal hygiene, including detailed instructions on foot and dental care, should be provided. All infections (especially pyogenic ones) provoke the release of high levels of insulin antagonists, such as catecholamines or glucagon, and thus bring about a marked increase in insulin requirements. Patients who are taking oral glucose-lowering agents may decompensate and temporarily require insulin. Patients should be told about community agencies, such as ADA chapters, that can serve as a continuing source of instruction.

Finally, vigorous efforts should be made to persuade patients with newly diagnosed diabetes who smoke cigarettes to stop, since large vessel peripheral vascular disease and debilitating retinopathy are less common in nonsmoking patients with diabetes.

B. Medications

Treatment must be individualized on the basis of the type of diabetes and specific needs of each patient. However, certain general principles of management can be outlined for hyperglycemic states of different types.

1. Type 1 diabetes—

A combination of rapidly acting insulin analogs and long-acting insulin analogs allows for more physiologic insulin replacement. Table 32–8 illustrates a regimen with a rapidly acting insulin analog and long-acting basal insulin that might be appropriate for a 70-kg person with type 1 diabetes eating meals providing standard carbohydrate intake and moderate to low fat content.

Insulin glargine or insulin degludec is usually given once in the evening to provide 24-hour coverage. There are occasional patients in whom insulin glargine does not last for 24 hours, and in such cases, it needs to be given twice a day.

The 24-hour basal dosage is usually based on age and body weight. An adolescent might need as much as 0.4 unit/kg/day; a young adult (< 25 years), 0.35 unit/kg/day; and an older adult, 0.25 unit/kg/day. Insulin pumps allow the setting of different basal rates throughout the 24 hours and permit bolus dose adjustments by as little as 0.05-unit increments. For example, a 70-kg, 30-year-old person may require a basal rate of 0.7 unit per hour throughout the 24 hours with the exception of 3 AM to 8 AM, when 0.8 unit per hour might be appropriate (given the "**dawn phenomenon**"—reduced tissue sensitivity to insulin between 5 AM and 8 AM). The meal bolus varies based on the time of day and the person's age. Adolescents and young adults usually require 1 unit for about 10 g of carbohydrate. Older adults usually require about 1 unit for 15 g of carbohydrate. The correction factor—how much insulin is needed to lower glucose levels by 50 mg/dL—can be calculated from the insulin-to-carbohydrate ratios. For example, if 1 unit is required for 15 g of carbohydrate, then 1 unit will lower glucose levels by 50 mg/dL. If 1.5 units of insulin are required for 15 g of carbohydrate (that is, 1 unit for 10 g carbohydrate), then 1.5 units of insulin will lower glucose levels by 50 mg/dL (that is, 1 unit will lower glucose level by 33 mg/dL). For a 70-kg, 30-year-old person, bolus ratios of 1 unit for 12–15 g of carbohydrate plus 1 unit for 50 mg/dL of blood glucose over a target value of 120 mg/dL would be reasonable starting point. Further adjustments to basal and bolus dosages would depend on the results of blood glucose monitoring. One of the more difficult therapeutic problems in managing patients with type 1 diabetes is determining the proper adjustment of insulin dose when the prebreakfast blood glucose level is high. Occasionally, the prebreakfast hyperglycemia is due to the **Somogyi effect**, in which nocturnal hypoglycemia leads to a surge of counterregulatory hormones to produce high blood glucose levels by 7 AM. However, a more common cause for prebreakfast hyperglycemia is the waning of circulating insulin levels by the morning.

Table 32–8. Examples of intensive insulin regimens using rapidly acting insulin analogs (insulin lispro, aspart, or glulisine) and long-acting insulin analogs (NPH insulin, or insulin glargine or degludec) in a 70-kg man with type 1 diabetes.[1–3]

	Pre-breakfast	Pre-lunch	Pre-dinner	At Bedtime
Rapidly acting insulin analog	5 units	4 units	6 units	
NPH[3]	6–7 units			8–9 units
or				
Rapidly acting insulin analog	5 units	4 units	6 units	—
Insulin glargine or degludec[3]		—		15–16 units

[1] Assumes that patient is consuming approximately 75 g carbohydrate at breakfast, 60 g at lunch, and 90 g at dinner.

[2] The dose of rapidly acting insulin can be raised by 1 or 2 units if extra carbohydrate (15–30 g) is ingested or if premeal blood glucose is > 170 mg/dL (9.4 mmol/L).

[3] Insulin glargine or NPH must be given as a separate injection.

NPH, neutral protamine Hagedorn.

The diagnosis of the cause of prebreakfast hyperglycemia can be facilitated by self-monitoring of blood glucose at 3 AM in addition to the usual bedtime and 7 AM measurements or by analyzing data from the continuous glucose monitor. This is required for only a few nights, and when a particular pattern emerges from monitoring blood glucose levels overnight, appropriate therapeutic measures can be taken. The Somogyi effect can be treated by lowering the basal insulin dose at bedtime or by eating a snack at bedtime. When a waning insulin level is the cause, then either increasing the evening basal insulin dose or shifting it from dinnertime to bedtime (or both) can be effective.

The currently available closed-loop systems enable patients to achieve close to normal glucose levels in the morning with a low risk of nocturnal hypoglycemia and to improve overall glucose control. ***All patients with type 1 diabetes who have good self-management skills should be using these systems.***

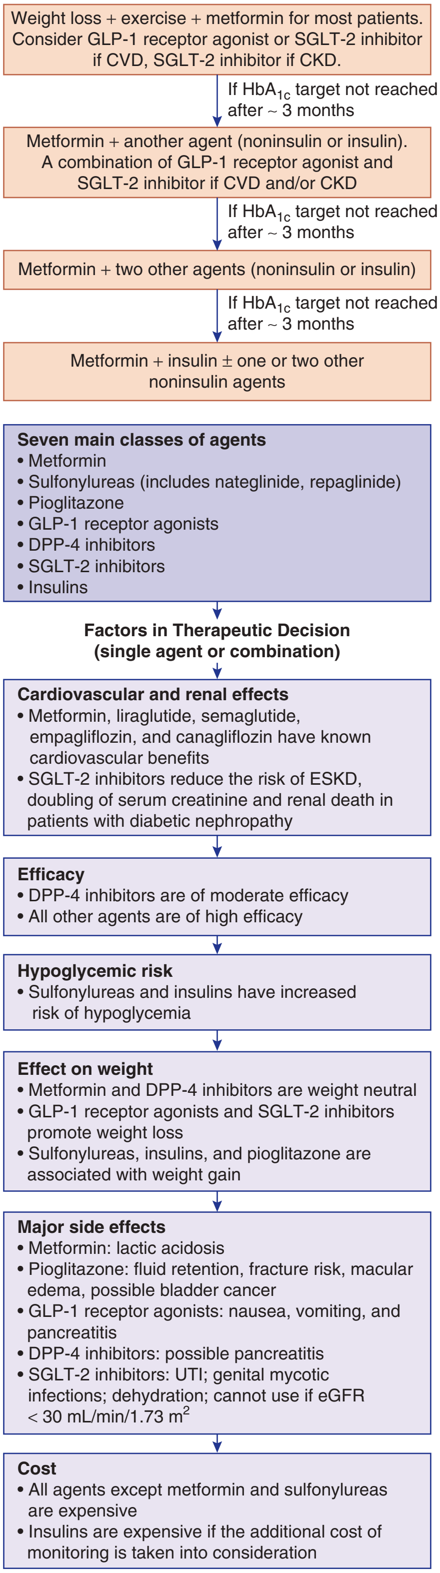
2. Type 2 diabetes—Therapeutic recommendations are based on the relative contributions of β cell insufficiency and insulin insensitivity in individual patients. The possibility that the individual patient has a specific etiologic cause for their diabetes should always be considered, especially when the patient does not have a family history of type 2 diabetes or does not have any evidence of central obesity or insulin resistance. Such patients should be evaluated for other types of diabetes such as **autoimmune (type 1)**, prior pancreatic injury, or MODY (Table 32–1). Patients with **autoimmune diabetes** should be prescribed insulin when the disease is diagnosed. Importantly, many patients with type 2 diabetes mellitus have a progressive loss of β cell function and will require additional therapeutic interventions with time.

Glucose-lowering agents—Figure 32–2 outlines the treatment approach based on a consensus algorithm by the ADA and the European Association for the Study of Diabetes. The current recommendation is to start pharmacologic therapy at diagnosis and not wait to see whether the patient can achieve target glycemic control with weight management and exercise. See discussion of the individual medications, above.

(1) Initial pharmacologic therapy—The presence of cardiovascular and/or kidney disease is an indication for prescribing a GLP-1 receptor agonist or an SGLT-2 inhibitor as initial therapy. Dulaglutide, liraglutide, and semaglutide are considered first line for patients with established atherosclerotic CVD and have proved beneficial for chronic kidney disease, particularly albuminuria. The SGLT-2 inhibitors canagliflozin, dapagliflozin, and empagliflozin have improved cardiovascular outcomes; these are especially beneficial in patients with HF, diabetes-associated nephropathy, or both. The need for weight loss should lead to the use of GLP-1 or dual GIP/GLP-1 receptor agonists in patients with or without CAD. Metformin remains an effective first-line agent if there is not underlying cardiovascular or kidney disease and is lower in cost.

(2) When initial pharmacologic therapy does not control glucose adequately—A second agent, usually a GLP-1 or GIP/GLP-1 receptor agonist or an SGLT-2 inhibitor, or metformin is added. Combined GLP-1 or GIP/GLP-1 receptor agonist and SGLT-2 inhibitor therapies should be considered for patients with cardiovascular disease and/or kidney disease. Sulfonylureas have been available for many years, and their use in combination with metformin is well established. They do, however, have the propensity to cause hypoglycemia and weight gain. In patients who experience hyperglycemia after a carbohydrate-rich meal (such as dinner), a short-acting secretagogue (repaglinide or nateglinide) before meals may suffice to get glucose levels into the target range. Patients with severe insulin resistance may be candidates for pioglitazone. Pioglitazone may also reduce the risk for recurrent stroke in patients who have a history of stroke or transient ischemic attack. If two agents are inadequate, then a third agent is added. The combination of metformin, a GLP-1 receptor agonist, and an SGLT-2 inhibitor should be considered in patients with obesity, heart disease, and kidney disease, although data regarding efficacy of such combined therapy are limited.

When the combination of non-insulin agents fails to achieve euglycemia in patients with type 2 diabetes, insulin treatment should be instituted. Various insulin regimens may be effective. One proposed regimen is to continue the oral agents (and injectable GLP-1 or dual GIP/GLP-1 receptor agonists) and then simply add a bedtime dose of long-acting insulin analog (insulin glargine, or degludec) to reduce excessive nocturnal hepatic glucose output and



Weight loss + exercise + metformin for most patients. Consider GLP-1 receptor agonist or SGLT-2 inhibitor if CVD, SGLT-2 inhibitor if CKD.
If HbA_{1c} target not reached after ~ 3 months
Metformin + another agent (noninsulin or insulin). A combination of GLP-1 receptor agonist and SGLT-2 inhibitor if CVD and/or CKD
If HbA_{1c} target not reached after ~ 3 months
Metformin + two other agents (noninsulin or insulin)
If HbA_{1c} target not reached after ~ 3 months
Metformin + insulin ± one or two other noninsulin agents
Seven main classes of agents
• Metformin
• Sulfonylureas (includes nateglinide, repaglinide)
• Pioglitazone
• GLP-1 receptor agonists
• DPP-4 inhibitors
• SGLT-2 inhibitors
• Insulins
Factors in Therapeutic Decision (single agent or combination)
Cardiovascular and renal effects
• Metformin, liraglutide, semaglutide, empagliflozin, and canagliflozin have known cardiovascular benefits
• SGLT-2 inhibitors reduce the risk of ESKD, doubling of serum creatinine and renal death in patients with diabetic nephropathy
Efficacy
• DPP-4 inhibitors are of moderate efficacy
• All other agents are of high efficacy
Hypoglycemic risk
• Sulfonylureas and insulins have increased risk of hypoglycemia
Effect on weight
• Metformin and DPP-4 inhibitors are weight neutral
• GLP-1 receptor agonists and SGLT-2 inhibitors promote weight loss
• Sulfonylureas, insulins, and pioglitazone are associated with weight gain
Major side effects
• Metformin: lactic acidosis
• Pioglitazone: fluid retention, fracture risk, macular edema, possible bladder cancer
• GLP-1 receptor agonists: nausea, vomiting, and pancreatitis
• DPP-4 inhibitors: possible pancreatitis
• SGLT-2 inhibitors: UTI; genital mycotic infections; dehydration; cannot use if eGFR < 30 mL/min/1.73 m^2
Cost
• All agents except metformin and sulfonylureas are expensive
• Insulins are expensive if the additional cost of monitoring is taken into consideration

▲ **Figure 32–2.** Algorithm for the treatment of type 2 diabetes based on the 2022 recommendations of the consensus panel of the American Diabetes Association/European Association for the Study of Diabetes.

improve fasting glucose levels. If the patient does not achieve target glucose levels during the day, then daytime insulin treatment can be initiated. If this regimen fails to achieve satisfactory glycemic goals or is associated with unacceptable frequency of hypoglycemic episodes, then a more intensive regimen of multiple insulin injections can be instituted as in patients with type 1 diabetes. Metformin principally reduces hepatic glucose output, and it is reasonable to continue with this medication when insulin therapy is instituted. Pioglitazone, which improves peripheral insulin sensitivity, can be used together with insulin but this combination is associated with more weight gain and peripheral edema. Sulfonylureas, GLP-1 receptor agonists, DPP-4 inhibitors, and SGLT-2 inhibitors also have been shown to be of continued benefit and may be continued with close monitoring for hypoglycemia. Weight-reducing interventions should continue even after initiation of insulin therapy and may allow for simplification of the therapeutic regimen in the future.

D. Acceptable Levels of Glycemic Control

A reasonable aim of therapy is to approach normal glycemic excursions without provoking severe or frequent hypoglycemia. Table 32–9 summarizes blood glucose and HbA$_{1c}$ goals for different patient groups. *The UKPDS study demonstrated that blood pressure control was as significant or more significant than glycemic control in patients with type 2 diabetes regarding the prevention of microvascular as well as macrovascular complications.*

Chronic Complications of Diabetes

Late clinical manifestations of diabetes mellitus include pathologic changes that involve small and large blood vessels, cranial and peripheral nerves, the skin, and the lens of the eye. These lesions lead to hypertension, ESKD, blindness, autonomic and peripheral neuropathy, amputations of the lower extremities, MI, and cerebrovascular accidents. These late manifestations correlate with the duration of the diabetic state subsequent to the onset of puberty. In type 1 diabetes, ESKD develops in up to 40% of patients, compared with < 20% of patients with type 2 diabetes. Proliferative retinopathy ultimately develops in both types of diabetes but has a slightly higher prevalence in type 1 diabetes (25% after 15 years' duration). In patients with type 1 diabetes, complications from ESKD are a major cause of death, whereas patients with type 2 diabetes are more likely to have macrovascular diseases leading to MI and stroke as the main causes of death. Cigarette use adds significantly to the risk of both microvascular and macrovascular complications in diabetes.

A. Ocular Complications

1. Diabetes-related cataracts—Premature cataracts occur in patients with diabetes and seem to correlate with both the duration of diabetes and the severity of chronic hyperglycemia. Nonenzymatic glycosylation of lens protein is twice as high in patients with diabetes as in age-matched persons without diabetes and may contribute to the premature occurrence of cataracts.

2. Diabetes-related retinopathy—The two main categories of diabetes-related retinopathy, nonproliferative and proliferative, are discussed in Chapter 7.

3. Glaucoma—Glaucoma occurs in approximately 6% of persons with diabetes. It is responsive to the usual therapy for open-angle disease. Neovascularization of the iris in patients with diabetes can predispose to closed-angle glaucoma, but this is relatively uncommon except after cataract extraction, when growth of new vessels has been known to progress rapidly, involving the angle of the iris and obstructing outflow.

Table 32–9. Glycemic targets for different groups of adults with either type 1 or type 2 diabetes.

	Blood Glucose mg/dL (mmol/L) Targets	HbA$_{1c}$ % (mmol/mol) Targets
Nonpregnant healthy adults	Premeal glucose 90–130 (5–7.2) 1-hour peak < 180 (10) 2-hour peak < 150 (8.3)	< 7 (53). Aim for < 6.5 (48) if it can be achieved without significant hypoglycemia or polypharmacy.
Pregnant women	Premeal glucose ≤ 95 (5.3) 1-hour peak ≤ 140 (7.8) 2-hour peak ≤ 120 (6.7)	6–6.5 (42–48). Aim for < 6 (42) if possible without significant hypoglycemia.
Older adults		
Healthy	Premeal 90–130 (5–7.2) Bedtime 90–150 (5–8.3)	< 7.5 (58)
Frail with limited life expectancy	Premeal 100–180 (5.6–10) Bedtime 110–200 (6.1–11.1)	< 8.5 (69)
Patients with history of severe hypoglycemia	Premeal 90–150 (5–8.3) Bedtime 100–180 (5.6–10)	< 8 (64)
Hospitalized patients	140–180 (7.8–10)	—
Patients with CKD	Glycemic targets in CKD are the same as those without CKD. HbA$_{1c}$ and fructosamine values may not be accurate in ESKD, and greater reliance should be placed on the home glucose measurements	

B. Diabetes-Related Nephropathy

Diabetes-related nephropathy is initially manifested by albuminuria; subsequently, as kidney function declines, urea and creatinine accumulate in the blood (see Chapter 25). An albumin-creatinine ratio in an early morning spot urine collected upon awakening is the preferred method to assess albumin excretion. In the early morning spot urine, a ratio of albumin (mg/dL) to creatinine (g/dL) < 30 mg/g is normal, a ratio of 30–300 mg/g suggests moderately increased albuminuria, and a ratio of > 300 mg/g suggests severe albuminuria. At least two early morning spot urine collections over a 3- to 6-month period should be abnormal before a diagnosis of moderately increased albuminuria is justified. Short-term hyperglycemia, exercise, UTIs, HF, and acute febrile illness can cause transient albuminuria and so testing should be postponed until resolution of these problems.

Subsequent ESKD can be predicted by persistent urinary albumin excretion rates exceeding 30 mcg/mg creatinine. Glycemic control as well as a protein diet of ~0.8 g/kg/day may reduce both the hyperfiltration and the elevated albuminuria in patients in the early stages of diabetes and those with incipient diabetes-related nephropathy. Antihypertensive therapy also decreases albuminuria. Evidence from some studies supports a specific role for ACE inhibitors in reducing intraglomerular pressure in addition to their lowering of systemic hypertension. An ACE inhibitor (captopril, 50 mg twice daily) in normotensive patients with diabetes impedes progression to proteinuria and prevents the increase in albumin excretion rate. SGLT-2 therapy should be instituted in patients with type 2 diabetes who have progression of kidney disease despite taking optimal antihypertensive therapy, which includes an ACE inhibitor or ARB.

C. Diabetes-Related Neuropathy

Diabetes-related neuropathies are the most common complications of diabetes, affecting up to 50% of older patients with type 2 diabetes.

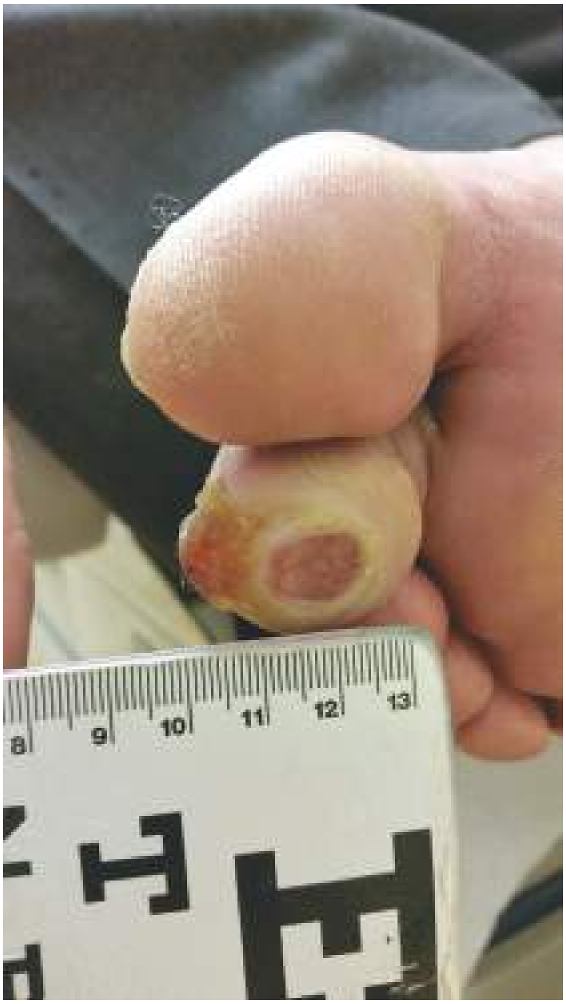
1. Peripheral neuropathy

A. Distal symmetric polyneuropathy—This is the most common form of diabetes-related peripheral neuropathy where loss of function appears in a stocking-glove pattern and is due to an axonal neuropathic process. Longer nerves are especially vulnerable, hence the impact on the foot. Both motor and sensory nerve conduction is delayed in the peripheral nerves, and ankle jerks may be absent.

Sensory involvement usually occurs first and is generally bilateral, symmetric, and associated with dulled perception of vibration, pain, and temperature. The pain can range from mild discomfort to severe incapacitating symptoms. The sensory deficit may eventually be of sufficient degree to prevent patients from feeling pain. Patients who have a sensory neuropathy should therefore be examined with a 5.07 Semmes-Weinstein filament and those who cannot feel the filament must be considered at risk for unperceived neuropathic injury.

The denervation of the small muscles of the foot can result in clawing of the toes and displacement of the submetatarsal fat pads anteriorly. These changes, together with the joint and connective tissue changes, alter the biomechanics of the foot and increase plantar pressures. This combination of decreased pain threshold, abnormally high foot pressures, and repetitive stress (such as from walking) can lead to calluses and ulcerations in the high-pressure areas such as over the metatarsal heads (Figure 32–3). Peripheral neuropathy, autonomic neuropathy, and trauma also predispose to the development of **Charcot arthropathy**. An acute case of Charcot foot arthropathy presents with pain and swelling, and if left untreated, leads to a "rocker bottom" deformity and ulceration. The early radiologic changes show joint subluxation and periarticular fractures. As the process progresses, there is frank osteoclastic destruction leading to deranged and unstable joints particularly in the midfoot.

Not surprisingly, the key issue for the healing of neuropathic ulcers in a foot with good vascular supply is



▲ **Figure 32–3.** Neuropathic foot ulcer in a patient with diabetes.

mechanical unloading. In addition, any infection should be treated with debridement and appropriate antibiotics; healing duration of 8–10 weeks is typical. Occasionally, when healing appears refractory, platelet-derived growth factor (becaplermin [Regranex]) should be considered for local application. Once ulcers are healed, therapeutic footwear is key to preventing recurrences. Custom molded shoes are reserved for patients with significant foot deformities. Other patients with neuropathy may require accommodative insoles that distribute the load over as wide an area as possible. Patients with foot deformities and loss of their protective threshold should get regular care from a podiatrist. Patients should be educated on appropriate footwear and those with loss of their protective threshold should be instructed to inspect their feet daily for reddened areas, blisters, abrasions, or lacerations.

In some patients, hypersensitivity to light touch and occasionally severe "burning" pain, particularly at night, can become physically and emotionally disabling. Nortriptyline or desipramine in doses of 25–150 mg/day orally may provide dramatic relief for pain from diabetes-related neuropathy, often within 48–72 hours. Patients often attribute the benefit to having a full night's sleep. Mild to moderate morning drowsiness is a side effect that generally improves with time or can be lessened by giving the medication several hours before bedtime. This medication should not be continued if improvement has not occurred after 5 days of therapy. Amitriptyline, 25–75 mg orally at bedtime, can also be used but has more anticholinergic effects. Tricyclic antidepressants, in combination with fluphenazine (3 mg daily in three divided doses), have been shown in two studies to be efficacious in painful neuropathy, with benefits unrelated to relief of depression. Gabapentin (900–1800 mg orally daily in three divided doses) has also been shown to be effective in the treatment of painful neuropathy and should be tried if the tricyclic medications prove ineffective. Pregabalin, a congener of gabapentin, has been shown in an 8-week study to be more effective than placebo in treating painful peripheral neuropathy. However, this medication was not compared with an active control. Also, because of its abuse potential, it is categorized as a schedule V controlled substance. Duloxetine (60–120 mg), a serotonin and norepinephrine reuptake inhibitor, is approved for the treatment of painful neuropathy. Capsaicin, a topical irritant, is effective in reducing local nerve pain; it is dispensed as a cream (Zostrix 0.025%, Zostrix-HP 0.075%) to be rubbed into the skin over the painful region two to four times daily. Gloves should be used for application since hand contamination could result in discomfort if the cream comes in contact with eyes or sensitive areas such as the genitalia. Application of a 5% lidocaine patch over an area of maximal pain has been reported to be of benefit. It is approved for treatment of postherpetic neuralgia.

Diabetes-related neuropathic cachexia is a syndrome characterized by a symmetric peripheral neuropathy, profound weight loss (up to 60% of total body weight), and painful dysesthesias affecting the proximal lower limbs, the hands, or the lower trunk. Treatment is usually with insulin and analgesics. The prognosis is generally good, and patients typically recover their baseline weight with resolution of the painful sensory symptoms within 1 year.

B. ISOLATED PERIPHERAL NEUROPATHY—Involvement of the distribution of only one nerve ("mononeuropathy") or of several nerves ("mononeuropathy multiplex") is characterized by sudden onset with subsequent recovery of all or most of the function. This neuropathology has been attributed to vascular ischemia or traumatic damage. Cranial and femoral nerves are commonly involved, and motor abnormalities predominate. The patient with cranial nerve involvement usually has diplopia and single third, fourth, or sixth nerve weakness on examination but the pupil is spared. A full recovery of function occurs in 6–12 weeks. Diabetic amyotrophy presents with onset of severe pain in the front of the thigh. Within a few days or weeks of the onset of pain, weakness and wasting of the quadriceps develops. As the weakness appears, the pain tends to improve. Management includes analgesia and improved diabetes control. The symptoms improve over 6–18 months.

2. Autonomic neuropathy—Neuropathy of the autonomic system occurs principally in patients with diabetes of long duration. It affects many diverse visceral functions including blood pressure and pulse, GI activity, bladder function, and erectile dysfunction. Treatment is directed specifically at each abnormality. Insulin neuritis or treatment-induced diabetic neuropathy occurs occasionally in patients who have had poor glucose control and then whose glucose levels improve rapidly in days or a few weeks. Symptoms include severe sensory neuropathic pains and sometimes autonomic functions. These symptoms improve over a few months.

A. GI SYSTEM—Involvement of the GI system may be manifested by nausea, vomiting, postprandial fullness, reflux or dysphagia, constipation or diarrhea (or both), and fecal incontinence. Gastroparesis should be considered in patients with type 1 diabetes in whom unexpected fluctuations and variability in their blood glucose levels develops after meals. Metoclopramide has been of some help in treating diabetic gastroparesis. It is given in a dose of 10 mg orally three or four times a day, 30 minutes before meals and at bedtime. Drowsiness, restlessness, fatigue, and lassitude are common adverse effects. Tardive dyskinesia and extrapyramidal effects can occur, especially when used for longer than 3 months, and the FDA has cautioned against the long-term use of metoclopramide.

Erythromycin appears to bind to motilin receptors in the stomach and has been found to improve gastric emptying over the short term in doses of 250 mg three times daily, but its effectiveness seems to diminish over time. In selected patients, injections of botulinum toxin into the pylorus can reduce pylorus sphincter resistance and enhance gastric emptying. Gastric electrical stimulation has been reported to improve symptoms and quality of life indices in patients with gastroparesis refractory to pharmacologic therapy.

Diarrhea associated with autonomic neuropathy has occasionally responded to broad-spectrum antibiotic therapy (such as rifaximin, metronidazole, amoxicillin/

clavulanate, ciprofloxacin, or doxycycline), although it often undergoes spontaneous remission. Refractory diabetes-related diarrhea is often associated with impaired sphincter control and fecal incontinence. Therapy with loperamide, 4–8 mg daily, or diphenoxylate with atropine, two tablets up to four times a day, may provide relief. In more severe cases, tincture of paregoric or codeine (60-mg tablets) may be required to reduce the frequency of diarrhea and improve the consistency of the stools. Clonidine has been reported to lessen diarrhea; however, its usefulness is limited by its tendency to lower blood pressure in these patients who already have autonomic neuropathy, resulting in orthostatic hypotension. Constipation usually responds to stimulant laxatives such as senna.

b. Genitourinary system—Incomplete emptying of the bladder can sometimes occur. Bethanechol in doses of 10–50 mg orally three times a day has occasionally improved emptying of the atonic urinary bladder. Catheter decompression of the distended bladder may improve its function, and considerable benefit has been reported after surgical severing of the internal vesicle sphincter.

Erectile dysfunction can result from neurologic, psychological, or vascular causes, or a combination of these causes. The phosphodiesterase type 5 (PDE5) inhibitors sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis) have been shown in placebo-controlled clinical trials to improve erections in response to sexual stimulation. The recommended dose of sildenafil for most patients is one 50-mg tablet taken approximately 1 hour before sexual activity. The peak effect is at 1.5–2 hours, with some effect persisting for 4 hours. Patients with diabetes mellitus using sildenafil reported 50–60% improvement in erectile function. The maximum recommended dose is 100 mg. The recommended dose of both vardenafil and tadalafil is 10 mg. The doses may be increased to 20 mg or decreased to 5 mg based on efficacy and side effects. Tadalafil has been shown to improve erectile function for up to 36 hours after dosing. Low doses are available for daily use. In clinical trials, only a few adverse effects have been reported—transient mild headache, flushing, dyspepsia, and some altered color vision. Priapism can occur with these medications, and patients should be advised to seek immediate medical attention if an erection persists for longer than 4 hours. The PDE5 inhibitors potentiate the hypotensive effects of nitrates, and their use is contraindicated in patients who are concurrently using organic nitrates in any form. *Caution is advised for men who have experienced a heart attack, stroke, or life-threatening arrhythmia within the previous 6 months; men who have resting hypotension or hypertension; and men who have a history of HF or have unstable angina*. Rarely, a decrease in vision or permanent visual loss has been reported after PDE5 inhibitor use.

c. Orthostatic hypotension—Use of Jobst fitted stockings, tilting the head of the bed, and arising slowly from the supine position can be helpful in treating symptoms of orthostatic hypotension. When such measures are inadequate, treatment with fludrocortisone 0.1–0.2 mg orally daily can be considered. This medication, however, can result in supine hypertension and hypokalemia. The α-agonist midodrine (10 mg orally three times a day) can also be used.

D. Cardiovascular Complications

1. Hypertension—The ADA recommends lowering systolic blood pressure to < 130 mm Hg and diastolic pressure to < 80 mm Hg in patients with diabetes. The Systolic Blood Pressure Intervention Trial reported that treating to a systolic blood pressure of < 120 mm Hg reduced cardiovascular events by 25% and death from cardiovascular causes by 43% during 3.26 years of follow-up. Persons with diabetes, however, were excluded from this study, and it is unclear if the results are applicable to this population. Patients with type 2 diabetes who have CAD or albuminuria should be treated with an ACE inhibitor or ARB as first-line therapy. Multidrug therapy is often required. If BP ≥ 150/90 mmHg, two agents should be initiated (ACE inhibitor/ARB, calcium channel blocker or diuretic). A mineralocorticoid receptor antagonist should be considered in resistant hypertension on 3 classes of antihypertensives and blood pressure is not at goal (see Chapter 13).

2. Cardiovascular disease—Atherosclerotic cardiovascular disease (ASCVD)—which includes CAD, stroke, and peripheral arterial disease—is the leading cause of morbidity and mortality in diabetes, and risk of death from ASCVD is two- to threefold higher than in those without diabetes. ASCVD in type 1 diabetes manifests primarily as CHD. ASCVD is more aggressive in individuals with type 1 diabetes than in individuals without diabetes. Premenopausal women who typically have lower rates of CAD lose this protection once diabetes develops. Women with type 1 diabetes have increased risk of fatal and nonfatal coronary artery disease. Microangiopathy occurs in the heart of patients with diabetes and may explain the etiology of congestive cardiomyopathies in those who do not have demonstrable CAD. Adults with type 1 and type 2 diabetes are at risk for HF. The ADA recommends screening asymptomatic adults for HF by measuring BNP or N-terminal pre-BNP and, if abnormal, obtaining echocardiogram so that treatment can be prescribed to lower risk of progression to stage C symptomatic HF. Individuals with type 2 diabetes often have risk factors for cardiovascular disease that may predate the development of diabetes, including dyslipidemia, visceral adiposity, hypertension, and hepatic steatosis. The increased ASCVD risk in patients with type 2 diabetes reflects the combination of hyperglycemia, hyperlipidemia, abnormalities of platelet adhesiveness, coagulation factors, hypertension, oxidative stress, and inflammation.

A risk-based approach for lipid-lowering therapy for primary prevention is recommended using the ACC/AHA risk calculator. Lowering LDL-C reduces first events in patients without known coronary disease and secondary events in patients with known coronary disease. For individuals with diabetes and known ASCVD, lipid-lowering therapy with statins to lower LDL-C to < 55 mg/dL is recommended due to very high-risk status of these individuals. If LDL-C goal is not attained, addition of ezetimibe, bempedoic acid, and/or PCSK9 inhibitor therapy is indicated. For primary ASCVD risk reduction (those without ASCVD), an LDL-C goal of < 70 mg/dL is recommended. Thus, most individuals with type 2 diabetes aged 40–75 years will need moderate-intensity statin therapy. For patients with type 2 diabetes aged 20–39 years, statin therapy should be discussed if there are additional ASCVD risk factors such as hypertension, obesity, or family history of ASCVD or CKD. Routine screening for CAD is not recommended in asymptomatic individuals with diabetes; however, patients with diabetes should already be receiving intensive therapy to optimize cardiovascular outcomes.

Aspirin at a dose of 81–325 mg daily is effective in reducing cardiovascular morbidity and mortality in patients who have a history of MI or stroke (secondary prevention). For primary prevention, a 2018 randomized study of 15,480 persons with diabetes but no evident CVD observed that 100 mg of aspirin reduced the first vascular event of MI, stroke, or transient ischemic attack or death from vascular event (excluding intracranial hemorrhage) (rate ratio 0.88; 95% CI 0.79 to 0.97). There were, however, more major bleeding events, especially GI, in the aspirin group (rate ratio 1.29; 95% CI 1.09 to 1.52). Thus, for primary prevention, the use of aspirin should only be considered for patients with diabetes who have high cardiovascular risk and low bleeding risk and generally not for adults older than 70 years. Based on the Early Treatment Diabetic Retinopathy Study, there does not appear to be a contraindication to aspirin use in patients who have diabetic proliferative retinopathy. Aspirin also does not seem to affect the severity of vitreous/preretinal hemorrhages or their resolution.

3. Peripheral arterial disease—In patients with diabetes, atherosclerosis is markedly accelerated in the larger arteries. It is often diffuse, with localized enhancement in certain areas of turbulent blood flow, such as at the bifurcation of the aorta or other large vessels. Clinical manifestations of peripheral arterial disease include ischemia of the lower extremities, erectile dysfunction, and intestinal angina. The ADA recommends screening individuals annually for peripheral artery disease with a history and physical examination, and if there are positive signs or symptoms, referring for noninvasive arterial vascular ultrasound studies. If a foot ulcer is present with abnormal noninvasive testing, immediate referral for vascular evaluation is warranted. Doppler ultrasonography should be repeated every 5 years if initial testing is normal.

The incidence of **gangrene of the feet** in patients with diabetes is 30 times that in age-matched controls. The factors responsible for its development, in addition to peripheral vascular disease, are small vessel disease, peripheral neuropathy with loss of both pain sensation and neurogenic inflammatory responses, and secondary infection. In two-thirds of patients with ischemic gangrene, pedal pulses are not palpable. In the remaining one-third who have palpable pulses, reduced blood flow through these vessels can be demonstrated by plethysmographic or Doppler ultrasound examination. Prevention of foot injury is imperative. Agents that reduce peripheral blood flow such as tobacco should be avoided. Control of other risk factors such as hypertension is essential. β-Blockers are relatively contraindicated because of presumed negative peripheral hemodynamic consequences but data that support this are lacking. Target LDL from treatment with cholesterol-lowering agents should be < 55 mg/dL (1.42 mmol/L) for established central or peripheral arterial disease. Patients should be advised to seek immediate medical care if a diabetic foot ulcer develops. Improvement in peripheral blood flow with endarterectomy and bypass operations is possible in certain patients.

E. Skin and Mucous Membrane Complications

Chronic pyogenic infections of the skin may occur, especially in patients with poorly controlled diabetes. Candidal infection can produce erythema and edema of intertriginous areas below the breasts, in the axillae, and between the fingers. It causes vulvovaginitis in women with chronically uncontrolled diabetes who have persistent glucosuria and is a frequent cause of pruritus. Glycosuria due to SGLT-2 administration can also increase the risk for candidal vulvovaginitis and balanoposthitis. While antifungal creams containing miconazole or clotrimazole offer immediate relief of vulvovaginitis, recurrence is frequent unless glucosuria is reduced.

In some patients with type 2 diabetes, poor glycemic control can cause severe hypertriglyceridemia, which can present as eruptive cutaneous xanthomas and pancreatitis. The skin lesions appear as yellow morbilliform eruptions 2–5 mm in diameter with erythematous areolae. They occur on extensor surfaces (elbows, knees, buttocks) and disappear after triglyceride levels are reduced.

Necrobiosis lipoidica diabeticorum is usually located over the anterior surfaces of the legs or the dorsal surfaces of the ankles. They are oval or irregularly shaped plaques with demarcated borders and a glistening yellow surface and occur in women two to four times more frequently than in men. Pathologically, the lesions show degeneration of collagen, granulomatous inflammation of subcutaneous tissues and blood vessels, capillary basement membrane thickening and obliteration of vessel lumina. The condition is associated with type 1 diabetes, although it can occur in patients with type 2 diabetes, and also in patients without diabetes. First-line therapy includes topical and subcutaneous corticosteroids. Improving glycemic control may help the condition.

"Shin spots" (diabetes-related dermopathy) are not uncommon in adults with diabetes. They are brownish, rounded, painless atrophic lesions of the skin in the pretibial area.

F. Bone and Joint Complications

Long-standing diabetes can cause progressive stiffness of the hand secondary to contracture and tightening of skin over the joints (diabetes-related cheiroarthropathy), frozen shoulder (adhesive capsulitis), carpal tunnel syndrome, and Dupuytren contractures. These complications are believed to be due to glycosylation of collagen and perhaps other proteins in connective tissue. There may also be an inflammatory component.

Data on bone mineral density and fracture risk in patients with diabetes are contradictory. Patients with type 2 diabetes do appear to be at increased risk for nonvertebral fractures. Women with type 1 diabetes have an increased risk of fracture when compared with women without diabetes. Other factors, such as duration of diabetes, and diabetes complications, such as neuropathy and kidney disease, likely affect both the bone mineral density and fracture risk.

Diffuse idiopathic skeletal hyperostosis is characterized by ossification of the anterior longitudinal ligaments of the spine and various extraspinal ligaments. It causes stiffness and decreased range of spinal motion. The peripheral joints most commonly affected are the metacarpophalangeal joints, elbows, and shoulders. Diabetes, obesity, hypertension, and dyslipidemia are risk factors for this condition.

Hyperuricemia and acute and tophaceous gout are more common in type 2 diabetes.

Bursitis, particularly of the shoulders and hips, occurs more frequently than expected in patients with diabetes.

▶ Special Situations

A. Diabetes Management in the Hospital

Hospitalized patients are generally not eating as usual and they are often fasting for procedures, which makes it challenging to use outpatient oral or insulin regimens. There may be an increase in the adverse reactions of diabetes medicines (eg, thiazolidinediones can cause fluid retention and worsen HF); metformin should not be used in patients with significant chronic kidney or liver disease or those getting contrast for radiographic studies; and SGLT-2 inhibitors may be associated with increased risk of diabetic ketoacidosis. The data on the use of CGM, insulin pumps, and hybrid closed-loop systems in hospitalized patients are insufficient. Whether patients stay on these systems in the hospital will depend on their severity of illness and access to specialist care. In general, decisions regarding insulin dosing should be made based on capillary blood glucose measurements and not on the data from CGM. Patients should be transitioned to a conventional basal bolus subcutaneous insulin regimen if they are unable to manage their pump and/or CGM because of their illness or if they decline to follow the institutional guidelines on using the pump or continuous monitor (eg, clinical staff are unable to motivate or enhance patient adherence). The systems have to be removed if the patient is getting an MRI.

On the **general medical and surgical inpatient services**, most patients are treated with subcutaneous insulin regimens. Limited cross-sectional and prospective studies suggest that the best glucose control is achieved on a combination of basal and bolus regimen with 50% of daily insulin needs provided by intermediate- or long-acting insulins. Standardized order sets can reduce errors, and they often include algorithms for recognition and treatment of hypoglycemia (see http://ucsfinpatientdiabetes.pbworks.com for examples). Oral medicines, especially metformin and sulfonylureas, can be resumed as the patient is being prepared for hospital discharge.

In the **ICUs**, glucose levels are controlled most frequently using insulin infusions (http://ucsfinpatientdiabetes.pbworks.com). Patients receiving total parenteral nutrition can have insulin added to the bag. Standard total parenteral nutrition contains 25% dextrose, so an infusion rate of 50 mL/hour delivers 12.5 g of dextrose per hour.

Based on the evidence available, ICU patients with diabetes and new-onset hyperglycemia with blood glucose levels above 180 mg/dL (10 mmol/L) should be treated with insulin, aiming for target glucose levels between 140 mg/dL (7.8 mmol/L) and 180 mg/dL (10 mmol/L). In the ICU setting, aiming for blood glucose levels close to 100 mg/dL (5.6 mmol/L) is not beneficial and may even be harmful. When patients leave the ICU, target glucose values between 100 mg/dL (5.6 mmol/L) and 180 mg/dL (10 mmol/L) may be appropriate, although this view is based on clinical observations rather than conclusive evidence.

Preoperative and perioperative diabetes management strategies are discussed in Chapter 3.

The morbidity and mortality in hospitalized patients with diabetes are twice those of patients without diabetes. Those with new-onset hyperglycemia (ie, those without a preadmission diagnosis of diabetes) have even higher mortality—almost eightfold that of patients without diabetes in one study. These observations have led to the question of whether tight glycemic control in the hospital improves outcomes.

B. Diabetes in Pregnancy

See Chapter 22.

HYPERGLYCEMIC CRISES

Hyperglycemic crises result in 1% of all hospital admissions in patients with diabetes. Coma may be due to causes not directly related to diabetes and requires differentiation (Table 32–10): (1) Hypoglycemic coma from excessive insulin or oral hypoglycemic agents. (2) Hyperglycemic coma with either severe insulin deficiency (DKA) or mild to moderate insulin deficiency (hyperglycemic hyperosmolar state). (3) Lactic acidosis, particularly when patients with diabetes have severe infections or cardiovascular collapse.

Table 32–10. Laboratory diagnosis of diabetic coma.

	Urine Glucose	Urine Ketones	Plasma Glucose	Serum Bicarbonate	Serum Ketones
Related to Diabetes					
Hypoglycemia	0[1]	0 or +	Low	Normal	0
Diabetic ketoacidosis	++++	++++	High	Low	++++
Hyperglycemic hyperosmolar state coma	++++	0 or +	High	Normal or slightly low	0
Lactic acidosis	0 or +	0 or +	Normal or low or high	Low	0 or +
Unrelated to Diabetes					
Alcohol or other toxic drugs	0 or +	0 or +	May be low	Normal or low[2]	0 or +
Cerebrovascular accident or head trauma	+ or 0	0	Often high	Normal	0
Uremia	0 or +	0	High or normal	Low	0 or +

[1] Leftover urine in bladder might still contain glucose from earlier hyperglycemia.
[2] Alcohol can elevate plasma lactate as well as keto acids to reduce pH.

1. Diabetic Ketoacidosis

ESSENTIALS OF DIAGNOSIS

- Hyperglycemia ≥ 200 mg/dL (13.9 mmol/L) or prior history of diabetes regardless of glucose value.
- Ketosis with serum β-hydroxybutyrate concentration > 3.0 mmol/L or urine ketone test strip ≥ 2+.
- Metabolic acidosis with blood pH < 7.3 and/or serum bicarbonate < 15 mEq/L.

General Considerations

DKA results from severe insulin deficiency and increasing levels of counterregulatory hormones (glucagon, cortisol, epinephrine, and growth hormones). The combination of insulin deficiency and increased counterregulatory hormones results in release of free fatty acids from adipose tissue, leading to unrestrained hepatic fatty acid oxidation, excess ketone body production, ketonemia, and metabolic acidosis.

DKA is a life-threatening condition that primarily occurs in patients with type 1 diabetes but can occasionally occur in patients with type 2 diabetes who have severe illness, such as sepsis or trauma. DKA may be the initial manifestation of type 1 diabetes or may be precipitated by an acute stressor or omission of insulin therapy. While DKA can occur at any age, most cases of DKA occur in adults < 45 years of age who have type 1 diabetes. However, in the United States, more than half of Black/African American and Hispanic/Latino adults with DKA and newly diagnosed diabetes have type 2 diabetes. DKA rates have increased in the past decade. Recurrent episodes of DKA are common in the same individual; therefore, it is important to identify triggers to prevent frequent episodes.

Reported mortality during hospital admission for DKA ranges from 0.20% in type 1 diabetes to 1.04% in type 2 diabetes. After an episode of DKA, there is a 1-year age-corrected 13-fold increase in mortality rate compared with the general population. Risk factors for DKA include acute infections (most commonly, especially UTI or pneumonia), intercurrent illnesses, psychological stress, and omission or insufficient use of insulin. DKA can also be precipitated by a stroke or MI, alcohol and substance use, acute pancreatitis, and trauma. Patients with diabetes and a history of DKA may have a higher prevalence of mental health disorders. The omission or rationing of insulin therapy, often in the setting of psychosocial stressors, is a major cause of DKA. DKA can occur in patients with type 1 diabetes who use insulin pumps, commonly precipitated by error in self-management and intercurrent illness rather than pump malfunction. Drugs such as corticosteroids, SGLT-2 inhibitors, atypical antipsychotics, and immune checkpoint inhibitors can precipitate DKA. DKA may occur with newly diagnosed type 1 diabetes during or after a COVID-19 infection.

Clinical Findings

A. Symptoms and Signs

In DKA, the time between initial symptoms and acute presentation may be hours to a few days. Polyuria, polydipsia, marked fatigue, nausea, vomiting, and abdominal pain may occur. If untreated, mental stupor ensues and can progress to coma. Drowsiness is common, but frank coma occurs only in ~10% of patients.

On physical examination, volume status should be assessed with vital signs. Hypotension with tachycardia indicates profound fluid and electrolyte depletion, and mild hypothermia is usually present. Evidence of dehydration in a stuporous patient with rapid deep breathing and a “fruity” breath odor due to the presence of acetone (a breakdown product of a ketone) strongly suggests the diagnosis. Abdominal pain and even tenderness may be present in the absence of abdominal disease. Conversely, cholecystitis or pancreatitis may occur with minimal symptoms and signs. Patients should be examined for signs of infection, ischemia, and other potential precipitating factors. An ECG should be performed to assess for evidence of peaked T waves from hyperkalemia and ischemia.

B. Laboratory Findings

The severity of DKA can be classified as mild, moderate, or severe based on the degree of metabolic acidosis (blood pH, serum bicarbonate, and ketone levels) and the presence of altered mental status. This categorization can help triage where a patient should receive care (eg, emergency department, ICU, or step-down unit) and whether patients with mild DKA can receive subcutaneous insulin dosing rather than intravenous insulin infusion. All criteria need not be fulfilled for classification as mild, moderate, or severe, and the decision for where an individual receives care in the hospital should be a clinical one. The difference between venous and arterial pH is 0.02 to 0.15 pH units and venous and arterial bicarbonate is 1.88 mEq/L. Although the classification of the severity of DKA is based in part on arterial pH, the small differences between arterial and venous values will not affect the diagnosis or the management of DKA, and there is no need to collect arterial blood for measuring the acid-base status.

1. Mild DKA—Patients are alert and have pH levels 7.25–7.30 or serum bicarbonate 15–18 mmol/L and β-hydroxybutyrate levels of 3–6 mmol/L. Mental status is alert.

2. Moderate DKA—Patients are alert or a little drowsy and have pH levels 7.0–7.25. Serum bicarbonate is 10 to < 15 mmol/L, and β-hydroxybutyrate levels are 3–6 mmol/L.

3. Severe DKA—Patients are stuporous and have a pH < 7.0. Serum bicarbonate is < 10 mmol/L, and β-hydroxybutyrate levels are > 6 mmol/L.

Typically, patients with moderately severe DKA have plasma glucoses of 350–900 mg/dL (19.4–50 mmol/L), serum ketones at a dilution of ≥ 1:8 or β-hydroxybutyrate > 4 nmol/L, hyperkalemia (serum potassium level of 5–8 mEq/L), mild hyponatremia (serum sodium of ~130 mEq/L), hyperphosphatemia (serum phosphate level of 6–7 mg/dL [1.9–2.3 mmol/L]), and elevated BUN and serum creatinine levels (Table 32–10). Acidosis may be severe (pH 6.9–7.2 and serum bicarbonate 5–15 mEq/L); Pco_2 is low (15–20 mm Hg) related to compensatory hyperventilation. Fluid depletion is marked, typically about 100 mL/kg. Lactate levels are usually elevated and > 2 mmol/L in > 50% of the patients. The hyperlactatemia is not due to hypoxia or sepsis and reflects metabolic fuel use in the insulin-deficient state. Higher glucose levels and lower pH levels are associated with higher lactate levels.

4. Euglycemic ketoacidosis—About 10% of patients with DKA have euglycemic DKA, with severe acidosis and fluid depletion but only modestly elevated plasma glucose levels, usually < 200 mg/dL (11.1 mmol/L). The most common cause of euglycemic DKA is SGLT-2 inhibitor use, but it also can occur from decreased food intake, pregnancy, or impaired gluconeogenesis (eg, alcohol use, liver failure).

The difference between venous and arterial pH is 0.02–0.15 pH units and venous and arterial bicarbonate is 1.88 mEq/L. These small differences will not affect the diagnosis or the management of DKA, and there is no need to collect arterial blood for measuring the acid-base status.

Hyperkalemia occurs despite total body potassium depletion because of the shift of potassium from the intracellular to extracellular spaces that occurs in systemic acidosis. The average total body potassium deficit resulting from osmotic diuresis, acidosis, and GI losses is ~3–5 mEq/kg. Similarly, despite the elevated serum phosphate, total body phosphate is generally depleted. Serum sodium is generally reduced due to loss of sodium ions (7–10 mEq/kg) by polyuria and vomiting and because severe hyperglycemia shifts intracellular water into the interstitial compartment. For every 100 mg/dL of plasma glucose, serum sodium decreases by 1.6 mEq/L (5.56 mmol/L). The decrease in serum sodium may be greater when patients have more severe hyperglycemia (> 400 mg/dL, 22.2 mmol/L), and a correction factor of 2.4 mEq/L may be used. Hypertriglyceridemia should be considered if the corrected sodium is very low. Serum osmolality can be directly measured by standard tests of freezing point depression or can be estimated by calculating the molarity of sodium, chloride, and glucose in the serum. A convenient method of estimating effective serum osmolality is as follows (normal values are 280–300 mOsm/kg):

$$\text{mOsm/kg} = 2\,[\text{measured Na}^+] + \frac{\text{Glucose (mg/dL)}}{18}$$

These calculated estimates are usually 10–20 mOsm/kg lower than values measured by standard cryoscopic techniques. CNS depression or coma occurs when the effective serum osmolality exceeds 320–330 mOsm/L. Coma in a patient with concurrent diabetes and lower osmolality should prompt a search for the cause of coma other than hyperosmolality (see Table 32–10 and Chapter 27).

5. Ketoacidemia—Ketoacidemia represents the effect of insulin lack at multiple enzyme loci. Insulin lack associated with elevated levels of growth hormone, catecholamines, and glucagon contributes to increases in lipolysis from adipose tissue and in hepatic ketogenesis. In addition, reduced ketolysis by insulin-deficient peripheral tissues contributes to the ketoacidemia. The only true “keto” acid present in DKA is acetoacetic acid which, along with its by-product acetone, is measured by nitroprusside reagents (Acetest and Ketostix). The sensitivity for acetone, however, is poor, requiring > 10 mmol/L, which is seldom reached in the plasma of ketoacidotic patients—although this detectable concentration is readily achieved in urine. Thus, in the plasma of ketotic patients, only acetoacetate is measured by these reagents. The more prevalent β-hydroxybutyric acid has no ketone group and is therefore not detected by conventional nitroprusside tests. This takes on special importance in the presence of circulatory collapse during DKA, wherein an increase in lactic acid can shift the redox state to increase β-hydroxybutyric acid at the expense of the readily detectable acetoacetic acid. Bedside diagnostic reagents are then unreliable, suggesting no ketonemia in cases where β-hydroxybutyric acid is a major factor in producing the acidosis. Combined glucose and ketone meters (Precision Xtra, Nova Max Plus) that measure blood β-hydroxybutyrate concentration on capillary blood are available. Many clinical laboratories also offer direct blood β-hydroxybutyrate measurement.

Nonspecific elevations of serum amylase and lipase occur in about 16–25% of cases of DKA, and an imaging study may be necessary if the diagnosis of acute pancreatitis is being seriously considered. Leukocytosis as high as 25,000/mcL (25 × 10^9/L) with a left shift may occur with or without associated infection. The presence of an elevated or even a normal temperature can suggest the presence of an infection since patients with DKA are generally hypothermic if uninfected.

Treatment

Most patients with uncomplicated mild or moderate DKA can be treated in the emergency department or step-down unit if close nursing supervision and monitoring are available. Patients with **severe DKA** or with critical illness as a precipitating cause should be admitted to the ICU.

Therapeutic goals are to restore plasma volume and tissue perfusion, reduce blood glucose and osmolality toward normal, correct acidosis, replenish electrolyte losses, and identify and treat precipitating factors. Gastric intubation is recommended in the comatose patient to prevent vomiting and aspiration that may occur as a result of gastric atony, a common complication of DKA. An indwelling urinary catheter may also be necessary. In patients with preexisting heart or kidney failure or those in severe cardiovascular collapse, a CVP catheter should be inserted to evaluate the degree of hypovolemia and to monitor subsequent fluid administration.

A comprehensive flow sheet that includes vital signs, serial laboratory data, and therapeutic interventions (eg, fluids, insulin) should be meticulously maintained by the clinician responsible for the patient's care. Plasma glucose should be recorded hourly and electrolytes and pH at least every 2–3 hours during the initial treatment period. Bedside glucose meters should be used to titrate the insulin therapy. The patient should not receive sedatives or opioids in order to avoid masking signs and symptoms of impeding cerebral edema (see Complications & Prognosis, below).

A. Fluid Replacement

In most patients with DKA, the fluid deficit is 4–5 L. Initially, 0.9% saline solution is the solution of choice to help re-expand the contracted vascular volume and should be started in the emergency department as soon as the diagnosis is established. The saline should be infused at an initial rate of 500–1000 mL/hour over the first 2–4 hours. Use 0.9% ("normal") saline unless the serum sodium is > 150 mEq/L, when 0.45% ("half normal") saline solution should be used. The volume status should be carefully monitored clinically. Failure to give enough volume replacement (at least 3–4 L in 8 hours) to restore normal perfusion is one of the most serious therapeutic shortcomings adversely influencing satisfactory recovery. Excessive fluid replacement (> 5 L in 8 hours) may contribute to acute respiratory distress syndrome or cerebral edema. Plasma glucose concentrations usually decrease to < 250 mg/dL (13.9 mmol/L) within 4–8 hours, even before ketoacidosis resolves. Therefore, when blood glucose falls to ~250 mg/dL (13.9 mmol/L), the fluids should be changed to a 5% glucose-containing solution to maintain serum glucose in the range of 250–300 mg/dL (13.9–16.7 mmol/L) to prevent the development of hypoglycemia and allow for continued insulin administration until the ketonemia resolves.

B. Insulin Replacement

Insulin therapy is the mainstay of treatment; therefore immediately after initiation of fluid replacement, regular insulin should be administered intravenously in a loading dose of 0.1 unit/kg as a bolus to prime the tissue insulin receptors. Following the initial bolus, intravenous doses of insulin as low as 0.1 unit/kg/hour are continuously infused or given hourly as an intramuscular injection; this is sufficient to replace the insulin deficit in most patients. A prospective randomized study showed that a bolus dose is not required if patients are given hourly insulin infusion at 0.14 unit/kg. Replacement of insulin deficiency helps correct the acidosis by reducing the flux of fatty acids to the liver, reducing ketone production by the liver, and also improving removal of ketones from the blood. Insulin treatment also reduces the hyperosmolality by reducing the hyperglycemia. It accomplishes this by increasing removal of glucose through peripheral utilization as well as by decreasing production of glucose by the liver. This latter effect is accomplished by direct inhibition of gluconeogenesis and glycogenolysis as well as by lowered amino acid flux from muscle to liver and reduced hyperglucagonemia.

The insulin infusion should be "piggy-backed" into the fluid line so the rate of fluid replacement can be changed without altering the insulin delivery rate. If the plasma glucose level fails to fall at least 10% in the first hour, a repeat loading dose (0.1 or 0.14 unit/kg) is recommended. Rarely, a patient with immune insulin resistance is encountered, and this requires doubling the insulin dose every 2–4 hours if hyperglycemia does not improve after the first two doses of insulin. The insulin dose should be adjusted to lower the glucose concentration by about 50–70 mg/dL/hour (2.8–3.9 mmol/L). If clinical circumstances prevent use of an insulin infusion, then the insulin can be given intramuscularly. An initial 0.15 unit/kg of regular insulin is given intravenously, and at the same time, the same size dose is given intramuscularly. Subsequently, regular insulin is given intramuscularly hourly at a dose of 0.1 unit/kg until the blood glucose falls to around 250 mg/dL, when the insulin can be given subcutaneously. Patients who typically take insulin glargine or insulin detemir can be given their usual maintenance doses during the initial treatment of their DKA. The continuation of their subcutaneous basal insulins means that lower doses of intravenous insulin will be needed, and there will be a smoother transition from intravenous insulin infusion to the subcutaneous regimen.

C. Potassium

Total-body potassium loss from polyuria and vomiting may be as high as 200 mEq. However, because of shifts of potassium from cells into the extracellular space as a consequence of acidosis, serum potassium is usually normal to slightly elevated prior to institution of treatment. As the acidosis is corrected, potassium flows back into the cells, and hypokalemia can develop if potassium replacement is not instituted. To avoid hypokalemia, serum potassium should be measured 2 hours after starting insulin administration and every 4 hours thereafter until the resolution of DKA. If the patient is not uremic and has an adequate urinary output, potassium chloride in doses of 10–30 mEq/hour should be infused during the second and third hours after beginning therapy as soon as the acidosis starts to resolve. Replacement should be started sooner if the initial serum potassium is inappropriately normal or low and should be delayed if serum potassium fails to respond to initial therapy and remains > 5 mEq/L, as in cases of CKD. Occasionally, a patient may present with a serum potassium level < 3.5 mEq/L, in which case insulin therapy should be delayed until the potassium level is corrected to > 3.5 mEq/L. An ECG can help monitor the patient's potassium status: High peaked T waves are a sign of hyperkalemia, and flattened T waves with U waves are a sign of hypokalemia.

D. Sodium Bicarbonate

Routine bicarbonate administration for treatment of DKA is not recommended. Potentially harmful consequences can occur including: (1) development of hypokalemia from rapid shift of potassium into cells if the acidosis is overcorrected; (2) tissue anoxia from reduced dissociation of oxygen from hemoglobin when acidosis is rapidly reversed (leftward shift of the oxygen dissociation curve); and (3) cerebral acidosis resulting from lowering of CSF pH. However, with very severe acidosis (arterial blood pH ≤ 7.0), administration of bicarbonate is recommended with careful monitoring to prevent overcorrection. If needed, 100 mmol of sodium bicarbonate (8.4% solution) in 400 mL of sterile water (an isotonic solution) can be given every 2 hours to achieve a pH of 7.1. (Note: Addition of sodium bicarbonate to 0.9% saline would produce a markedly hypertonic solution that could aggravate the hyperosmolar state already present.) *Bicarbonate should not be given if the pH is ≥ 7.1* since additional bicarbonate would increase the risk of rebound metabolic alkalosis as ketones are metabolized. Alkalosis shifts potassium from serum into cells, which could precipitate a fatal cardiac arrhythmia.

E. Phosphate

Phosphate replacement is seldom required in treating DKA. However, if severe hypophosphatemia of < 1 mg/dL (0.32 mmol/L) develops during insulin therapy, a small amount of phosphate can be replaced per hour as the potassium salt. Three randomized studies, though, in which phosphate was replaced in patients with DKA did not show any apparent clinical benefit from phosphate administration. Moreover, attempts to use potassium phosphate as the sole means of replacing potassium have led to a number of reported cases of severe hypocalcemia with tetany. To minimize the risk of inducing tetany from too-rapid replacement of phosphate, the average deficit of 40–50 mmol of phosphate should be replaced intravenously at a rate *no greater than 3–4 mmol/hour* in a 60- to 70-kg person. A stock solution provides a mixture of 1.12 g KH_2PO_4 and 1.18 g K_2HPO_4 in a 5-mL single-dose vial (this equals 22 mmol of potassium and 15 mmol of phosphate). One-half of this vial (2.5 mL) should be added to 1 L of either 0.45% saline or 5% dextrose in water. Two liters of this solution, infused at a rate of 400 mL/hour will correct the phosphate deficit at the optimal rate of 3 mmol/hour while providing 4.4 mEq of potassium per hour. (Additional potassium should be administered as potassium chloride to provide a total of 10–30 mEq of potassium per hour, as noted above.) If the serum phosphate remains < 2.5 mg/dL (0.8 mmol/L) after this infusion, a repeat 5-hour infusion can be given.

F. Hyperchloremic Acidosis During Therapy

Because of the considerable loss of keto acids in the urine during the initial phase of therapy, substrate for subsequent regeneration of bicarbonate is lost and correction of the total bicarbonate deficit is hampered. A portion of the bicarbonate deficit is replaced with chloride ions infused in large amounts as saline to correct the dehydration. In most patients, as the ketoacidosis clears during insulin replacement, a hyperchloremic, low-bicarbonate pattern emerges with a normal anion gap. This is a relatively benign condition that reverses itself over the subsequent 12–24 hours once intravenous saline is no longer being administered. Using a balanced electrolyte solution with a pH of 7.4 and 98 mEq/L chloride such as Plasma-Lyte instead of normal saline (pH ~5.5; chloride 154 mEq/L) has been reported to prevent the hyperchloremic acidosis.

G. Treatment of Associated Infection

Antibiotics are prescribed as indicated (Table 35–5). Cholecystitis and pyelonephritis may be particularly severe in these patients.

H. Transition to Subcutaneous Insulin Regimen

Once the DKA is controlled and the patient is awake and able to eat, subcutaneous insulin therapy can be initiated. The patient with type 1 diabetes may have persistent significant tissue insulin resistance and may require a total daily insulin dose of approximately 0.6 unit/kg. The amount of insulin required in the previous 8 hours can also be helpful in estimating the initial insulin doses. Half the total daily dose can be given as a long-acting basal insulin and the other half as short-acting insulin premeals. The patient should receive subcutaneous basal insulin and rapid-acting insulin analog with the first meal and the insulin infusion discontinued an hour later. The overlap of the subcutaneous insulin action and insulin infusion is necessary to prevent relapse of the DKA. In patients with preexisting diabetes, giving their basal insulin by subcutaneous injection at initiation of treatment simplifies the transition from intravenous to subcutaneous regimen. The increased insulin resistance is only present for a few days, and it is important to reduce both the basal and bolus insulins to avoid hypoglycemia. A patient with new-onset type 1 diabetes usually still has significant β cell function and may not need any basal insulin and only very low doses of rapid-acting insulin before meals after recovery from the ketoacidosis. Patients with type 2 diabetes and DKA due to severe illness may initially require insulin therapy but can often transition back to oral agents during outpatient follow-up.

Complications & Prognosis

Low-dose insulin infusion and fluid and electrolyte replacement combined with careful monitoring of patients' clinical and laboratory responses to therapy have dramatically reduced the mortality rates of DKA to < 5% in individuals < 40 years of age. However, this complication remains a significant risk in the aged who have mortality rates > 20% and in patients in profound coma in whom treatment has been delayed. Acute MI and infarction of the bowel following prolonged hypotension worsen the outlook. A serious prognostic sign is ESKD, and prior kidney dysfunction worsens the prognosis considerably because the kidney plays a key role in compensating for massive pH and electrolyte abnormalities. Symptomatic cerebral edema occurs primarily in the pediatric population. Risk factors for its development include severe baseline acidosis, rapid correction of hyperglycemia, and excess volume administration in the first 4 hours. Onset of headache or deterioration in mental status during treatment should lead to consideration of this complication. Intravenous mannitol at a dosage of 1–2 g/kg given over 15 minutes is the mainstay of treatment. Excess crystalloid infusion can precipitate pulmonary edema. Acute respiratory distress syndrome is a rare complication of treatment of DKA.

After recovery and stabilization, patients should be instructed on how to recognize the early symptoms and signs of ketoacidosis. Urine ketones or capillary blood β-hydroxybutyrate should be measured in patients with signs of infection or in insulin pump-treated patients when capillary blood glucose remains unexpectedly and persistently high. When heavy ketonuria and glycosuria persist on several successive examinations, supplemental rapid-acting insulin should be administered and liquid foods such as lightly salted tomato juice and broth should be ingested to replenish fluids and electrolytes. The patient should be instructed to contact the clinician if ketonuria persists, and especially if there is vomiting and inability to keep down fluids. Recurrent episodes of severe ketoacidosis often indicate poor adherence with the insulin regimen, and these patients will require intensive counseling.

Dhatariya KK; Joint British Diabetes Societies for Inpatient Care. The management of diabetic ketoacidosis in adults—an updated guideline from the Joint British Diabetes Society for Inpatient Care. Diabet Med. 2022;39:e14788. [PMID: 35224769]

2. Hyperglycemic Hyperosmolar State

ESSENTIALS OF DIAGNOSIS

- Glucose > 600 mg/dL (33.3 mmol/L).
- Serum osmolality > 310 mOsm/kg.
- No acidosis; blood pH > 7.3.
- Serum bicarbonate > 15 mEq/L.
- Normal anion gap (< 14 mEq/L).

General Considerations

This second most common form of hyperglycemic coma is characterized by severe hyperglycemia in the absence of significant ketosis, with hyperosmolality and dehydration. It occurs in patients with mild or occult diabetes, and most patients are typically middle-aged or older. Accurate figures are not available as to its true incidence, but from data on hospital discharges, it is rarer than DKA even in older age groups. Underlying CKD or HF is common, and the presence of either worsens the prognosis. A precipitating event such as infection, MI, stroke, or recent operation is often present. Certain medications such as phenytoin, diazoxide, corticosteroids, and diuretics have been implicated in its pathogenesis, as have procedures associated with glucose loading such as peritoneal dialysis.

Pathogenesis

A partial or relative insulin deficiency may initiate the syndrome by reducing glucose utilization of muscle, fat, and liver while inducing hyperglucagonemia and increasing hepatic glucose output. With massive glycosuria, obligatory water loss ensues. If a patient is unable to maintain adequate fluid intake because of an associated acute or chronic illness or has experienced excessive fluid loss, marked dehydration results. As the plasma volume contracts, kidney function becomes impaired, limiting the urinary glucose losses and exacerbating the hyperglycemia. Severe hyperosmolality develops that causes mental confusion and finally coma. It is not clear why ketosis is virtually absent under these conditions of insulin insufficiency, although reduced levels of growth hormone may be a factor, along with portal vein insulin concentrations sufficient to restrain ketogenesis.

Clinical Findings

A. Symptoms and Signs

Onset may be insidious over a period of days or weeks, with weakness, polyuria, and polydipsia. The lack of features of DKA (eg, vomiting, rapid deep breathing, acetone odor) may retard recognition of the syndrome and delay therapy until dehydration becomes more profound than in ketoacidosis. Reduced intake of fluid is not an uncommon historical feature, due to either inappropriate lack of thirst, nausea, or inaccessibility of fluids to patients who are bedridden and frail. A history of ingestion of large quantities of glucose-containing fluids, such as soft drinks or orange juice, can occasionally be obtained. Lethargy and confusion develop as serum osmolality exceeds 310 mOsm/kg, and convulsions and coma can occur if osmolality exceeds 320–330 mOsm/kg. Physical examination confirms the presence of profound dehydration in a lethargic or comatose patient without Kussmaul respirations.

B. Laboratory Findings

Severe hyperglycemia is present, with blood glucose values ranging from 800 mg/dL to 2400 mg/dL (44.4 mmol/L to 133.2 mmol/L) (Table 32–10). In mild cases, where dehydration is less severe, dilutional hyponatremia as well as urinary sodium losses may reduce serum sodium to 120–125 mEq/L, which protects to some extent against extreme hyperosmolality. However, as dehydration progresses, serum sodium can exceed 140 mEq/L, producing serum osmolality readings of 330–440 mOsm/kg. Ketosis and acidosis are usually absent or mild. Prerenal azotemia is the rule, with serum urea nitrogen elevations > 100 mg/dL (35.7 mmol/L) being typical.

▶ Treatment

A. Fluid Replacement

Fluid replacement is of paramount importance in treating the nonketotic hyperglycemic state. Fluid deficit may be as much as 6–10 L.

If hypovolemia is present as evidenced by hypotension and oliguria, fluid therapy should be initiated with 0.9% saline. In all other cases, 0.45% saline appears to be preferable as the initial replacement solution because the body fluids of these patients are markedly hyperosmolar. As much as 4–6 L of fluid may be required in the first 8–10 hours. Careful monitoring of the patient is required for proper sodium and water replacement. An important end point of fluid therapy is to restore urinary output to 50 mL/hour or more. Once blood glucose reaches 250 mg/dL (13.9 mmol/L), fluid replacement should include 5% dextrose in either water, 0.45% saline solution, or 0.9% saline solution. The rate of dextrose infusion should be adjusted to maintain glycemic levels of 250–300 mg/dL (13.9–16.7 mmol/L) in order to reduce the risk of cerebral edema.

B. Insulin

Less insulin may be required to reduce the hyperglycemia in nonketotic patients as compared to those with diabetic ketoacidotic coma. In fact, fluid replacement alone can reduce hyperglycemia considerably by correcting the hypovolemia, which then increases both glomerular filtration and renal excretion of glucose. Insulin treatment should therefore be delayed unless the patient has significant ketonemia (β-hydroxybutyrate > 1 mmol/L). Start the insulin infusion rate at 0.05 unit/kg/hour (bolus is not needed) and titrate to lower blood glucose levels by 50–70 mg/dL per hour (2.8–3.9 mmol/L/hour). Once the patient has stabilized and the blood glucose falls to around 250 mg/dL (13.9 mmol/L), insulin can be given subcutaneously.

C. Potassium

With the absence of acidosis, there may be no initial hyperkalemia unless associated ESKD is present. This results in less severe total potassium depletion than in DKA, and less potassium replacement is therefore needed. However, because initial serum potassium is usually not elevated and because it declines rapidly as a result of insulin's effect on driving potassium intracellularly, it is recommended that potassium replacement be initiated earlier than in ketotic patients, assuming that no CKD or oliguria is present. Potassium chloride (10 mEq/L) can be added to the initial bottle of fluids administered if the patient's serum potassium is not elevated.

D. Phosphate

If severe hypophosphatemia (serum phosphate < 1 mg/dL [0.32 mmol/L]) develops during insulin therapy, phosphate replacement can be given as described for ketoacidotic patients (at 3 mmol/hour).

▶ Complications & Prognosis

The severe dehydration and low output state may predispose the patient to complications such as MI, stroke, PE, mesenteric vein thrombosis, and disseminated intravascular coagulation. Fluid replacement remains the primary approach to the prevention of these complications. Low-dose heparin prophylaxis is reasonable, but benefits of routine anticoagulation remain doubtful. Rhabdomyolysis is a recognized complication and should be looked for and treated.

The overall mortality rate of hyperglycemic hyperosmolar state coma is > 10 times that of DKA, chiefly because of its higher incidence in older patients, who may have compromised cardiovascular systems or associated major illnesses and whose dehydration is often excessive because of delays in recognition and treatment. (When patients are matched for age, the prognoses of these two hyperglycemic emergencies are reasonably comparable.) When prompt therapy is instituted, the mortality rate can be reduced from nearly 50% to that related to the severity of coexistent disorders.

After the patient is stabilized, the appropriate form of long-term management of the diabetes must be determined. Insulin treatment should be continued for a few weeks, but patients usually recover sufficient endogenous insulin secretion to make a trial of diet or diet plus oral agents worthwhile. When the episode occurs in a patient who has known diabetes, then education of the patient and caregivers should be instituted. They should be taught how to recognize situations (nausea and vomiting, infection) that predispose to recurrence of the hyperglycemic, hyperosmolar state, as well as detailed information on how to prevent the escalating dehydration that culminates in hyperosmolar coma (small sips of sugar-free liquids, increase in usual hypoglycemic therapy, or early contact with the clinician).

LACTIC ACIDOSIS

ESSENTIALS OF DIAGNOSIS

- Severe metabolic acidosis with compensatory hyperventilation.
- Blood pH < 7.30.
- Serum bicarbonate < 15 mEq/L.
- Anion gap > 15 mEq/L.
- Absent serum ketones.
- Serum lactate > 5 mmol/L.

General Considerations

Lactic acidosis is characterized by accumulation of excess lactic acid in the blood. Normally, the principal sources of this acid are the erythrocytes (which lack enzymes for aerobic oxidation), skeletal muscle, skin, and brain. Conversion of lactic acid to glucose and its oxidation principally by the liver but also by the kidneys represent the chief pathways for its removal. Hyperlactatemia and acidosis occur when lactate production exceeds lactate consumption. Causes include tissue hypoxia, disorders that increase epinephrine levels (severe asthma with excess β-adrenergic agonist use, cardiogenic or hemorrhagic shock, pheochromocytoma), and drugs that impair oxidative phosphorylation (antiretroviral agents and propofol). Metformin-associated lactic acidosis is uncommon and most cases occurred in patients in whom there were contraindications to the use of metformin, in particular kidney failure. Metformin levels are usually > 5 mcg/L when metformin is implicated as the cause of lactic acidosis. Other causes of lactic acidosis include several inborn errors of metabolism and the MELAS syndrome (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes). D-Lactic acidosis can occur in patients with short bowel syndrome when unabsorbed carbohydrates are presented as substrate for fermentation by colonic bacteria.

Clinical Findings

A. Symptoms and Signs

The main clinical feature of lactic acidosis is marked hyperventilation. When lactic acidosis is secondary to tissue hypoxia or vascular collapse, the clinical presentation is variable, being that of the prevailing catastrophic illness. However, in the idiopathic, or spontaneous, variety, the onset is rapid (usually over a few hours), blood pressure is normal, peripheral circulation is good, and there is no cyanosis.

B. Laboratory Findings

Plasma bicarbonate and blood pH are quite low, indicating the presence of severe metabolic acidosis. Ketones are usually absent from plasma and urine or at least not prominent. The first clue may be a high anion gap (serum sodium minus the sum of chloride and bicarbonate anions [in mEq/L] should be no > 15). A higher value indicates the existence of an abnormal compartment of anions. If this cannot be clinically explained by an excess of keto acids (diabetes), inorganic acids (uremia), or anions from medication overdosage (salicylates, methyl alcohol, ethylene glycol), then lactic acidosis is probably the correct diagnosis (see also Chapter 24). In the absence of azotemia, hyperphosphatemia may be a clue to the presence of lactic acidosis for reasons that are not clear. The diagnosis is confirmed by a plasma lactic acid concentration of ≥ 5 mmol/L (values as high as 30 mmol/L have been reported). Normal plasma values average 1 mmol/L, with a normal lactate/pyruvate ratio of 10:1. This ratio is greatly exceeded in lactic acidosis.[1]

Treatment

Aggressive treatment of the precipitating cause of lactic acidosis is the main component of therapy, such as ensuring adequate oxygenation and vascular perfusion of tissues. Empiric antibiotic coverage for sepsis should be given after culture samples are obtained in any patient in whom the cause of the lactic acidosis is not apparent (Table 35–5).

Alkalinization with intravenous sodium bicarbonate to keep the pH above 7.2 has been recommended by some in the emergency treatment of lactic acidosis; as much as 2000 mEq in 24 hours has been used. However, there is no evidence that the mortality rate is favorably affected by administering bicarbonate, and its use remains controversial. Hemodialysis may be useful in cases where large sodium loads are poorly tolerated and in cases associated with metformin toxicity.

Prognosis

The mortality rate of spontaneous lactic acidosis is high. The prognosis in most cases is that of the primary disorder that produced the lactic acidosis.

Yang CC et al. Clinical presentations and prognosis of metformin-associated lactic acidosis patients in the intensive care unit: a 20-year survey. Medicine (Baltimore). 2022;101:e29918. [PMID: 35801742]

---

[1] In collecting samples, it is essential to rapidly chill and separate the blood in order to remove red cells, whose continued glycolysis at room temperature is a common source of error in reports of high plasma lactate. Frozen plasma remains stable for subsequent assay.

THE HYPOGLYCEMIC STATES

Spontaneous hypoglycemia in adults is of two principal types: fasting and postprandial. Symptoms begin at plasma glucose levels in the range of 60 mg/dL (3.3 mmol/L) and impairment of brain function at approximately 50 mg/dL (2.8 mmol/L). Fasting hypoglycemia is often subacute or chronic and usually presents with neuroglycopenia as its principal manifestation; postprandial hypoglycemia is relatively acute and is often heralded by symptoms of neurogenic autonomic discharge (sweating, palpitations, anxiety, tremulousness).

Differential Diagnosis

Fasting hypoglycemia may occur in certain endocrine disorders, such as hypopituitarism, Addison disease, or myxedema; in disorders related to liver malfunction, such as acute alcohol use disorder, or liver failure; and in instances of ESKD, particularly in patients requiring dialysis (Table 32–11). These conditions are usually obvious, with hypoglycemia being only a secondary feature. When fasting hypoglycemia is a primary manifestation developing in adults without apparent endocrine disorders or inborn metabolic diseases from childhood, the principal diagnostic possibilities include (1) hyperinsulinism, due to either pancreatic β cell tumors or iatrogenic or surreptitious administration of insulin or sulfonylurea; and (2) hypoglycemia due to extrapancreatic tumors.

Postprandial (reactive) hypoglycemia may occur after GI surgery and is particularly associated with the dumping syndrome after gastrectomy and Roux-en-Y gastric bypass surgery. Occult diabetes very occasionally presents with postprandial hypoglycemia.

Alcohol-related hypoglycemia is due to hepatic glycogen depletion combined with alcohol-mediated inhibition of gluconeogenesis. It is most common in malnourished individuals with excessive alcohol intake but can occur in anyone who is unable to ingest food after acute alcohol use followed by gastritis and vomiting.

Immunopathologic hypoglycemia is an extremely rare condition in which anti-insulin antibodies or antibodies to insulin receptors develop spontaneously.

Table 32–11. Common causes of hypoglycemia in adults.[1]

Fasting hypoglycemia
Pancreatic β cell tumor
Surreptitious administration of insulin or sulfonylureas
Extrapancreatic tumors
Postprandial hypoglycemia
Gastric surgery
Occult diabetes mellitus
Alcohol-related hypoglycemia
Immunopathologic hypoglycemia
Idiopathic anti-insulin antibodies (which release their bound insulin)
Antibodies to insulin receptors (which act as agonists)
Drug-induced hypoglycemia

[1] In the absence of clinically obvious endocrine, kidney, or liver disorders and exclusive of diabetes mellitus treated with hypoglycemic agents.

HYPOGLYCEMIA DUE TO PANCREATIC β CELL TUMORS

ESSENTIALS OF DIAGNOSIS

- Hypoglycemic symptoms—often neuroglycopenic (confusion, blurred vision, anxiety, convulsions).
- Immediate recovery upon administration of glucose.
- Blood glucose 40–50 mg/dL (2.2–2.8 mmol/L) with a serum insulin level of ≥ 6 microunits/mL.

General Considerations

Fasting hypoglycemia in an otherwise healthy, well-nourished adult is rare and is most commonly due to an adenoma of the islets of Langerhans. Ninety percent of such tumors are single and benign, but multiple adenomas can occur as well as malignant tumors with functional metastases. Adenomas may be familial, and multiple adenomas have been found in conjunction with tumors of the parathyroids and pituitary (MEN type 1 [MEN 1]). More than 99% of insulinomas are located within the pancreas and < 1% in ectopic pancreatic tissue.

Clinical Findings

A. Symptoms and Signs

The most important prerequisite to diagnosing an insulinoma is simply to consider it, particularly in relatively healthy-appearing persons who have fasting hypoglycemia with some degree of CNS dysfunction such as confusion or atypical behavior. A delay in diagnosis can result in unnecessary treatment for epilepsy or psychiatric disorders and may cause irreversible brain damage. In long-standing cases, obesity can result as a consequence of overeating to relieve symptoms.

The so-called Whipple triad is characteristic of hypoglycemia regardless of the cause. It consists of (1) a history of hypoglycemic symptoms, (2) an associated low plasma glucose level (40–50 mg/dL), and (3) relief of symptoms upon ingesting fast-acting carbohydrates in approximately 15 minutes. The hypoglycemic symptoms in insulinoma often develop in the early morning or after missing a meal. Occasionally, they occur after exercise.

Patients typically have neuroglycopenic symptoms such as blurred vision or diplopia, headache, feelings of detachment, slurred speech, and weakness. Personality and mental changes vary from anxiety to psychotic behavior, and neurologic deterioration can result in convulsions or coma. Hypoglycemic unawareness is very common, and

Table 32–12. Diagnostic criteria for insulinoma after a 72-hour fast.

Laboratory Test	Result
Plasma glucose	< 45 mg/dL (2.5 mmol/L)
Plasma insulin (RIA)	≥ 6 microunits/mL (36 pmol/L)
Plasma insulin (ICMA)	≥ 3 microunits/mL (18 pmol/L)
Plasma C-peptide	≥ 200 pmol/L (0.2 nmol/L, 0.6 ng/mL)
Plasma proinsulin	≥ 5 pmol/L
β-Hydroxybutyrate	≤ 2.7 mmol/L
Sulfonylurea screen (including repaglinide and nateglinide)	Negative

ICMA, immunochemiluminometric assays; RIA, radioimmunoassay.

adrenergic symptoms of palpitations and sweating may be blunted. Patients can sometimes document blood glucose levels in the 40s and 50s with a home blood glucose monitor at the time of symptoms. Access to sulfonylureas or insulin should be explored—does a family member have diabetes, or does the patient or family member work in the medical field? Medication-dispensing errors should be excluded—has the patient's prescription medication changed in shape or color? Patients with insulinoma or factitious hypoglycemia usually have an unremarkable physical examination.

B. Laboratory Findings

β Cell adenomas do not reduce secretion of insulin in the presence of hypoglycemia, and the critical diagnostic test is to demonstrate inappropriately elevated serum insulin, proinsulin, and C-peptide levels, at a time when plasma glucose level is < 45 mg/dL or when the patient has neuroglycopenic symptoms.

The diagnostic criteria for insulinoma after a 72-hour fast are listed in Table 32–12. Other causes of hyperinsulinemic hypoglycemia include factitious administration of insulin or sulfonylureas. Factitious use of insulin will result in suppression of endogenous insulin secretion and low C-peptide levels. In patients who have injected insulin, the insulin/C-peptide ratio (pmol/L) will be > 1. An elevated circulating proinsulin level in the presence of fasting hypoglycemia is characteristic of most β cell adenomas and does not occur in factitious hyperinsulinism. Thus, C-peptide levels (by immunochemiluminometric assays [ICMA]) of > 200 pmol/L and proinsulin levels (by radioimmunoassay [RIA]) of > 5 pmol/L are characteristic of insulinomas. In patients with insulinoma, plasma β-hydroxybutyrate levels are suppressed to ≤ 2.7 mmol/L. No single hormone measurement (insulin, proinsulin, C-peptide) is 100% sensitive and specific for the diagnosis of insulinoma, and persons diagnosed with insulinoma can have insulin levels < 3 microunits/mL (ICMA assay) or proinsulin level < 5 pmol/L. These hormonal assays are also not standardized, and there can be significant variation in the test results. Therefore, the diagnosis should be based on multiple biochemical parameters.

In patients with epigastric distress, a history of renal calculi, or menstrual or erectile dysfunction, a serum calcium, gastrin, or prolactin level may be useful in screening for MEN 1 associated with insulinoma.

C. Diagnostic Tests

If the history is consistent with episodic spontaneous hypoglycemia, patients should be given a home blood glucose monitor and advised to monitor blood glucose levels at the time of symptoms and before consumption of carbohydrates, if this can be done safely. Patients with insulinomas frequently report fingerstick blood glucose levels between 40 mg/dL (2.2 mmol/L) and 50 mg/dL (2.8 mmol/L) at the time of symptoms. The diagnosis, however, cannot be made based on a fingerstick blood glucose. It is necessary to have a low laboratory glucose concomitantly with elevated plasma insulin, proinsulin, and C-peptide levels and a negative sulfonylurea screen. When patients give a history of symptoms after only a short period of food withdrawal or with exercise, then an outpatient assessment can be attempted. The patient should be brought by a family member to the office after an overnight fast and observed in the office. Activity such as walking should be encouraged and fingerstick blood glucose measured repeatedly during observation. If symptoms occur or fingerstick blood glucose is < 50 mg/dL (2.8 mmol/L), then samples for plasma glucose, insulin, C-peptide, proinsulin, sulfonylurea screen, serum ketones, and antibodies to insulin should be sent. If outpatient observation does not result in symptoms or hypoglycemia and if the clinical suspicion remains high, then the patient should undergo an inpatient supervised 72-hour fast. A suggested protocol for the supervised fast is shown in Table 32–13.

In 30% of patients with insulinoma, the blood glucose levels often drop below 45 mg/dL (2.5 mmol/L) after an overnight fast, but some patients require up to 72 hours to develop symptomatic hypoglycemia. However, the term "72-hour fast" is actually a misnomer in most cases since the fast should be immediately terminated as soon as symptoms appear and laboratory confirmation of hypoglycemia is available. Typically, in males, the blood glucose does not fall below 55–60 mg/dL (3.1–3.3 mmol/L) during a 3-day fast. In contrast, for normal premenopausal women, the plasma glucose can reach values as low as 35 mg/dL (1.9 mmol/L). In these cases, however, the women are not symptomatic, presumably owing to the development of sufficient ketonemia to supply energy needs to the brain. Insulinoma patients, on the other hand, become symptomatic when plasma glucose drops to subnormal levels, since inappropriate insulin secretion restricts ketone formation. Moreover, the demonstration of a nonsuppressed insulin level of 3 microunits/mL or more using an ICMA assay (> 6 microunits/mL using an RIA assay) in the presence of hypoglycemia suggests the diagnosis of insulinoma. If hypoglycemia does not develop in a male patient after fasting for up to 72 hours—and particularly when this prolonged fast is terminated with a period of moderate exercise—insulinoma must be considered an unlikely diagnosis.

Table 32–13. Suggested hospital protocol for supervised fast in diagnosis of insulinoma.

(1) Place intravenous cannula and obtain baseline plasma glucose, insulin, proinsulin, β-hydroxybutyrate, and C-peptide measurements at onset of fast.
(2) Permit only calorie-free and caffeine-free fluids and encourage supervised activity (such as walking).
(3) Obtain fingerstick glucose measurements every 4 hours until values < 60 mg/dL are obtained. Then increase the frequency of fingersticks to 1–2 hours, and when capillary glucose value is < 45 mg/dL send a venous blood sample to the laboratory for plasma glucose.[1] Check frequently for manifestations of neuroglycopenia.
(4) At 48 hours into the fast, send a venous blood sample for plasma glucose, insulin, proinsulin, C-peptide, β-hydroxybutyrate, and sulfonylurea measurement.
(5) If symptoms of hypoglycemia occur ***or*** if a laboratory value of serum glucose is < 45 mg/dL, ***or*** if 72 hours have elapsed, conclude the fast with a final blood sample for plasma glucose,[1] insulin, proinsulin, C-peptide, β-hydroxybutyrate, and sulfonylurea measurements. Then give oral fast-acting carbohydrate followed by a meal. If the patient is confused or unable to take oral agents, administer 50 mL of 50% dextrose intravenously over 3–5 minutes. Do not conclude a fast based simply on a capillary blood glucose measurement—wait for the laboratory glucose value—unless the patient is very symptomatic and it would be dangerous to wait.

[1] Glucose sample should be collected in sodium fluoride containing tube on ice to prevent glycolysis and the plasma separated immediately upon receipt at the laboratory. Arrange for the laboratory to run the glucose samples "stat."

An oral glucose tolerance test is of no value in the diagnosis of insulin-secreting tumors. HbA_{1c} levels may be low, but there is considerable overlap with patients who do not have insulinomas and no particular value is diagnostic.

D. Preoperative Localization of β Cell Tumors

After the diagnosis of insulinoma has been unequivocally made by clinical and laboratory findings, studies to localize the tumor should be initiated. Most tumors are in the pancreas, and ectopic cases are rare.

Because of the small size of these tumors (averaging 1.5 cm in diameter in one large series), imaging studies do not necessarily identify all of them. A pancreatic dual phase helical CT scan with thin section can identify 82–94% of the lesions. MRI scans with gadolinium can be helpful in detecting a tumor in 85% of cases. One case report suggests that diffusion-weighted MRI can be useful for detecting and localizing small insulinomas, especially for those with no hypervascular pattern. PET/CT scans using gallium-labeled somatostatin analogs such as DOTA-1-NaI3-octreotide (DOTA-NOC) have been reported to be useful in localizing the tumors. Insulinomas express GLP-1 receptors, and radiolabeled GLP-1 receptor agonists such as Lys(40)(Ahx-hydrazinonicotinamide [HYNIC]-[(99m)Tc) NH(2)]-exendin-4 for SPECT/CT have also been reported to visualize the tumors. If the imaging study is normal, then an endoscopic ultrasound should be performed. In experienced hands, about 80–90% of tumors can be detected with this procedure. Fine-needle aspiration of the identified lesion can be attempted to confirm the presence of a neuroendocrine tumor. If the tumor is not identified or the imaging result is equivocal, then the patient should undergo selective calcium-stimulated angiography, which has been reported to localize the tumor to a particular region of the pancreas approximately 90% of the time. In this test, angiography is combined with injections of calcium gluconate into the gastroduodenal, splenic, and superior mesenteric arteries, and insulin levels are measured in the hepatic vein effluent. The procedure is performed after an overnight fast. Calcium stimulates insulin release from insulinomas but not normal islets, and so a step-up from baseline in insulin levels (twofold or greater) regionalizes the source of the hyperinsulinism to the head of the pancreas for the gastroduodenal artery, the uncinate process for the superior mesenteric artery, and the body and tail of the pancreas for the splenic artery calcium infusions. These studies combined with careful intraoperative ultrasonography and palpation by a surgeon experienced in insulinoma surgery identifies up to 98% of tumors.

Treatment

The treatment of choice for insulin-secreting tumors is surgical resection. While waiting for surgery, patients should be given oral diazoxide. Divided doses of 300–400 mg/day usually suffice, although an occasional patient may require up to 800 mg/day. Side effects include edema due to sodium retention, gastric irritation, and mild hirsutism. Hydrochlorothiazide, 25–50 mg daily, can be used to counteract the sodium retention and edema as well potentiate diazoxide's hyperglycemic effect.

In patients with a single benign pancreatic β cell adenoma, 90–95% have a successful cure at the first surgical attempt when intraoperative ultrasound is used by a skilled surgeon.

In patients with inoperable functioning islet cell carcinoma with and without hepatic metastasis and in approximately 5–10% of MEN 1 cases when subtotal removal of the pancreas has failed to produce cure, the treatment approach is the same as for other types of pancreatic neuroendocrine tumors (pNETs). Diazoxide is the treatment of choice in preventing hypoglycemia. Frequent carbohydrate feedings (every 2–3 hours) also can be helpful, although weight gain can become a problem. The somatostatin analogs octreotide or lanreotide should be considered if diazoxide is ineffective or if there is tumor progression. Surgery or embolization (bland, chemo-, and radio-) or thermal ablation (radiofrequency, microwave, and cryoablation) can be used to reduce tumor burden and also provide symptomatic relief. Chemotherapy regimens that can be considered include combination of streptozocin, 5-fluorouracil, and doxorubicin; capecitabine and oxaliplatin; and capecitabine and temozolomide. Everolimus, an inhibitor of mTOR, is approved for treatment of advanced pNETs. Sunitinib has been shown to slow growth of pNETs. Treatment with radioisotopes (indium-111, yttrium-90, or lutetium-177) linked to a somatostatin analog has been reported to show benefit in a proportion of patients.

NONISLET CELL TUMOR HYPOGLYCEMIA

These rare causes of hypoglycemia include mesenchymal tumors such as retroperitoneal sarcomas, hepatocellular carcinomas, adrenocortical carcinomas, and miscellaneous epithelial-type tumors. The tumors are frequently large and readily palpated or visualized on CT scans or MRI.

In many cases the hypoglycemia is due to the expression and release of an incompletely processed insulin-like growth factor 2 (IGF-2) by the tumor.

The diagnosis is supported by serum insulin levels < 5 microunit/mL with plasma glucose levels of ≤ 45 mg/dL (2.5 mmol/L). Values for growth hormone and IGF-1 are also decreased. Levels of IGF-2 may be increased but often are "normal" in quantity, despite the presence of the immature, higher-molecular-weight form of IGF-2, which can be detected only by special laboratory techniques.

Not all the patients with non–islet cell tumor hypoglycemia have elevated pro-IGF-2. Ectopic insulin production has been described in bronchial carcinoma, ovarian carcinoma, and small cell carcinoma of the cervix. Hypoglycemia due to IgF-1 released from a metastatic large cell carcinoma of the lung has also been reported. GLP-1–secreting tumors (ovarian and pNETs) can also cause hypoglycemia by stimulating insulin release from normal pancreatic islets.

The prognosis for these tumors is generally poor, and surgical removal should be attempted when feasible. Dietary management of the hypoglycemia is the mainstay of medical treatment.

POSTPRANDIAL HYPOGLYCEMIA

1. Hypoglycemia Following Gastric Surgery

Hypoglycemia sometimes develops in patients who have undergone gastric surgery (eg, gastrectomy, vagotomy, pyloroplasty, gastrojejunostomy, Nissan fundoplication, Billroth II procedure, and Roux-en-Y), especially when they consume foods containing high levels of readily absorbable carbohydrates. This late dumping syndrome occurs about 1–3 hours after a meal and is a result of rapid delivery of high concentration of carbohydrates in the proximal small bowel and rapid absorption of glucose. The hyperinsulinemic response to the high carbohydrate load causes hypoglycemia. Excessive release of GI hormones such as GLP-1 likely play a role in the hyperinsulinemic response. The symptoms include lightheadedness, sweating, confusion and even loss of consciousness after eating a high carbohydrate meal. To document hypoglycemia, the patient should consume a meal that leads to symptoms during everyday life. An oral glucose tolerance test is not recommended because many persons without diabetes have false-positive test results. There have been case reports of insulinoma in patients with hypoglycemia following Roux-en-Y surgery. It is unclear how often this occurs. A careful history may identify patients who have a history of hypoglycemia with exercise or missed meals, and these individuals may require a formal 72-hour fast to rule out an insulinoma.

Treatment for secondary dumping includes dietary modification, but this may be difficult to sustain. Patients can try more frequent meals with smaller portions of less rapidly digested carbohydrates. α-Glucosidase therapy may be a useful adjunct to a low-carbohydrate diet. Octreotide 50 mcg administered subcutaneously two or three times a day 30 minutes prior to each meal has been reported to improve symptoms due to late dumping syndrome. Treatment with exendin 9-39 (avexitide), a GLP-1 receptor agonist, may prevent post gastric bypass hypoglycemia. SGLT-2 inhibitors may ameliorate the postprandial glucose rise, the subsequent insulin response, and hypoglycemia. There is a report of a patient with Roux-en-Y surgery who had complete resolution of both hyperglycemia and hypoglycemia when she was given canagliflozin. Various surgical procedures to delay gastric emptying have been reported to improve symptoms but long-term efficacy studies are lacking.

2. Functional Alimentary Hypoglycemia

Patients have symptoms suggestive of increased sympathetic activity, including anxiety, weakness, tremor, sweating, or palpitations, after meals. Physical examination and laboratory tests are normal. It is not recommended that patients with symptoms suggestive of increased sympathetic activity undergo either a prolonged oral glucose tolerance test or a mixed meal test. Instead, the patients should be given home blood glucose monitors (with memories) and instructed to monitor fingerstick glucose levels at the time of symptoms. Only patients who have symptoms when their fingerstick blood glucose is low (< 50 mg/dL) and who have resolution of symptoms when the glucose is raised by eating rapidly released carbohydrate need additional evaluation. Patients who do not have evidence for low glucose levels at time of symptoms are generally reassured by their findings. Counseling and support should be the mainstays in therapy, with dietary manipulation only an adjunct.

3. Occult Diabetes

This condition is characterized by a delay in early insulin release from pancreatic β cells, resulting in initial exaggeration of hyperglycemia during a glucose tolerance test. In response to this hyperglycemia, an exaggerated insulin release produces a late hypoglycemia 4–5 hours after ingestion of glucose. These patients frequently have obesity and a family history of diabetes mellitus.

Patients with this type of postprandial hypoglycemia often respond to reduced intake of refined sugars with multiple, spaced, small feedings high in dietary fiber. In patients with obesity, treatment is directed at weight reduction to achieve ideal weight. These patients should be considered to have prediabetes or early diabetes (type 1 or 2) and advised to have periodic medical evaluations.

4. Autoimmune Hypoglycemia

Patients with autoimmune hypoglycemia have early postprandial hyperglycemia followed by hypoglycemia 3–4 hours later. The hypoglycemia is attributed to a dissociation of insulin-antibody immune complexes, releasing free insulin.

The disorder is associated with methimazole treatment for Graves disease, although it can also occur in patients treated with various other sulfhydryl-containing medications (captopril, penicillamine) as well as other drugs such as hydralazine, isoniazid, and procainamide. In addition, it has been reported in patients with autoimmune disorders such as rheumatoid arthritis, SLE, and polymyositis as well as in plasma cell myeloma and other plasma cell dyscrasias where paraproteins or antibodies cross-react with insulin. There is also an association with the HLA class II alleles (DRB1*0406, DQA1*0301, and DQB1*0302). These alleles are 10 to 20 times more common in Japanese and Korean populations, which explains why the disorder has been reported mostly in Japanese patients.

High titers of insulin autoantibodies, usually IgG class, can be detected. Insulin, proinsulin, and C-peptide levels may be elevated, but the results may be erroneous because of the interference of the insulin antibodies with the immunoassays for these peptides.

In most cases, the hypoglycemia is transient and usually resolves spontaneously within 3–6 months of diagnosis, particularly when the offending medications are stopped. The most consistent therapeutic benefit in management of this syndrome has been achieved by dietary treatment with small, frequent low-carbohydrate meals. Prednisone (30–60 mg orally daily) has been used to lower the titer of insulin antibodies.

FACTITIOUS HYPOGLYCEMIA

Factitious hypoglycemia may be difficult to document. A suspicion of self-induced hypoglycemia is supported when the patient is associated with the health professions or has access to diabetic medications taken by a member of the family who has diabetes. The triad of hypoglycemia, high immunoreactive insulin, and suppressed plasma C-peptide immunoreactivity is pathognomonic of exogenous insulin administration. Insulin and C-peptide are secreted in a 1:1 molar ratio. A large fraction of the endogenous insulin is cleared by the liver, whereas C-peptide, which is cleared by the kidney, has a lower metabolic clearance rate. For this reason, the molar ratio of insulin and C-peptide in a hypoglycemic patient should be < 1.0 in cases of insulinoma and is > 1.0 in cases of exogenous insulin administration (see Hypoglycemia Due to Pancreatic β Cell Tumors, above). When sulfonylureas, repaglinide, and nateglinide are suspected as a cause of factitious hypoglycemia, a plasma level of these medications to detect their presence may be required to distinguish laboratory findings from those of insulinoma.

HYPOGLYCEMIA DUE TO INSULIN RECEPTOR ANTIBODIES

Hypoglycemia due to insulin receptor autoantibodies is an extremely rare syndrome; most cases have occurred in women often with a history of autoimmune disease. Almost all of these patients have also had episodes of insulin-resistant diabetes and acanthosis nigricans. Their hypoglycemia may be either fasting or postprandial and is often severe and is attributed to an agonistic action of the antibody on the insulin receptor. Balance between the antagonistic and agonistic effects of the antibodies determines whether insulin-resistant diabetes or hypoglycemia occurs. Hypoglycemia was found to respond to corticosteroid therapy but not to plasmapheresis or immunosuppression.

MEDICATION- & ETHANOL-INDUCED HYPOGLYCEMIA

A number of medications apart from diabetic medications can occasionally cause hypoglycemia. Common offenders include the fluoroquinolones such as gatifloxacin and levofloxacin, pentamidine, quinine, ACE inhibitors, salicylates, and β-adrenergic blocking agents. The fluoroquinolones, particularly gatifloxacin, have been associated with both hypoglycemia and hyperglycemia. It is thought that the drug acts on the ATP-sensitive potassium channels in the β cell. Hypoglycemia is an early event, and hyperglycemia occurs several days into therapy. Intravenous pentamidine is cytotoxic to β cells and causes acute hyperinsulinemia and hypoglycemia followed by insulinopenia and hyperglycemia. Fasting patients taking noncardioselective β-blockers can have an exaggerated hypoglycemic response to starvation. The β-blockade inhibits fatty acids and gluconeogenesis substrate release and reduces plasma glucagon response. Therapy with ACE inhibitors increases the risk of hypoglycemia in patients who are taking insulin or sulfonylureas presumably because these drugs increase sensitivity to circulating insulin by increasing blood flow to the muscle. Some opioids cause hypoglycemia. Tramadol use has been associated with increased risk of hospitalization for hypoglycemia. Methadone overdose has also been reported to cause hypoglycemia, and a rapid dose escalation of methadone in cancer patients can lower glucose levels.

Ethanol-associated hypoglycemia may be due to hepatic alcohol dehydrogenase activity depleting nicotinamide adenine dinucleotide (NAD). The resultant change in the redox state—increase in nicotinamide adenine dinucleotide + hydrogen (NADH) to NAD^+ ratio—causes a partial block at several points in the gluconeogenic pathway. With prolonged starvation, glycogen reserves become depleted within 18–24 hours and hepatic glucose output becomes totally dependent on gluconeogenesis. Under these circumstances, a blood concentration of ethanol as low as 45 mg/dL (9.8 mmol/L) can induce profound hypoglycemia by blocking gluconeogenesis. Neuroglycopenia in a patient whose breath smells of alcohol may be mistaken for alcoholic stupor. Prevention consists of adequate food intake during ethanol ingestion. Therapy consists of glucose administration to replenish glycogen stores until gluconeogenesis resumes.

When sugar-containing soft drinks are used as mixers to dilute alcohol in beverages (gin and tonic, rum and cola), there seems to be a greater insulin release than when the soft drink alone is ingested and a tendency for more of a late hypoglycemic overswing to occur 3–4 hours later. Prevention would consist of avoiding sugar mixers while ingesting alcohol and ensuring supplementary food intake to provide sustained absorption.

Lipid Disorders

Michael J. Blaha, MD, MPH

33

The "Lipid Hypothesis" of CVD—stating that cholesterol is causal in the development of atherosclerotic CVD (ASCVD) and that lowering cholesterol produces lower cardiovascular event rates—is widely accepted throughout the medical community. For patients with known ASCVD (secondary prevention), studies have shown that cholesterol lowering leads to a consistent reduction in total mortality and in recurrent cardiovascular events in men and women; other studies have documented lowered mortality and events in middle-aged and older patients. Among patients without ASCVD (primary prevention), the data are generally consistent, with rates of cardiovascular events, heart disease mortality, and all-cause mortality differing among studies. Treatment guidelines have been designed to assist clinicians in selecting patients for cholesterol-lowering therapy based predominantly on their overall risk of developing CVD as well as their baseline cholesterol levels.

There are several genetic disorders that provide insight into the pathogenesis of lipid-related diseases. **Familial hypercholesterolemia,** rare in the homozygous state (about one per million), causes markedly high LDL-C levels and early ASCVD. The most common genetic defects involve absent or defective LDL receptors, resulting in unregulated LDL metabolism, genetic pathogenic variants of apolipoprotein B, or gain of function in proprotein convertase subtilisin/kexin type 9 (PCSK9), a protein that regulates breakdown of LDL receptors. Patients with two abnormal genes (homozygotes) have extremely high levels—up to eight times normal—and present with atherosclerotic disease in childhood. Patients with two abnormal genes (homozygotes) may require liver transplantation or plasmapheresis to correct their severe lipid abnormalities; early treatment with statins appears to confer lifetime benefits in such patients. Those with one defective gene (heterozygotes) have LDL concentrations up to two or three times normal; persons with this condition have variable risk, but CVD may develop as early as in their 30s or 40s. With current treatment options, nearly all patients with heterozygous familial hypercholesterolemia can achieve normal cholesterol values with combinations of therapies.

Another rare condition is caused by an abnormality of lipoprotein lipase, the enzyme that enables peripheral tissues to take up triglyceride from chylomicrons and very-low-density lipoprotein (VLDL) particles. Patients with this condition, one cause of **familial chylomicronemia syndrome (FCS),** have marked hypertriglyceridemia with recurrent pancreatitis and hepatosplenomegaly in childhood. The first medication therapy for FCS, an apoC-III inhibitor called olezarsen, was approved in 2024.

Numerous other genetic abnormalities of lipid metabolism are named for the abnormality noted when serum is electrophoresed (eg, dysbetalipoproteinemia, characterized by elevated levels of remnant lipoproteins) or from polygenic combinations of lipid abnormalities in families (eg, familial combined hyperlipidemia). **Sitosterolemia** is an autosomal recessive condition causing abnormalities in the ability to pump plant sterols from the body, resulting in mild to moderate elevations in total cholesterol, atherosclerosis, and very high blood levels of sitosterol identified on specialized blood tests.

▶ When to Refer

Refer to a lipidologist or preventive cardiologist for:

- Known genetic lipid disorders.
- Striking family history of hyperlipidemia or premature atherosclerosis.
- Extremely high serum LDL cholesterol (LDL-C), triglycerides, and/or lipoprotein(a), as well as extremely low or extremely high serum HDL-C.

LIPID FRACTIONS & THE RISK OF CORONARY HEART DISEASE

In serum, cholesterol is carried primarily on three different lipoproteins—VLDL, LDL, and HDL. Total cholesterol equals the sum of these three components:

$$\text{Total cholesterol} = \text{HDL cholesterol} + \text{VLDL cholesterol} + \text{LDL cholesterol}$$

Using these assumptions, the **Friedewald equation** states that LDL-C can be estimated as:

$$\begin{array}{c}\text{LDL}\\\text{cholesterol}\end{array} = \begin{array}{c}\text{Total}\\\text{cholesterol}\\\text{(mg/dL)}\end{array} - \begin{array}{c}\text{HDL}\\\text{cholesterol}\\\text{(mg/dL)}\end{array} - \frac{\begin{array}{c}\text{Triglycerides}\\\text{(mg/dL)}\end{array}}{5}$$

When using SI units, the formula becomes

$$\begin{array}{c}\text{LDL}\\\text{cholesterol}\end{array} = \begin{array}{c}\text{Total}\\\text{cholesterol}\\\text{(mmol/L)}\end{array} - \begin{array}{c}\text{HDL}\\\text{cholesterol}\\\text{(mmol/L)}\end{array} - \frac{\begin{array}{c}\text{Triglycerides}\\\text{(mmol/L)}\end{array}}{2.2}$$

Modern research has questioned several of the assumptions underlying the Friedewald equation, particularly the assumption that VLDL is always best estimated as triglycerides/5, which is inaccurate when triglycerides are above 150 mg/dL and when LDL-C is < 70 mg/dL. Therefore, many commercial laboratories have switched to the **Martin-Hopkins equation**, which uses a flexible factor for deriving VLDL from triglycerides (as opposed to always using 5). The Martin-Hopkins equation reduces the systematic underestimation of LDL-C when triglycerides are > 150 mg/dL and LDL is < 70 mg/dL and is more accurate in estimating LDL from nonfasting blood specimens.

Non–HDL-C is increasingly recognized as an important measure of the total quantity of apolipoprotein B–containing atherogenic lipid particles. Non–HDL-C is calculated as: total cholesterol − HDL-C. Advantages of calculating non–HDL-C are that it is directly measured, requires no additional cost, is less sensitive to fasting status, and is a better predictor of cardiovascular risk compared to LDL-C. The serum concentration of apolipoprotein B (ApoB) can also be directly measured, and ApoB treatment targets can be considered alongside or in place of non-HDL-C targets.

Lipoprotein(a), a subfraction of LDL that is largely genetically determined, has also been recognized as a causal factor in atherosclerosis. One-time measurement of lipoprotein(a) in patients with a strong family history, with manifestations of early ASCVD, or with familial hypercholesterolemia is useful. As of 2024, the National Lipid Association recommends one-time screening of the entire adult population and recommends cascade screening in family members of those with severe hypercholesterolemia, including elevated lipoprotein(a). Values > 50 mg/dL or > 100 nmol/L are considered elevated. A novel antisense oligonucleotide therapy (pelacarsen) associated with a nearly 80% reduction in lipoprotein(a) is being tested in a pivotal phase 3 cardiovascular outcomes trial of patients with prior MI and high lipoprotein(a). The results from this Lp(a) HORIZON trial are due in 2025 or early 2026. Lipoprotein(a) should be more commonly measured and used as a risk-enhancing factor favoring early and more aggressive statin treatment.

It becomes difficult to assign a "normal" range for serum lipids. This is because our cholesterol values are vastly higher than our evolutionary ancestors (whose LDL-C may have been 30–50 mg/dL). Mean LDL-C levels are currently declining in the United States, including in youths. There is *no* evidence available that adult cholesterol levels can be "too low"; that is, there is *no* evidence that very low LDL-C is linked with any major side effects (eg, cognitive dysfunction).

Soffer DE et al. Role of apolipoprotein B in the clinical management of cardiovascular risk in adults: an expert clinical consensus from the National Lipid Association. J Clin Lipidol. 2024;18:e647. [PMID: 39256087]

THERAPEUTIC EFFECTS OF LOWERING CHOLESTEROL

Reducing cholesterol levels in healthy middle-aged men without CHD (*primary prevention*) reduces risk in direct proportion to the reduction in LDL-C. Treated adults have clinically important reductions in the rates of MIs, new cases of angina, need for coronary artery bypass or other revascularization procedures, peripheral artery disease, and stroke. The West of Scotland Study showed a 31% decrease in MIs in middle-aged men treated with pravastatin compared with placebo. The Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS) study showed similar results with lovastatin. As with any primary prevention interventions, large numbers of healthy patients need to be treated to prevent a single event. The numbers of patients needed to treat (NNT) to prevent one nonfatal MI or one CAD death in these two studies were 46 and 50, respectively. The Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT) study of atorvastatin in persons with hypertension and other risk factors but without CHD demonstrated a 36% reduction in CHD events. The Justification for the Use of Statins in Prevention: An Intervention Trial Evaluating Rosuvastatin (JUPITER) study showed a 44% reduction in a combined end point of MI, stroke, revascularization, hospitalization for unstable angina, or death from cardiovascular causes in both men and women. The estimated 5-year NNT to prevent one event was 20. The Heart Outcomes Prevention Evaluation (HOPE-3) trial of rosuvastatin showed a 24% reduction in cardiovascular events. The NNT over 5.6 years was 91. The Randomized Trial to Prevent Vascular Events in HIV (REPRIEVE) showed a 35% reduction in cardiovascular death, MI, hospitalization for unstable angina, stroke, transient ischemic attack, peripheral arterial ischemia, revascularization, or death from an undetermined cause using pitavastatin in 7769 persons with HIV at low to moderate risk of CVD. The 5-year number needed to treat was 106. However, primary prevention studies have found a less consistent effect on total mortality.

In *secondary prevention* studies among patients with established ASCVD, the mortality benefits of cholesterol lowering are clearer. *Major trials with statins have shown significant reductions in cardiovascular events, cardiovascular deaths, and all-cause mortality in men and women with*

CAD. The NNT to prevent a nonfatal MI or a CAD death in these studies was between 12 and 34. Aggressive cholesterol lowering with these agents causes regression of atherosclerotic plaques in some patients, reduces the progression of atherosclerosis in saphenous vein grafts, and can slow or reverse carotid artery atherosclerosis. Results with other classes of medications, particularly those with little effect on LDL or the LDL receptor, have been less consistent. The benefits and adverse effects of cholesterol lowering may be specific to each type or mechanism of medication.

The disparities in absolute event lowering between primary and secondary prevention studies highlight a critical aspect of clinical cholesterol lowering. *The net benefits from cholesterol lowering depend on the underlying risk of ASCVD as well as the competing risks of other diseases.* In middle-aged patients with atherosclerosis and high cholesterol, morbidity and mortality rates are high, and measures that reduce cholesterol-related risk are more likely to provide a robust net benefit to the patient. In older patients with little atherosclerosis and lower cholesterol levels, there may be no meaningful net clinical benefit to cholesterol lowering.

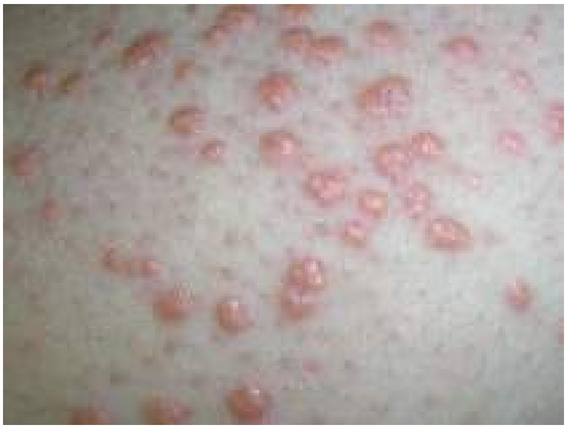
Mhaimeed O et al. The importance of LDL-C lowering in atherosclerotic cardiovascular disease prevention: lower for longer is better. Am J Prev Cardiol. 2024;18:100649. [PMID: 38576462]

SECONDARY CONDITIONS THAT AFFECT LIPID METABOLISM

Several factors, including medications, can influence serum lipids. These are important for two reasons: abnormal lipid levels (or changes in lipid levels) may be the presenting sign of some of these conditions, and correction of the underlying condition may obviate the need to treat an apparent lipid disorder. Thyroid disease, particularly hypothyroidism, is associated with a high LDL-C. Poorly controlled diabetes mellitus and alcohol use are commonly associated with high triglyceride levels that decline with improvements in glycemic control or reduction in alcohol use, respectively. Thus, secondary causes of high blood lipids should be considered in each patient with a lipid disorder before lipid-lowering therapy is started.

CLINICAL PRESENTATIONS

Most patients with high cholesterol levels have no specific symptoms or signs. The vast majority of patients with lipid abnormalities are detected by the laboratory, either as part of the workup of a patient with CVD or as part of a preventive screening strategy. Extremely high levels of chylomicrons or VLDL particles (triglyceride level above 1000 mg/dL or 10 mmol/L) result in the formation of **eruptive xanthomas** (Figure 33–1) (red-yellow papules, especially on the buttocks). High LDL-C concentrations result in **tendinous xanthomas** on certain tendons (Achilles, patella, back of the hand). Such xanthomas usually indicate one of the underlying genetic hyperlipidemias.



▲ **Figure 33–1. Eruptive xanthomas on the arm of a man with untreated hyperlipidemia and diabetes mellitus.** (Reproduced with permission from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

SCREENING & TREATMENT OF HIGH BLOOD CHOLESTEROL

While screening of all children for cholesterol disorders remains controversial, *all adults should have their lipids checked before middle age*. Patients with documented atherosclerosis and diabetes mellitus deserve the most scrutiny of their lipids since these patients are at the highest risk for suffering additional manifestations in the near term and thus have the most to gain from lipid lowering. Additional risk reduction measures for atherosclerosis are discussed in Chapter 10; lipid lowering should be just one aspect of a program to reduce the progression and effects of atherosclerosis.

Several algorithms have been developed to guide the clinician in treatment decisions, but management decisions must always be individualized based on the patient's ASCVD risk to maximize net benefit.

The 2018 American Heart Association/American College of Cardiology (AHA/ACC)/Multi-society guidelines recommend screening of all adults aged 20 years or older for high blood cholesterol. The 2016 USPSTF guidelines recommend beginning at age 20 years only if there are other cardiovascular risk factors such as tobacco use, diabetes, hypertension, obesity, or a family history of premature CVD. For men without other risk factors, screening is recommended beginning at age 35 years.

Individuals without CVD should have their 10-year risk of CVD calculated, with lifetime risk also considered. *Although those with LDL-C > 190 mg/dL (4.91 mmol/L) are recommended for treatment independent of their 10-year risk of CVD, all other patients are recommended for treatment based on their overall cardiovascular risk.* While other calculators (such as *SCORE2* or *QRISK*) may be more appropriate for other parts of the world, *the best method for estimating 10-year ASCVD risk in the United States is the Pooled Cohort Equations*. First introduced in the 2013 ACC/AHA guidelines, the Pooled Cohort Equations include separate equations for White and Black patients and estimate the 10-year risk of heart attack, stroke, and cardiovascular death. The ACC/AHA risk estimator can be found at https://tools.acc.org/ASCVD-Risk-Estimator-Plus/#!/calculate/estimate, and mobile apps are available. While it has been shown to overestimate risk in some modern populations, including those of at least moderate socioeconomic status, the ACC/AHA risk estimator remains an excellent starting point for a risk discussion. The *LIFE-CVD model* is the best for illustrating lifetime risk and benefit of therapy (https://www.u-prevent.com/calculators/lifeCvd). The *PREVENT equations* were released in 2023 to model the combined risk of ASCVD and HF over both 10- and 30-year time horizons in addition to adding other cardiometabolic risk factors and social determinants, while eliminating race from the equations.

Shared decision-making is a central part of cholesterol management in primary prevention. Therefore, the 2018 AHA/ACC/Multi-society guidelines and the 2019 ACC/AHA primary prevention guidelines identify a set of "*risk-enhancing factors*" that might influence a clinician and patient to favor cholesterol-lowering treatment. Table 33–1 lists these risk-enhancing factors that may be considered, particularly for patients at borderline to intermediate risk (5–20% 10-year cardiovascular risk).

Importantly, the 2018 AHA/ACC/Multi-society guidelines and the 2019 ACC/AHA primary prevention guidelines also identify the *coronary artery calcium score* as the single best test for additional risk stratification. The coronary calcium score is a simple noncontrast cardiac-gated CT scan that takes about 10–15 minutes to perform, is associated with approximately 1 mSv of radiation, and costs between $50 and $300. As opposed to the risk-enhancing factors, which may incline a clinician and patient toward treatment, *the coronary artery calcium score may also help identify patients who are unlikely to benefit from cholesterol-lowering therapy*. For example, when the coronary artery calcium score is zero in the absence of smoking or diabetes, the patient is low risk and less likely to receive net benefit from therapy; instead, the coronary artery calcium score can be repeated in approximately 3 years for higher-risk patients and 7 years for lower-risk patients. The USPSTF does *not* endorse calcium scoring as a broad screening test; rather it says the test should be reserved for situations in which additional data will inform shared decision-making and potentially change a therapeutic decision.

Table 33–1. Risk-enhancing factors that help identify patients who may benefit most from lipid-lowering therapy: 2018 AHA/ACC/Multi-society guidelines.

Family history of premature disease (males, age < 55 years; females, age < 65 years)
Primary hypercholesterolemia (LDL-C, 160–189 mg/dL [4.1–4.8 mmol/L]; non–HDL-C, 190–219 mg/dL [4.9–5.6 mmol/L])
Metabolic syndrome
CKD (not ESKD)
Chronic inflammatory conditions, such as psoriasis, rheumatoid arthritis, or HIV/AIDS
History of preeclampsia or of premature menopause before age 40 years
High-risk race/ethnicities (eg, South Asian ancestry)
Persistently high triglycerides ≥ 175 mg/dL
Elevated high-sensitivity CRP (≥ 2.0 mg/L)
Elevated lipoprotein(a) (≥ 50 mg/dL or ≥ 125 nmol/L)
Elevated apolipoprotein B (≥ 130 mg/dL)
Ankle brachial index < 0.9

AHA/ACC, American Heart Association/American College of Cardiology; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol.

Statins are nearly always the first-line therapy (Tables 33–2 and 33–3). Treatment decisions are based on the presence of clinical CVD or diabetes, LDL-C > 190 mg/dL (4.91 mmol/L), patient age, and the estimated 10-year risk of developing CVD. The 2018 AHA/ACC/Multi-society guidelines define four groups of patients who benefit from statin medications: (1) individuals with clinical ASCVD; (2) individuals with primary elevation of LDL-C > 190 mg/dL (4.91 mmol/L); (3) individuals aged 40–75 with diabetes and LDL ≥ 70 mg/dL (1.81 mmol/L); and (4) individuals aged 40–75 without clinical ASCVD or diabetes, with LDL 70–189 mg/dL (1.81–4.91 mmol/L), and estimated 10-year ASCVD risk of 7.5% or higher.

Ezetimibe, PCSK9 inhibitors, and bempedoic acid (Table 33–2) have the strongest recommendations as second-line therapy for patients with (1) CVD whose LDL on statin therapy remains above the relevant treatment threshold of 55 mg/dL or 70 mg/dL; (2) possible familial hypercholesterolemia with baseline LDL > 190 mg/dL (4.91 mmol/L) whose LDL remains above the 100 mg/dL treatment threshold; or (3) documented statin intolerance. *Statin intolerance* is commonly defined as inability or perceived inability to tolerate at least two different statin therapies, including at least one attempt at the lowest approved dose or a trial of an alternate-day dosing strategy. Table 33–4 outlines modified versions of the 2022 ACC therapeutic recommendations for adults with hypercholesterolemia who are intolerant of statins. In high-risk patients, ezetimibe therapy is favored in part due to reduced cost, while in very high-risk patients, PCSK9 inhibitor therapy should be considered. As shown in the CLEAR OUTCOMES trial, bempedoic acid is an excellent alternative when documented statin intolerance is present.

Screening & Treatment in Older Patients

Meta-analysis of evidence relating cholesterol to CVD in older adults suggests that cholesterol is a somewhat weaker risk factor for CVD for persons over age 75 years. The 2018 AHA/ACC/Multi-society guidelines suggest continuing statin treatment in patients over age 75 who have CVD. The guidelines, however, suggest selectively treating patients over the age of 75 who do not have evidence of CVD. Individual patient decisions to discontinue statin therapy should be based on overall functional status and life expectancy, comorbidities, and patient preference and

Table 33–2. Effects of selected lipid-modifying medications (listed in alphabetical order).

Medication	Lipid-Modifying Effects			Regimens	Approximate Cost[1]
	LDL-C	HDL-C	Triglyceride		
Alirocumab (Praluent)[2]	−45 to −60%	±	±	*Initial:* 75 mg once subcutaneously every 2 weeks *Maximum:* 150 mg once subcutaneously every 2 weeks	$$$

should be made in context with overall therapeutic goals and end-of-life decisions.

Screening & Treatment in Patients with HIV

Patients with HIV have higher CVD risk than matched patients without HIV, independent of traditional cardiovascular risk factors. The mechanisms for this include immune activation, inflammation, and the impact of HIV therapies on risk factors including cholesterol. The striking results of the REPRIEVE cardiovascular outcomes trial, in which baseline LDL was just 108 mg/dL, argues for routine statin therapy for nearly all patients with HIV who have no contraindications. Treatments with pitavastatin may have fewer drug-drug interactions than certain other statins (ie, simvastatin).

Table 33–3. Indications for high-intensity and moderate-intensity statins: recommendations of the 2018 AHA/ACC/Multi-society guidelines.

Indications	Treatment Recommendation
Presence of clinical ASCVD	High-intensity statin[1] **or** moderate-intensity statin[2] if over age 75 years
Primary elevation of LDL-C ≥ 190 mg/dL (4.91 mmol/L)	High-intensity statin
Age 40–75 years Presence of diabetes LDL-C ≥ 70 mg/dL (1.81 mmol/L)	Moderate-intensity statin **or** high-intensity statin if diabetes and 10-year CVD risk ≥ 7.5% or other risk-enhancing criteria[3]
Age 40–75 years No clinical ASCVD or diabetes LDL-C 70–189 mg/dL (1.81–4.91 mmol/L) Estimated 10-year CVD risk ≥ 7.5% or coronary artery calcium score ≥ 100 or ≥ 75th percentile	Moderate- to high-intensity statin

[1] High-intensity statins include atorvastatin 40–80 mg orally daily or rosuvastatin 20–40 mg orally daily.
[2] Moderate-intensity statin includes following oral agents: atorvastatin, 10–20 mg daily; fluvastatin, 40 mg twice daily; lovastatin, 40–80 mg daily; pitavastatin, 1–4 mg daily; pravastatin, 40–80 mg daily; rosuvastatin, 5–10 mg daily; or simvastatin, 20–40 mg daily.
[3] Diabetes duration > 10 years, microalbuminuria, CKD, and ankle brachial index < 0.9 favor aggressive treatment even for patients aged 20–39 years.
AHA/ACC, American Heart Association/American College of Cardiology; ASCVD, atherosclerotic CVD; LDL-C, low-density lipoprotein cholesterol.

Table 33–4. Modified 2022 ACC therapeutic recommendations for adult hypercholesterolemic patients with statin intolerance.[1]

Indications	Treatment Recommendations		
	First-Line Therapy	Second-Line Therapy	Third-Line Therapy
No clinical ASCVD but at increased risk[2]	Ezetimibe	Bempedoic acid (ie, ezetimibe/bempedoic acid combination)	BAS (eg, colesevelam)
No clinical ASCVD but with LDL-C ≥ 190 mg/dL (≥ 5.1 mmol/L)	Ezetimibe and/or PCSK9 inhibitor (monoclonal antibody)	Bempedoic acid or inclisiran	Evinacumab for HoFH
Clinical ASCVD but not at very high risk[3]	Ezetimibe and/or PCSK9 inhibitor (monoclonal antibody)	Bempedoic acid or inclisiran	
Clinical ASCVD at very high risk[3] or with LDL-C ≥ 190 mg/dL (≥ 5.1 mmol/L)	Ezetimibe and/or PCSK9 inhibitor (monoclonal antibody)	Bempedoic acid or inclisiran	Evinacumab for HoFH

[1] Statin intolerance is defined as development of statin-associated side effects (myopathy or rhabdomyolysis, hepatic inflammation, hyperglycemia, memory loss or confusion) on at least two statins with one attempt on the lowest FDA-approved daily dose (or a trial of an alternative dosing regimen).

[2] For example, diabetes or with coronary artery calcium score ≥100 or ≥ 75th percentile.

[3] Very high risk ASCVD includes patients with an ACS within the past 12 months, or history of MI or ischemic stroke, or peripheral vascular disease.

ACC, American College of Cardiology; ASCVD, atherosclerotic cardiovascular disease; BAS, bile acid sequestrant such as colesevelam; HoFH, homozygous familial hypercholesterolemia; LDL-C, low-density lipoprotein cholesterol; PCSK9, proprotein convertase subtilisin/kexin type 9.

TREATMENT OF HIGH LDL CHOLESTEROL

Reduction of LDL-C with statins is just one part of a program to reduce the risk of CVD. Other measures—including diet, exercise, smoking cessation, hypertension control, weight loss, diabetes control, and antithrombotic therapy—are also of central importance. For example, exercise (and weight loss) may reduce the LDL-C, increase the HDL, and decrease triglycerides.

The use of medications to raise the HDL-C has ***not*** *been demonstrated to provide additional benefit*. The addition of niacin to statins has been carefully studied in the AIM-HIGH trial and the HPS2-THRIVE trial in patients at high risk for CVD; no cardiovascular outcome benefit has been shown.

Banach M et al; International Lipid Expert Panel (ILEP). 2024 recommendations on the optimal use of lipid-lowering therapy in established atherosclerotic cardiovascular disease and following acute coronary syndromes: a position paper of the International Lipid Expert Panel (ILEP). Drugs. 2024;84:1541. [PMID: 39497020]

Diet Therapy

Studies of nonhospitalized adults have reported only modest cholesterol-lowering benefits of individual dietary therapies, typically in the range of a 5–10% decrease in LDL-C, and even less over the long term. The effect of diet therapies, however, may be additive; some patients will have striking reductions in LDL-C—up to a 25–30% decrease—whereas others will have clinically important increases. Thus, the results of diet therapy should be assessed about 4–12 weeks after initiation.

Several nutritional approaches to diet therapy are available. Most Americans eat over 35% of calories as fat, of which 15% is saturated fat. A traditional cholesterol-lowering diet recommends reducing total fat to 25–30% and saturated fat to < 7% of calories, with complete elimination of trans fats. These diets replace fat, particularly saturated fat, with carbohydrate. Other diet plans, including the Dean Ornish Diet and most vegetarian diets, restrict fat even further. Low-fat, high-carbohydrate diets may, however, result in insulin resistance, elevated triglycerides, and reductions in HDL-C. This is particularly true when "real" foods are replaced with ultra-processed foods, particularly ultra-processed carbohydrates. *Emphasis has therefore shifted to healthier fats.*

A strategy with strong supporting evidence is the **Mediterranean diet**, which maintains total fat at approximately 35–40% of total calories but replaces saturated fat with monounsaturated fat such as that found in canola oil and in olives, peanuts, avocados, and their oils. This diet, which like others calls for elimination of highly processed or prepackaged food, is equally effective at lowering LDL-C and is less likely to lead to reductions in HDL-C. Several studies have suggested that this diet may also be associated with reductions in endothelial dysfunction, insulin resistance, and markers of vascular inflammation. A clinical trial demonstrated reduced cardiovascular events in persons on a Mediterranean diet supplemented with additional nuts or extra-virgin olive oil compared to persons on a less intensive standard Mediterranean diet.

Other dietary changes may also result in beneficial changes in blood lipids. **Soluble fiber**, such as that found in oat bran or psyllium, may reduce LDL-C by 5–10%. Plant stanols and sterols can reduce LDL-C by 10%. Studies have suggested that when all of these elements are combined into a single dietary prescription, the impact of diet on LDL-C may approach that of statin medications, lowering LDL-C by close to 30%. In contrast, over-the-counter supplements (ie, garlic, cinnamon, turmeric, etc) have been tested and are generally ineffective at lowering LDL-C, especially when directly compared to rosuvastatin in a head-to-head trial.

Pharmacologic Therapy

There are eight classes of medications available for consideration in patients who require pharmacologic treatment of an elevated cholesterol (statins, ezetimibe, PCSK9 inhibitors, omega-3 fatty acids, bempedoic acid, bile-acid–binding resins, fibrates, and niacin). As discussed above, statins are the cornerstone of nearly all medical regimens, and guidelines define four groups of patients who benefit from statin medications (*adults with diabetes mellitus, those with existing ASCVD, LDL-C > 190 mg/dL, or 10-year risk of ASCVD > 7.5%*). Among non-statin medications that are considered for managing LDL-C, the evidence is strongest for ezetimibe, PCSK9 inhibitors, and bempedoic acid; for triglycerides, the evidence is strongest for adding prescription-grade omega-3 fatty acid preparations. There is far less evidence for cholesterol absorption inhibitors, fibrates, and niacin; these medications should generally be used sparingly.

A. Statins (Hydroxymethylglutaryl-Coenzyme A [HMG-CoA] Reductase Inhibitors)

The statins (HMG-CoA reductase inhibitors) work by inhibiting the rate-limiting enzyme in the formation of cholesterol. Cholesterol synthesis in the liver is reduced, with a compensatory increase in hepatic LDL receptors (so that the liver can take more of the cholesterol that it needs from the blood) and a reduction in the circulating LDL-C level by 50% or more at the highest doses. There are also modest increases in HDL levels, substantial decreases in triglyceride levels, and marked reductions in high-sensitivity CRP levels.

The 2018 AHA/ACC/Multi-society guidelines divide statins into two categories: "*high-intensity*" and "*moderate-intensity*" statins (Table 33–3). High-intensity statins lower LDL-C by approximately 50%. Examples include high-dose atorvastatin 40–80 mg/day and rosuvastatin 20–40 mg/day (Table 33–2). Moderate-intensity statins lower LDL-C by approximately 30–50%. Examples include pitavastatin 2–4 mg/day, simvastatin 20–40 mg/day, and pravastatin 40–80 mg/day, as well as low-dose atorvastatin 10–20 mg/day and rosuvastatin 5–10 mg/day. All statins are given once daily in the morning or evening.

Statin-associated muscle aches, with normal serum creatine kinase levels, occur in up to 10% of patients, and often such patients can tolerate the statin upon rechallenge. The SAMSON trial demonstrated the importance of the nocebo effect with perceived statin intolerance (reported side effects being due to patient expectations); in this trial, 90% of the symptoms associated with statin rechallenge were also noted with placebo. The *Statin-Associated Muscle Symptom Clinical Index (SAMS-CI)* is a useful tool to help differentiate statin-related symptoms from symptoms unrelated to statins. More serious, but very uncommon, muscle disease includes myositis and rhabdomyolysis, with moderate and marked elevations of serum creatine kinase levels, respectively. Such muscle disease occurs more often in older patients and when the statin is taken with niacin or a fibrate, as well as with erythromycin, antifungal medications, nefazodone, or cyclosporine. Liver disease, with elevations of serum transaminases, is another uncommon side effect of statin therapy and is again more common in patients who are also taking fibrates or niacin. Manufacturers of statins recommend monitoring liver enzymes before initiating therapy and as clinically indicated thereafter; current guidelines do *not* recommend routine monitoring. Finally, *statin therapy is associated with a 10% increase in risk of developing diabetes mellitus in at-risk individuals* (eg, those with the metabolic syndrome).

B. Ezetimibe

Ezetimibe inhibits the intestinal absorption of dietary and biliary cholesterol across the intestinal wall by inhibiting a cholesterol transporter. The dose of ezetimibe is 10 mg/day orally. Ezetimibe reduces LDL-C between 15% and 20% when used as monotherapy, reduces high-sensitivity CRP, and can further reduce LDL-C in patients taking statins in whom the therapeutic goal has not been reached (Table 33–2). Side effects are uncommon. While beneficial effects of ezetimibe monotherapy on cardiovascular outcomes are available only from a large open-label trial, the double-blind IMPROVE-IT trial showed that adding ezetimibe to a statin resulted in a small incremental 5–10% relative risk reduction in detrimental cardiovascular outcomes. At the end of 7 years of study, patients taking ezetimibe-simvastatin had a 2% absolute reduction in cardiovascular events compared to patients taking simvastatin alone. *Current guidelines recommend adding ezetimibe therapy to maximally tolerated statin therapy in patients at high risk for*

CVD whose LDL-C remains above the treatment threshold of 70 mg/dL.

C. Proprotein Convertase Subtilisin/Kexin Type 9 (PCSK9) Inhibitors

The most commonly used PCSK9 inhibitors are fully human monoclonal antibodies that inhibit PCSK9-mediated LDL-receptor degradation and lower LDL-C levels by 50–60% and lipoprotein(a) by up to 20–30%. Two agents, alirocumab and evolocumab, are FDA-approved for use in patients with familial hypercholesterolemia or in patients with CVD or high risk of CVD who require further lowering of LDL-C. These medications are injected subcutaneously every 2–4 weeks. No significant increase in adverse events has been observed compared to placebo. The FOURIER (Further Cardiovascular Outcomes Research with PCSK9 Inhibition in Subjects with Elevated Risk) trial compared evolocumab with placebo in 27,564 patients with established atherosclerotic disease already taking statin therapy; participants were monitored for a median of 2.2 years. LDL-C was reduced by 59% to a mean value of ~30 mg/dL. Patients receiving the evolocumab plus statin had a 15% reduction in the primary composite endpoint of cardiovascular death, MI, stroke, hospital admission for unstable angina, or coronary revascularization and a 20% reduction in the secondary outcome of cardiovascular death, MI, or stroke. Long-term open-label follow-up of the FOURIER population demonstrated a 23% reduction in cardiovascular death with randomization to evolocumab over 5 years. The ODYSSEY-OUTCOMES study randomized 18,924 patients with recent ACS to alirocumab or placebo, demonstrating a 15% reduction in the primary composite cardiovascular endpoint and a 15% reduction in all-cause mortality in secondary statistical testing after median 2.8-year follow-up.

However, despite these encouraging results from multiple clinical trials, their very high cost meant that initial cost-effectiveness models found that these PCSK9 inhibitors were not cost-effective. Over time, PCSK9 inhibitors have moved closer to being cost-effective; however, *most guidelines indicate that their relatively high cost must still remain part of any consideration regarding their use*. Current guidelines recommend addition of PCSK9 inhibitors to statins at maximally tolerated doses in patients with coronary artery calcium scores > 1000 or at very high risk for recurrent CVD when on-treatment LDL-C remains well above 55 or 70 mg/dL (or above 100 mg/dL in patients with familial hypercholesterolemia without known CVD). Patients considered to be at very high-risk for CVD include those with recent ACS within 12 months; multiple prior MIs or strokes; significant unrevascularized CAD; and polyvascular disease (CAD plus cerebrovascular or peripheral vascular disease).

The PCSK9 inhibitor inclisiran reduces overproduction of PCSK9 protein by approximately 80%. After an initial subcutaneous dose and another at 3 months, inclisiran can be administered subcutaneously every 6 months (two doses annually). This regimen produces sustained LDL-C reductions of approximately 51%. Twice-yearly dosing is novel for lipid-lowering therapy; inclisiran enables new delivery strategies, including in-clinic administration. The results of the large cardiovascular outcomes trial testing inclisiran, called ORION-4, will likely be available in 2026.

D. Bempedoic Acid

Like statins, bempedoic acid targets cholesterol synthesis in the liver, ultimately resulting in upregulation of expression of the LDL receptor. Bempedoic acid is a small-molecule prodrug that inhibits adenosine triphosphate citrate lyase, an enzyme that is two steps upstream of the mechanism of statins (inhibition of HMG-CoA reductase, the rate-limiting step). Because bempedoic acid is not activated in skeletal muscle, muscle-specific side effects are more limited than they are with statins. Bempedoic acid lowers LDL-C approximately 17–20% on top of the lowering produced by moderate- to high-intensity statins. Bempedoic acid is also marketed in combination with ezetimibe; this combination provides approximately 38% LDL-C reduction on top of background lipid-lowering therapy. Treatment with bempedoic acid may mildly decrease both high-sensitivity CRP and risk of diabetes mellitus. Patients treated with bempedoic acid should be monitored for hyperuricemia and potential onset or worsening of gout as well as cholelithiasis. Bempedoic acid also appears to modestly increase the risk of tendon rupture. Bempedoic acid should not be used with > 20 mg of simvastatin daily or 40 mg of pravastatin daily. The CLEAR OUTCOMES study reported that bempedoic acid reduces cardiovascular events by approximately 13% in patients with established CVD (or in primary prevention and at high risk for CVD), documented statin intolerance, and LDL-C ≥ 100 mg/dL.

E. Omega-3 Fatty Acid Preparations

Omega-3 fatty acids are essential fatty acids that must be consumed in the diet and are a prominent feature of Mediterranean-style diets. In pharmacologic doses, omega-3 fatty acid preparations can lower triglycerides by up to 30%. Pharmacologic therapy should be differentiated from dietary omega-3 fatty acid supplements. The former is an FDA-approved product usually given at a much higher dose; dietary supplements are variable, the supporting evidence is much weaker, and they are not currently regulated.

There is modest evidence from meta-analyses that omega-3 fatty acid supplementation reduces MIs, although with no reduction in total or cardiovascular mortality. Omega-3 ethyl esters have not been associated with cardiovascular event reduction when added to statin therapy.

In contrast, icosapent ethyl, which is a highly purified eicosapentaenoic acid (EPA) only preparation, was shown to reduce cardiovascular deaths, nonfatal MIs, nonfatal strokes, coronary revascularizations, and unstable angina by 25% in statin-treated patients with triglycerides > 135 mg/dL in the 8179 person REDUCE-IT randomized clinical trial compared to a mineral oil placebo. The mechanism of action of icosapent ethyl is not yet clear but likely involves multiple mechanisms beyond lipid lowering, including antiplatelet activity, anti-inflammatory activity, and ventricular arrhythmia prevention. Icosapent ethyl is

FDA approved for the broad indication of CVD event–lowering in patients with triglycerides over 150 mg/dL and either established CVD or diabetes mellitus plus two or more additional risk factors for CVD. However, there remains controversy about the efficacy of omega-3 therapies, since the 2020 STRENGTH trial showed no CVD benefit of omega-3 carboxylic acids; it remains unclear if this result was due to a different omega-3 fatty acid preparation, to a much smaller benefit of omega-3 fatty acids preparations than originally demonstrated, to use of a different placebo (corn oil versus mineral oil), or to chance.

F. Bile Acid–Binding Resins

The bile acid–binding resins include cholestyramine, colesevelam, and colestipol. In the pre-statin era, treatment with these agents reduced the incidence of coronary events in middle-aged men by about 20%, with no significant effect on total mortality. The resins work by binding bile acids in the intestine. The resultant reduction in the enterohepatic circulation causes the liver to increase its production of bile acids, using hepatic cholesterol. Thus, hepatic LDL-receptor activity increases, with a decline in plasma LDL-C levels. The triglyceride level tends to increase in some patients treated with bile acid–binding resins; these resins should be used with caution in patients with elevated triglycerides and not at all in patients who have triglyceride levels above 500 mg/dL. The clinician can anticipate a reduction of 15–25% in the LDL-C level, with insignificant effects on the HDL level. Resins are the only lipid-modifying medication considered safe in pregnancy.

These agents may interfere with the absorption of fat-soluble vitamins (thereby complicating the management of patients receiving warfarin) and may bind other drugs in the intestine. They often cause GI symptoms, such as constipation and gas.

G. Fibric Acid Derivatives

The fibrates are peroxisome proliferative-activated receptor-α (PPAR-α) agonists that result in significant reductions of plasma triglycerides and increases in HDL-C. They reduce LDL-C levels by about 10–15% (although the result is variable) and triglyceride levels by about 40% and raise HDL levels by about 15–20%. The fibric acid derivatives or fibrates approved for use in the United States are gemfibrozil and fenofibrate.

Gemfibrozil monotherapy reduced CHD rates in hypercholesterolemic middle-aged men free of coronary disease in the Helsinki Heart Study. The effect was observed only among those who also had lower HDL-C levels and high triglyceride levels. In a Veterans Affairs study, gemfibrozil monotherapy was also shown to reduce cardiovascular events in men with existing CHD whose primary lipid abnormality was a low HDL-C.

However, fibrates have *not* been shown to reduce cardiovascular events in all statin-treated patients with CVD or diabetes. For example, in the ACCORD study, addition of fenofibrate to statin in patients with diabetes and mild triglyceride elevations resulted in no benefit. Clinical interest in using fibrates has declined after publication of the PROMINENT trial of a newer fibrate, pemafibrate, which is a selective PPAR-α receptor modulator. The results of this large trial showed that pemafibrate lowered triglyceride levels but did not reduce ApoB levels; in addition, pemafibrate did not impact the incidence of cardiovascular events. Fenofibrate has slightly fewer side effects than gemfibrozil.

H. Niacin (Nicotinic Acid)

Niacin reduces the production of VLDL particles, with secondary reduction in LDL-C and increases in HDL-C levels; niacin also lowers lipoprotein(a) levels by 15–25%. The average effect of full-dose niacin therapy is a 15–25% reduction in LDL-C and a 25–35% increase in HDL-C.

There is very little evidence to support the use of niacin. In two large pivotal clinical trials, AIM-HIGH and HPS2-THRIVE, extended-release niacin did not reduce cardiovascular events when added to statin therapy in high-risk patients. Therefore, niacin should be rarely used.

Treatment Algorithms

For patients who require a lipid-modifying medication, an HMG-CoA reductase inhibitor (statin) is recommended. In patients with ASCVD, this should be at its maximally tolerated dose.

Combination therapy has become commonplace in clinical practice; changing to combination therapy reduces LDL-C and improves clinical outcomes more than increasing the dose of monotherapy. Combination therapy is indicated for (1) patients with familial hypercholesterolemia in whom LDL-C remains above 100 mg/dL with treatment; (2) patients with advanced subclinical atherosclerosis (coronary artery calcium scores > 100 particularly those > 1000), or high-risk patients with existing CVD in whom LDL-C remains above 70 mg/dL with treatment; (3) very high-risk patients with existing CVD in whom LDL-C remains above 55 mg/dL with treatment; and (4) many high-risk patients with triglycerides > 150 mg/dL or non–HDL-C > 100 mg/dL.

Patients with heterozygous familial hypercholesterolemia, premature atherosclerosis, or CVD may need two or more medications to get below the treatment threshold, while those without CVD or without advanced subclinical atherosclerosis (primary prevention) will less commonly require multiple medications. The 2018 AHA/ACC/Multisociety guidelines prioritize addition of ezetimibe in high-risk patients, while reserving PCSK9 inhibitor therapy for very high-risk patients or those taking maximally tolerated statin therapy and ezetimibe with LDL-C still not below 70 mg/dL (Table 33–5). Notably, the 2019 ESC guidelines were the first to endorse an LDL-C treatment goal of < 55 mg/dL in very high-risk patients, which uniquely include patients with at least two 50% coronary artery stenoses identified by coronary CT angiography, or in the carotid arteries by ultrasound. These guidelines further endorse an LDL-C goal of < 40 mg/dL in the highest-risk patients with multiple recent CVD events. In 2022, the ACC Expert Consensus Decision Pathway likewise endorsed an LDL-C of < 55 mg/dL in very high-risk patients (Table 33–5).

Table 33–5. Therapeutic recommendations for adult hypercholesterolemic patients with clinical ASCVD.

Indications	Therapeutic Recommendations		
	First-Line	Second-Line	Third-Line
Very high-risk ASCVD[1]	High-intensity statin[2]/ maximal-dose statin	If LDL-C remains > 55 mg/dL [1.8 mmol/L] on maximal-dose statin, add ezetimibe[3]	If LDL-C still > 55 mg/dL [1.8 mmol/L], consider PCSK9 inhibitor[4]
Not very high-risk ASCVD[1]			
Age ≤ 75 y	High-intensity statin[2]; if high-intensity not tolerated, use moderate-intensity statin[5]	If on maximal-dose statin and LDL-C remains > 70 mg/dL [1.8 mmol/L], add ezetimibe[3]	
Age > 75 y	Moderate-intensity statin[5]	High-intensity statin[2]	

[1] Very high-risk ASCVD includes those patients with an ACS in the past 12 months, those with significant unrevascularized CAD, and those with history of multiple prior MIs or ischemic strokes.
[2] High-intensity statin includes atorvastatin, 40–80 mg orally daily; or rosuvastatin, 20–40 mg orally daily.
[3] Ezetimibe, 10 mg orally daily.
[4] PCSK9 inhibitors include evolocumab, 140 mg subcutaneously every 2 weeks; alirocumab, 75 mg subcutaneously every 2 weeks; or optionally inclisiran, 284 mg at baseline, 3 months, then every 6 months.
[5] Moderate-intensity statin includes atorvastatin, 10–20 mg orally daily; fluvastatin, 40 mg orally twice daily; lovastatin, 40–80 mg orally daily; pitavastatin, 1–4 mg orally daily; pravastatin, 40–80 mg orally daily; rosuvastatin, 5–10 mg orally daily; or simvastatin, 20–40 mg orally daily.
ASCVD, atherosclerotic cardiovascular disease; LDL-C, low-density lipoprotein cholesterol; PCSK9, proprotein convertase subtilisin/kexin type 9 inhibitor.
Data from in the 2022 ACC Expert Consensus Decision Pathway on the Role of Nonstatin Therapies for LDL-Cholesterol Lowering in the Management of Atherosclerotic Cardiovascular Disease Risk. J Am Coll Cardiol. 2022;80:1366. [PMID: 36031461]

Patients with homozygous familial hypercholesterolemia may need plasmapheresis, special lipid-lowering therapies, or both (Table 33–2).

HIGH BLOOD TRIGLYCERIDES

Patients with very high levels of serum triglycerides (> 1000 mg/dL) are at risk for pancreatitis. The pathophysiology is not certain since pancreatitis never develops in many patients with very high triglyceride levels. Most patients with congenital abnormalities in triglyceride metabolism present in childhood; hypertriglyceridemia-induced pancreatitis first presenting in adults is more commonly due to an acquired problem in lipid metabolism.

Although there are no clear triglyceride levels that predict pancreatitis, most clinicians consider treating fasting levels above 500 mg/dL (5 mmol/L). The risk of pancreatitis may be more related to the triglyceride level following consumption of a fatty meal. Because postprandial increases in triglyceride are inevitable if fat-containing foods are eaten, fasting triglyceride levels in persons prone to pancreatitis should be kept well below that level.

The primary therapy for high triglyceride levels is dietary, avoiding alcohol, simple sugars, refined starches, and saturated and trans fatty acids, and restricting total calories. Control of secondary causes of high triglyceride levels may also be helpful. In patients with fasting triglycerides ≥ 500 mg/dL (5 mmol/L) despite adequate dietary adherence—and certainly in those with a previous episode of pancreatitis—therapy with a triglyceride-lowering medication (eg, statins, omega-3 preparations, or fibric acid derivatives) is indicated. Olezarsen can be used for patients with FCS.

Pharmacologic treatment for patients with triglycerides > 150 mg/dL (1.5 mmol/L) but < 500 mg/dL is reserved for those with established CVD with well-controlled LDL-C on maximally tolerated therapy with statins or other agents. Data are strongest for icosapent ethyl, while GLP1-RAs are also effective in the setting of being overweight or having obesity.

NUTRITIONAL DISORDERS

PROTEIN–ENERGY MALNUTRITION

ESSENTIALS OF DIAGNOSIS

- Inadequate intake of energy and/or protein, increased nutrient losses, or increased nutrient requirements.
- **Kwashiorkor:** caused by protein deficiency.
- **Marasmus:** caused by combined protein and energy deficiency.
- Protein–calorie malnutrition may be mild, moderate, or severe.
- Protein loss correlates with weight loss.
- 35–40% total body weight loss can be fatal.

General Considerations

Protein–energy malnutrition occurs because of a relative or absolute deficiency of energy and protein. It may be primary, due to inadequate food intake; secondary, as a result of other illness and associated inflammation; or a combination of both. For many developing nations, primary protein–energy malnutrition remains a significant health problem. There are two distinct syndromes: **kwashiorkor**, which is caused by a deficiency of protein in the presence of adequate energy, and **marasmus**, which is caused by combined protein and energy deficiency.

In industrialized societies, malnutrition is more often a sequela of other diseases than pure starvation. Although there is no universally accepted definition of malnutrition, there are several internationally recognized malnutrition assessment tools that have been developed to standardize malnutrition identification and promote nutrition interventions. Examples include the Subjective Global Assessment (SGA), the American Society for Parenteral and Enteral Nutrition (ASPEN) and Academy of Nutrition and Dietetics (AND) Criteria, the European Society for Parenteral and Enteral Nutrition (ESPEN) Criteria, and the Global Leadership Initiative on Malnutrition (GLIM) Criteria. The widely used ASPEN/AND criteria have an etiology-based approach that recognizes the role of inflammation in the development of malnutrition.

Clinical Findings

Clinical manifestations of protein–energy malnutrition include mild growth restriction in children, weight loss in adults, and several distinct clinical syndromes. Clinical manifestations of protein–energy malnutrition are determined by the patient’s nutritional status prior to illness, the disease process itself, associated treatments, and severity of the malnutrition.

Performing a nutrition-focused physical assessment is essential to determine clinical manifestations of protein–energy malnutrition. Wasting begins with weight loss and can be seen in adipose tissue, muscle mass, or both. Cachexia is defined as loss of lean body mass only, irrespective of adipose tissues changes, and it is associated with inflammation and protein catabolism. Muscle mass depletion is seen in the temples, clavicles, shoulders, scapulae, hands, thighs, and calves. Subcutaneous body fat loss may be evident in the orbital areas, triceps, and rib cage. Dependent edema, ascites, or anasarca may develop and can be assessed on physical examination. Laboratory studies may be unremarkable—serum albumin, for example, tends to be normal in patients with malnutrition related to social, behavioral, or environmental etiologies; however, levels decline in the presence of inflammation and tend to be low in patients who have malnutrition related to acute and chronic diseases. Overall, albumin is not considered a good marker of malnutrition and should not be used as part of diagnosis. Similarly, laboratory assessment of micronutrient deficiencies may not be reliable in the presence of inflammation.

Treatment

The treatment of protein–energy malnutrition should be a slow process and requires great care, especially in chronic and severe cases. In early treatment, the focus is to prevent refeeding syndrome, which is defined as a range of electrolyte alterations following the provision of calories (glucose) after a period of decreased or absent caloric intake. Patients who are refed too quickly are at risk for developing HF due to fluid and electrolyte shifts.

Initial efforts should be directed at correcting fluid and electrolyte abnormalities, particularly phosphorus, potassium, and magnesium. The second phase of treatment is directed at cautiously repleting calories, protein, and micronutrients. Although patients can receive adequate amounts of protein, this may be difficult to achieve with the conservative initiation and advancement of total calories. Depending on the severity of malnutrition, patients may benefit from as little as 5–20 kcal/kg/day for the first few days with advancement of calories as tolerated over the next 7 days. Once out of the initial refeeding window, most patients should receive at least 30–35 kcal/kg/day and 1.5 g protein/kg/day, although some may require significantly more depending on their BMI and severity of malnutrition. All patients should receive thiamine 100 mg daily for at least 5–7 days.

Refeeding edema is benign but must be differentiated from HF. Changes in renal sodium reabsorption and poor skin and blood vessel integrity may result in dependent edema. Treatment includes elevation of the edematous area and sodium restriction, if appropriate. Diuretics should not be used.

Nutrition screening is essential for identifying patients who are malnourished or at risk for becoming malnourished. These patients require a formal nutrition assessment with targeted interventions and close monitoring.

OBESITY

ESSENTIALS OF DIAGNOSIS

- Disorder of energy homeostasis; BMI ≥ 30.
- Central obesity (abdomen and flank) is a greater health risk than excess weight in the lower body (buttocks and thighs).
- Associated with numerous comorbid conditions including type 2 diabetes mellitus, hypertension, hyperlipidemia, heart disease, stroke, and obstructive sleep apnea.

Definition & Measurement

Obesity is a multifactorial, chronic disease characterized by an accumulation of visceral and subcutaneous fat, which promotes adipocyte dysfunction. Obesity predisposes to a wide variety of comorbid conditions. **BMI** typically correlates with excess adipose tissue but does not reflect body composition. It is calculated by dividing body weight in kilograms by height in meters squared (kg/m^2). The NIH defines healthy BMI as 18.5–24.9. Overweight is defined as BMI 25–29.9. BMI for class I obesity is 30–34.9, class II is 35–39.9, and class III is 40 and above. Central obesity (excess adipose tissue around the waist and flank) is a greater health risk than lower body obesity (adipose tissue in the thighs and buttocks). Patients with obesity and increased abdominal circumference (> 102 cm or 40 inches in men and 88 cm or 35 inches in women) or high waist–hip ratios (> 1.0 in men and 0.85 in women) have a greater risk of weight-related comorbid conditions and early death than patients with the same BMI and lower ratios. There are different abdominal circumference cutoffs for different populations. Visceral fat within the abdominal cavity is more hazardous to health than subcutaneous fat around the abdomen. Over 40% of Americans have obesity.

Health Consequences of Obesity

Obesity is associated with significant increases in both morbidity and mortality, and many disorders occur with greater frequency in patients with obesity. Obesity-related comorbidities include many leading causes of preventable death such as heart disease, stroke, type 2 diabetes, and many cancers. Over 200 health conditions ranging from hypertension and CAD to thromboembolic and skin disorders are more prevalent in patients with obesity. Patients with obesity have increased surgical and obstetric risks. Most patients with excess weight have experienced weight bias, stigma, and discrimination.

Etiology

Many factors, including genetics and environment, contribute to the development of obesity. Twin studies demonstrate that genetics account for 40–90% of variation in body weight, although only a small percentage is due to single gene mutations. Most obesity develops from interactions among multiple genes, certain medical conditions, obesogenic medications, environmental factors, and behavioral factors.

Medical Evaluation of the Patient with Obesity

Medical history should include the age at onset of weight gain, lifetime weight fluctuations, family history of obesity, occupational history, activity and eating behaviors, previous obesity interventions, and psychosocial factors, including assessment for mood and eating disorders.

Physical examination should assess BMI, body composition, and nutritional status.

Signs of secondary causes of obesity should be pursued; however, < 1% of patients have an identifiable cause. Cushing syndrome is an example that can be diagnosed by physical examination and laboratory testing (see Chapter 29). All patients should be screened for weight-related comorbid conditions, including obstructive sleep apnea. Blood pressure, waist circumference, fasting glucose, comprehensive metabolic profile, lipid panel, TSH, and hemoglobin A_{1c} should be measured as well as other clinically indicated laboratory tests.

Treatment

Weight loss of 5–10% total body weight is sufficient in many patients with obesity to achieve clinically relevant health benefits and the magnitude of these benefits is "dose-related." Magnitude of weight loss at 1 year is strongly associated with improvements in many parameters including blood sugar, blood pressure, triglycerides, HDL cholesterol, and various inflammatory markers.

Successful treatment of obesity requires a multidisciplinary approach to counteract the body's resistance to weight loss. While most individuals with obesity require medical obesity treatment for long-term disease management, diet, physical activity, and behavioral modifications are the cornerstone of obesity care. A variety of **dietary strategies** can improve health. Recommendations should be tailored to a patient's dietary preferences, as adherence is associated with better outcomes. Dietary instructions should emphasize intake of predominantly "unprocessed" foods, with special attention to limiting foods that provide large amounts of calories without other nutrients, such as ultra-processed foods, sugary drinks, fast food, junk food, and sweets. A Mediterranean diet can be a good option for patients at high cardiovascular risk, since it has been shown to reduce the incidence of major cardiovascular events. A low-glycemic-index diet can curb hunger and decrease cravings by reducing blood sugar fluctuations. Registered dietitians can provide dietary education and customize dietary plans.

Long-term changes in eating behavior as well as **behavior modification** strategies are necessary to support ongoing obesity management. It is important to emphasize meal planning and self-monitoring, including weighing at regular intervals. Some patients maintain a food log to track caloric intake. Self-monitoring aids in behavioral change and provides the clinician with data to guide recommendations. Weight maintenance can be more challenging than initial weight loss, so it is important to continue regular follow-up to ensure adherence to a treatment plan.

Physical activity is an important component of obesity treatment. Aerobic exercise increases daily energy expenditure and partially prevents the decrease in basal energy expenditure (BEE) resulting from weight loss. It supports long-term weight maintenance and helps preserve lean body mass. The combination of exercise and diet results in greater weight loss than diet or exercise alone. Up to 1 hour of moderate exercise per day is associated with long-term weight maintenance.

The American College of Sports Medicine recommends 150 minutes of moderate-intensity aerobic physical activity (such as tennis or brisk walking) per week, 75 minutes of vigorous-intensity aerobic exercise (such as jogging or swimming laps) per week, or an equivalent combination of moderate- and vigorous-intensity aerobic activity. Exercise should be spread throughout the week. Resistance training is also recommended at least twice per week. Exercise physiologists and physical therapists can provide support for patients.

Medications can have unpredictable and variable effects on patients' weight, so it is important to review patients' medication regimens and balance their benefits against the probability of weight gain. Many medications are associated with weight gain, including corticosteroids, contraceptives (and other hormonal agents), and certain antidiabetic, antihypertensive, antidepressant, antipsychotic, antiepileptic, and antihistamine agents. Table 34–1 provides an overview of weight-gaining medications as well as potential alternatives. When possible, clinicians should prescribe weight-neutral– or weight-loss–promoting medications. If there are no alternatives, weight gain can be prevented or mitigated by selecting the lowest effective medication dose for the shortest duration.

Weight loss achieved by lifestyle modification alone is often limited and difficult to maintain. Reduced calorie intake and increased energy expenditure are counteracted by adaptive physiologic responses. Appetite increases and resting metabolic rate (RMR) decreases disproportionately to what would be expected based on changes in body composition. As a result, patients often require obesity medications, bariatric surgery, devices, endoscopic bariatric therapies, or a combination of these interventions to achieve and maintain significant long-term weight loss.

Obesity medications (OMs) (Table 34–2) should be considered in patients with a BMI 30 or higher, or a BMI 27 or higher with weight-related comorbidities who have been unsuccessful in managing their disease with lifestyle changes alone. Most agents affect mechanisms regulating appetite through nutrient-stimulated hormone, serotonergic, dopaminergic, or noradrenergic pathways. They target the arcuate nucleus of the hypothalamus to stimulate the anorexigenic pro-opiomelanocortin (POMC) neurons, which promote satiety. OMs should be prescribed as part of a comprehensive and personalized treatment plan including lifestyle intervention (diet, exercise, and behavioral modification). The seven most widely prescribed FDA-approved OMs are phentermine, orlistat, phentermine/topiramate extended-release (ER), naltrexone sustained-release (SR)/bupropion SR, liraglutide, semaglutide, and tirzepatide. In addition to producing weight loss, each OM improves biomarkers including blood sugar, blood pressure, and lipids. Three OMs have stopping rules, which provide weight loss thresholds after 12–16 weeks of treatment under which medication discontinuation is suggested.

Liraglutide 3.0 mg daily and **semaglutide 2.4 mg weekly** are subcutaneous injectable GLP-1 receptor agonists. GLP-1 is a hormone released by GI L-cells during a meal that delays gastric emptying, stimulates glucose-dependent insulin secretion, and reduces food intake. Liraglutide 1.8 mg and semaglutide 2.0 mg are FDA-approved for the treatment of type 2 diabetes and cardiovascular risk reduction in patients with type 2 diabetes. Liraglutide 3.0 mg was approved for weight management in 2014. It is initiated at a dose of 0.6 mg subcutaneously daily and increased by 0.6 mg each week to a maximum of 3.0 mg daily. In a 2022 meta-analysis of 8 RCTs, liraglutide 3.0 mg is associated with 4.81% greater total body weight

Table 34–1. Medications and their effects on weight.

Drug Class	Result: Weight Gain	Result: Weight Neutral (or Minor Weight Gain)	Result: Weight Loss
Antidiabetics	Insulin Meglitinides Sulfonylureas Thiazolidinediones	α-Glucosidase inhibitors Bromocriptine Colesevelam DPP-4 inhibitors	GLP-1 agonists Metformin Pramlintide SGLT-2 inhibitors
Antihypertensives	α-Blockers β-Blockers (atenolol, metoprolol, nadolol, propranolol)	ACE inhibitors ARBs β-Blockers (carvedilol, nebivolol) Calcium channel blockers Thiazides	
Antidepressants	Lithium MAO inhibitors Mirtazapine SNRIs (duloxetine, venlafaxine) SSRIs (citalopram, paroxetine) Tricyclic antidepressants (amitriptyline, desipramine, doxepin, imipramine, nortriptyline)	SSRIs (fluoxetine, sertraline)	Bupropion
Antipsychotics	Clozapine Haloperidol Olanzapine Quetiapine Risperidone	Lurasidone Ziprasidone	
Antiepileptics	Carbamazepine Gabapentin Pregabalin Valproic acid	Lamotrigine Levetiracetam Phenytoin	Topiramate Zonisamide
Contraceptives	Medroxyprogesterone acetate	Barrier methods IUDs Surgical sterilization	
Antihistamines	First-generation antihistamines	Second- and third-generation antihistamines	
Steroids	Glucocorticoids	Inhaled steroids Topical steroids	

DPP-4, dipeptidyl peptidase-4.

loss than placebo. In 2021, **semaglutide 2.4 mg** was FDA-approved for the treatment of obesity. It is initiated at a dose of 0.25 mg subcutaneously weekly and titrated to a maximum dose of 2.4 mg weekly. In a 2022 meta-analysis of eight RCTs, semaglutide is associated with a 10.76% greater mean total body weight loss than placebo. In the 2023 SELECT cardiovascular outcomes trial, semaglutide 2.4 mg reduced the risk of major adverse cardiovascular events (MACE) by 20% in adults aged 45 and older who were overweight (BMI > 27) or had obesity and preexisting CVD without type 2 diabetes. This is the first OM to demonstrate reduced incidence of MACE. Both liraglutide and semaglutide may cause nausea, vomiting, constipation, or diarrhea, and a small increase in pancreatitis and cholecystitis.

Tirzepatide is a subcutaneous injectable agonist targeting receptors of both GLP-1 as well as glucose-dependent insulinotropic polypeptide (GIP), which is another nutrient-stimulated hormone that regulates energy balance through signaling in the brain and adipose tissue. In 2022, tirzepatide was approved by the FDA for the treatment of type 2 diabetes, and in 2023, it was approved for weight management. In 2024, tirzepatide received an expanded indication for the treatment of moderate to severe obstructive sleep apnea in adults with obesity. It is initiated at a dose of 2.5 mg subcutaneously weekly and increased by 2.5 mg each month to a maximum of 15 mg subcutaneously weekly. In the SURMOUNT-1 trial, tirzepatide 15 mg weekly produced a 20.9% total body weight loss compared to 3.1% with placebo. Tirzepatide is associated with the same contraindications, adverse events, and boxed warnings as liraglutide and semaglutide but is typically better tolerated. Tirzepatide delays gastric emptying and has the potential to impact the absorption of concomitantly administered oral medications including oral contraceptives.

Phentermine is the most prescribed adrenergic agonist and OM in the United States. In a 28-week controlled trial, participants taking phentermine 15 mg daily lost an

average of 6.0 kg compared with 1.5 kg among those assigned to placebo. In a 2022 AGA meta-analysis of seven short-term RCTs, phentermine was associated with 3.63% greater total body weight loss than placebo. The maximum recommended dosage of phentermine is 37.5 mg daily, but the dosage should be individualized to the lowest effective dose. Phentermine is indicated for short-term use (3 months), as there are no longer-term trials of phentermine monotherapy; however, many prescribers prescribe it for longer periods for ongoing weight management. It was approved in combination with topiramate ER for long-term therapy. Since obesity is a chronic disease, many providers prescribe phentermine for > 3 months as off-label therapy for ongoing weight management depending on individual state restrictions.

Phentermine is approved in combination with **topiramate ER** for long-term obesity treatment. The combination of phentermine and topiramate ER (3.75 mg/23 mg orally daily for 14 days, then 7.5 mg/46 mg orally daily, to a maximum dosage of 15 mg/92 mg orally daily) targets two different weight-regulation mechanisms simultaneously. A 2022 AGA meta-analysis of three RCTs with 52–56 weeks of follow-up found that phentermine-topiramate resulted in 8.45% greater total body weight loss than placebo. There is a potential increased risk of orofacial clefts in infants exposed to topiramate during the first trimester of pregnancy.

The combination of **naltrexone SR** and **bupropion SR** (8 mg/90 mg, increasing from 1 tablet orally daily by 1 additional daily tablet each week to a maximum of 2 tablets twice daily) reduces both appetite and food cravings by targeting two areas of the brain: the arcuate nucleus of the hypothalamus and the mesolimbic dopamine reward circuit. Naltrexone 32 mg/bupropion 360 mg is associated with a 6.1% reduction in body weight compared to 1.3% with placebo after 56 weeks. As with all antidepressants, bupropion carries a black box warning related to a potential increase in suicidality among patients under age 24 years during the early phase of treatment.

Orlistat works in the GI tract to inhibit intestinal lipase, thus reducing dietary fat absorption. Orlistat may thereby cause steatorrhea, fecal urgency, abdominal discomfort, and reduced absorption of fat-soluble vitamins. An AGA meta-analysis of RCTs found that individuals taking orlistat lost 2.8% more total body weight compared with placebo. A 2022 AGA guideline suggests against the use of orlistat due to the small magnitude of weight loss and the moderate rate of discontinuation due to side effects.

Metabolic and bariatric surgery is associated with significant and sustained weight loss, reduction or resolution of obesity-related comorbidities, and improved quality of life. Metabolic and bariatric surgery is associated with lower incidence of cardiovascular events, decreased number of cardiovascular deaths, and reduced overall mortality compared to usual care. The two most common metabolic and bariatric procedures in the United States are the sleeve gastrectomy and the Roux-en-Y gastric bypass. The laparoscopic adjustable gastric band and other surgical procedures are performed less frequently. Metabolic and bariatric surgery can be considered in patients with a BMI of 40 or higher or with a BMI of 35 or higher with at least one obesity-related complication who failed to achieve sufficient weight loss following lifestyle modification, with or without obesity medication. Long-term medical follow-up, lifestyle changes, and adherence to a vitamin regimen are crucial to the success of metabolic and bariatric surgery. Many patients experience some degree of weight recurrence. Despite the known benefits of metabolic and bariatric surgery, < 1% of eligible patients undergo surgery to treat their obesity. This is likely due to limited patient knowledge of the health benefits of surgery, limited provider comfort in recommending surgery, inadequate insurance coverage, and the growing list of effective OMs.

Sleeve gastrectomy involves removing approximately 70% of the stomach body and antrum along the greater curvature. The fundus of the stomach, which secretes ghrelin, a hormone that stimulates appetite, is also removed. Sleeve gastrectomy is associated with approximately 25% total body weight loss after 1 year. Because this procedure is mainly restrictive (versus the Roux-en-Y gastric bypass, which is also malabsorptive), there is a lower risk of nutritional deficiencies. In general, sleeve gastrectomy is associated with fewer complications than the Roux-en-Y gastric bypass. Late complications include gastroesophageal reflux, nutritional deficiencies, and stomach expansion, leading to decreased restriction. Unlike Roux-en-Y gastric bypass, sleeve gastrectomy is not reversible.

The **Roux-en-Y gastric bypass** involves a staple partition across the proximal stomach with attachment of a small proximal stomach to a jejunal limb, thus bypassing the remainder of the stomach, duodenum, and the proximal jejunum. Roux-en-Y gastric bypass is associated with approximately 30% total body weight loss at 1 year and greater improvements in comorbid disease markers compared to the sleeve gastrectomy. Roux-en-Y gastric bypass is associated with a lower rate of gastroesophageal reflux than sleeve gastrectomy and can even alleviate gastroesophageal reflux in patients who have it. It is often recommended over sleeve gastrectomy for patients with type 2 diabetes because it leads to greater long-term remission. Late adverse events include nutritional deficiencies (eg, vitamins B_1, B_{12}, D, and iron) and anastomosis ulceration. Dumping syndrome can develop at any time. Roux-en-Y gastric bypass is technically a reversible procedure; however, it is generally only reversed in extreme circumstances.

Patients who cannot achieve clinically meaningful weight loss with obesity medications and who do not undergo bariatric surgery fall into a “treatment gap.” Several **devices and endoscopic procedures** are available that are reversible and minimally invasive. In addition, they may be less expensive and safer than metabolic and bariatric surgery for poor surgical candidates.

▶ When to Refer

- Patients with obesity (BMI ≥ 30) or who are overweight (BMI ≥ 27) with at least one weight-related comorbid condition may be referred to an obesity medicine specialist.
- Patients with a BMI ≥ 40 or ≥ 35 with at least one obesity-related comorbid condition who have not achieved

sufficient weight loss to address health goals following behavioral treatment, with or without obesity medication, may be referred to a bariatric surgeon.

EATING DISORDERS

ANOREXIA NERVOSA

ESSENTIALS OF DIAGNOSIS

- Restriction of energy intake leading to a significantly low body weight in the context of age, sex, developmental trajectory, and physical health.
- Intense fear of gaining weight or behavior that prevents weight gain.
- Distorted perception of body image, with undue influence of weight on self-worth.
- Denial of the medical seriousness of underweight status.

General Considerations

Anorexia nervosa is characterized by low body weight, intense fear of gaining weight, and distorted perception of body image. Anorexia nervosa typically begins in the years between adolescence and young adulthood but often persists into older adulthood.

The prevalence of anorexia nervosa is greater than previously suggested. The American Psychiatric Association's *DSM-5* classifies the severity of anorexia according to BMI: mild, BMI 17–18.49; moderate, BMI 16–16.99; severe, BMI 15–15.99; extreme, BMI < 15.

There are two subtypes of anorexia nervosa: binge-eating/purging type and restricting type. The binge-eating/purging subtype is characterized by recurrent episodes of binge-eating or purging (ie, self-induced vomiting and/or abuse of diuretics, laxatives, enemas, cathartics). The restricting subtype is characterized by dieting, fasting, or excessive exercising without associated binge-eating or purging.

The cause of anorexia nervosa is not known. Although multiple endocrinologic abnormalities exist in patients with anorexia nervosa, most authorities believe they are secondary to malnutrition and not the primary disorder. Most experts favor a primary psychiatric origin, but no hypothesis explains all cases. The patient characteristically comes from a family whose members are highly goal oriented. Patients are often perfectionistic in behavior, exhibit obsessional personality characteristics, or have preoccupation with food.

Clinical Findings

A. Symptoms and Signs

Patients with anorexia nervosa may exhibit severe emaciation and frequently report cold intolerance or constipation. Bradycardia, hypotension, and hypothermia may be present in severe cases. Examination demonstrates loss of body fat, dry and scaly skin, and increased lanugo body hair. Parotid enlargement and edema may also occur. In females of reproductive age, cessation of menstruation is common.

B. Laboratory Findings

Laboratory findings are variable but may include anemia, leukopenia, electrolyte abnormalities, and elevations of BUN and serum creatinine. Serum cholesterol levels are often increased. Endocrine abnormalities include depressed levels of LH and FSH and impaired response of LH to gonadotropin-releasing hormone.

Diagnosis & Differential Diagnosis

The diagnosis is based on energy restriction, significantly low body weight, distorted body image, intense fear of weight gain or of loss of control over food intake, and refusal to exceed a minimal healthy weight. Other medical or psychiatric illnesses that can account for anorexia and weight loss must be excluded.

The differential diagnosis includes bulimia nervosa, binge-eating disorder, endocrine and metabolic disorders (eg, panhypopituitarism, Addison disease, hyperthyroidism, and diabetes mellitus), GI disorders (eg, Crohn disease and gluten enteropathy), chronic infections (eg, tuberculosis), cancers (eg, lymphoma), and rare CNS disorders (eg, hypothalamic tumor).

Treatment

The goal of treatment is restoration of healthy body weight and improvement in psychological comorbidities. Hospitalization may be necessary, especially when refeeding syndrome and severe electrolyte abnormalities are anticipated. Treatment programs delivered by experienced teams successfully restore healthy weight in approximately two-thirds of cases. The remainder continue to experience difficulties with underweight, disordered eating behaviors, and associated psychiatric conditions. Up to 6% of patients die of complications of the disorder or by suicide.

Various treatment methods have been used without clear evidence of superiority of one over another. Supportive care by clinicians and family is the most important feature of any therapy. Cognitive-behavioral therapy, intensive psychotherapy, and family therapy may be tried. A variety of medications including tricyclic antidepressants, SSRIs, and lithium are effective in some cases. Patients with severe malnutrition must be hemodynamically stabilized and may require enteral or parenteral feeding. Forced feedings should be reserved for life-threatening situations, since the goal of treatment is to reestablish healthy eating behavior.

When to Refer

- Adolescents and young adults with otherwise unexplained profound weight loss should be evaluated by a psychiatrist or eating disorders specialist.
- All patients with diagnosed anorexia nervosa should be managed by a multidisciplinary team, including physicians, psychiatrists, social workers, and dietitians.

When to Admit

- Signs of hypovolemia, major electrolyte disorders, and severe protein–energy malnutrition.
- Failure to improve with outpatient management.

Muratore AF et al. Psychopharmacologic management of eating disorders. Curr Psychiatry Rep. 2022;24:345. [PMID: 35576089]

BULIMIA NERVOSA

ESSENTIALS OF DIAGNOSIS

- Uncontrolled episodes of binge-eating at least once weekly for 3 months.
- Recurrent inappropriate compensatory behavior to prevent weight gain such as self-induced vomiting, laxatives, diuretics, fasting, or excessive exercise.
- Excessive concern with body weight and body shape, with undue influence of weight on self-worth.

General Considerations

Bulimia nervosa is the episodic uncontrolled ingestion of large quantities of food followed by recurrent inappropriate compensatory behavior to prevent weight gain, such as self-induced vomiting, diuretic or cathartic use, strict dieting, or vigorous exercise. Bulimia nervosa is more difficult to detect than anorexia as patients often maintain a normal or higher BMI.

Clinical Findings

Patients with bulimia nervosa typically consume large quantities of easily ingested high-calorie foods, usually in secrecy. Some patients may have several such episodes per day over multiple days; others report regular and persistent patterns of binge-eating. Binging is usually followed by vomiting, cathartics, or diuretics and accompanied by feelings of guilt or depression. Periods of binging may be followed by intervals of self-imposed starvation. Body weight may fluctuate but generally remains within 20% of normal BMI.

Family and psychological conditions are generally similar to those of patients with anorexia nervosa. Patients with bulimia, however, have a higher incidence of obesity, greater use of cathartics and diuretics, and more impulsive or antisocial behavior. Menstruation is typically preserved.

Medical complications are numerous. Gastric dilatation and pancreatitis have been reported after binges. Vomiting can result in poor dentition, pharyngitis, esophagitis, aspiration, and electrolyte abnormalities. Cathartic and diuretic abuse can also cause electrolyte abnormalities or dehydration. Constipation is common.

Treatment

Treatment of bulimia nervosa requires supportive care and psychotherapy. Individual, group, family, and behavioral therapy have all been utilized. Antidepressant medications may be helpful. The best results have been with fluoxetine and other SSRIs. Although death from bulimia is rare, the long-term psychiatric prognosis in severe bulimia is worse than anorexia nervosa.

When to Refer

All patients with diagnosed bulimia should be managed by a multidisciplinary team, including physicians, psychiatrists, social workers, and dietitians.

DISORDERS OF VITAMIN METABOLISM

THIAMINE (B_1) DEFICIENCY

Most thiamine deficiency in the United States is due to alcohol use disorder, with poor dietary intake of thiamine and impaired thiamine absorption, metabolism, and storage. It is also associated with malabsorption (eg, following metabolic and bariatric surgery), dialysis, and other causes of chronic protein–calorie undernutrition. Thiamine depletion can be precipitated when patients with low thiamine are given a large carbohydrate load, such as enteral or parenteral nutrition.

Clinical Findings

Early manifestations of thiamine deficiency include anorexia, muscle cramps, paresthesia, and irritability. Advanced deficiency primarily affects the cardiovascular system ("wet beriberi") or the nervous system ("dry beriberi"). Wet beriberi occurs in thiamine deficiency accompanied by severe physical exertion and high carbohydrate intake. Dry beriberi occurs in thiamine deficiency accompanied by inactivity and low-calorie intake.

Wet beriberi is characterized by marked peripheral vasodilation resulting in high-output HF with dyspnea, tachycardia, cardiomegaly, pulmonary edema, and peripheral edema with warm extremities mimicking cellulitis.

Dry beriberi involves both the peripheral and central nervous system. Peripheral nerve involvement is typically a symmetric motor and sensory neuropathy with pain, paresthesia, and loss of reflexes. Legs are affected more than arms. CNS involvement results in Wernicke-Korsakoff syndrome. Wernicke encephalopathy consists of nystagmus progressing to ophthalmoplegia, truncal ataxia, and confusion. Korsakoff syndrome includes amnesia, confabulation, and impaired learning.

Diagnosis

In most instances, the clinical response to empiric thiamine therapy is used to support a diagnosis of thiamine deficiency. The most common biochemical tests measure thiamine concentration directly, while other assays measure erythrocyte transketolase activity and urinary thiamine excretion. Normal thiamine values typically range from 70 nmol/L to 180 nmol/L.

Treatment

Thiamine deficiency is treated with large parenteral doses of thiamine. Fifty to 100 mg/day is initially administered intravenously, followed by daily oral doses of 5–100 mg/day. It is important to note that thiamine supplementation is only effective if magnesium is replete. All patients should simultaneously receive therapeutic doses of other water-soluble vitamins. Treatment results in complete resolution in one-fourth of patients immediately and another one-fourth over days, but half achieve only partial or no benefit.

When to Refer

Patients with signs of dry beriberi or Wernicke-Korsakoff syndrome should be referred to a neurologist. Patients with signs of wet beriberi should be referred to a cardiologist.

THIAMINE TOXICITY

There is no known toxicity of thiamine.

Keating EM et al. Thiamine deficiency disorders in women and children. Paediatr Int Child Health. 2023;43:40. [PMID: 36645721]

Schostak T et al. Thiamine deficiency: a commonly unrecognised but easily treatable condition. Postgrad Med J. 2023;99:844. [PMID: 37125640]

RIBOFLAVIN (B_2) DEFICIENCY

Clinical Findings

Riboflavin deficiency usually occurs in combination with other vitamin deficiencies. Dietary inadequacy, interactions with medications, alcohol use disorder, and other causes of protein–calorie undernutrition are the most common causes.

Manifestations of riboflavin deficiency include cheilosis, angular stomatitis, glossitis, seborrheic dermatitis, weakness, corneal vascularization, and anemia.

Diagnosis

Riboflavin deficiency can be confirmed by measuring the riboflavin-dependent enzyme erythrocyte glutathione reductase.

Treatment

When suspected, riboflavin deficiency is usually treated empirically with foods such as meat, fish, and dairy products or with oral preparations of the vitamin. Administration of 10–20 mg/day until clinical findings resolve is usually adequate. Riboflavin can also be given parenterally.

RIBOFLAVIN TOXICITY

There is no known toxicity of riboflavin.

McNulty H et al. Causes and clinical sequelae of riboflavin deficiency. Annu Rev Nutr. 2023;43:101. [PMID: 37603429]

NIACIN DEFICIENCY

"Niacin" is a generic term for nicotinic acid and other derivatives with similar nutritional activity. Unlike most other vitamins, niacin can be synthesized from the amino acid tryptophan. Niacin is an essential component of the co-enzymes nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which are involved in many oxidation-reduction reactions. The major food sources of niacin are proteins containing tryptophan (meat, fish, poultry) and enriched cereals and grains.

Niacin in the form of nicotinic acid is used therapeutically for the treatment of hypercholesterolemia and hypertriglyceridemia. Niacinamide (the form of niacin generally used to treat niacin deficiency) does not exhibit the lipid-lowering effects of nicotinic acid.

Clinical Findings

As with other B vitamins, early manifestations of niacin deficiency are nonspecific—anorexia, weakness, irritability, mouth soreness, glossitis, stomatitis, and weight loss. More advanced deficiency results in the classic triad of pellagra: dermatitis, diarrhea, and dementia. The dermatitis is symmetric, involving sun-exposed areas. Skin lesions are dark, dry, and scaly. The dementia begins with insomnia, irritability, and apathy and progresses to confusion, memory loss, hallucinations, and psychosis. The diarrhea can be severe and may result in malabsorption due to atrophy of the intestinal villi. Advanced pellagra can result in death.

Diagnosis

In early deficiency, diagnosis requires a high index of suspicion. Low levels may be found in patients with generalized undernutrition. In advanced cases, the diagnosis of pellagra can be made clinically. Niacin can be measured in urine, serum, or plasma.

Treatment

Niacin deficiency can be effectively treated with oral niacin, usually given as nicotinamide (10–150 mg/day). Advanced stages of pellagra are treated via intramuscular injections of nicotinic acid (50–100 ng/day) three times daily for 3 to 4 days, followed by oral therapy of nicotinic acid.

NIACIN TOXICITY

At the high doses of niacin used to treat hyperlipidemia, side effects are common. These include cutaneous flushing (partially prevented by pretreatment with aspirin, 81–325 mg/day, and use of extended-release nicotinic acid preparations) and gastric irritation. Elevation of liver enzymes, hyperglycemia, and gout are less common side effects.

Berger MM et al. ESPEN micronutrient guideline. Clin Nutr. 2022;41:1357. [PMID: 35365361]

Hołubiec P et al. Pathophysiology and clinical management of pellagra—a review. Folia Med Cracov. 2021;61:125. [PMID: 34882669]

VITAMIN B_6 DEFICIENCY

Vitamin B_6 deficiency most commonly occurs as a result of alcohol use disorder or interactions with medications, especially isoniazid, and oral contraceptives. A number of inborn errors of metabolism and other pyridoxine-responsive syndromes, particularly pyridoxine-responsive anemia, are not clearly due to vitamin deficiency but commonly respond to high doses of the vitamin. Patients with common variable immunodeficiency may have concomitant vitamin B_6 deficiency.

Clinical Findings

Vitamin B_6 deficiency results in clinical symptoms similar to those of other B vitamin deficiencies, including mouth soreness, glossitis, cheilosis, weakness, and irritability. Severe deficiency can result in peripheral neuropathy, anemia, and seizures.

Diagnosis

The diagnosis of vitamin B_6 deficiency can be confirmed by measurement of pyridoxal phosphate in blood, urinary excretion of 4-pyridoxic acid, and erythrocyte AST or ALT.

Treatment

Vitamin B_6 deficiency can be treated effectively with vitamin B_6 supplements (100 mg/day orally). Some patients taking medications that interfere with pyridoxine metabolism (such as isoniazid) may require prophylactic vitamin B_6 (50–100 mg/day orally) to prevent deficiency. This is true for patients who are more likely to have diets marginally adequate in vitamin B_6, such as older adults and patients with alcohol use disorder.

VITAMIN B_6 TOXICITY

A sensory neuropathy, at times irreversible, can occur in patients receiving large doses of vitamin B_6 (200–2000 mg/day).

VITAMIN B_{12} & FOLATE

Vitamin B_{12} (cobalamin) and folate are reviewed in Chapter 15.

VITAMIN C (Ascorbic Acid) DEFICIENCY

Most cases of vitamin C deficiency in the United States are due to dietary inadequacy in older adults, malabsorptive disorders, and alcohol use disorder. Patients with chronic illnesses such as cancer and individuals who smoke cigarettes are also at risk.

Clinical Findings

Early manifestations of vitamin C deficiency are nonspecific and include malaise and weakness. In more advanced stages, the typical features of scurvy develop. Manifestations include perifollicular hemorrhages, perifollicular hyperkeratotic papules, petechiae, purpura, splinter hemorrhages, bleeding gums, hemarthroses, and subperiosteal hemorrhages. Anemia is common, and wound healing is impaired. The late stages of scurvy are characterized by edema, oliguria, neuropathy, intracerebral hemorrhage, and death.

Diagnosis

The diagnosis of advanced scurvy can be made clinically based on skin lesions in the proper clinical setting. Atraumatic hemarthrosis is also highly suggestive. The diagnosis can be confirmed with decreased plasma ascorbic acid levels, typically below 0.2 mg/dL.

Treatment

Adult scurvy can be treated with ascorbic acid 300–1000 mg/day orally. Improvement generally occurs within days.

Golder JE et al. Exploring the relationship between vitamin C deficiency and protein-energy malnutrition in adult hospitalised patients: a cross-sectional study. Nutr Diet. 2025;82:152. [PMID: 39648345]

VITAMIN C TOXICITY

Excessive doses of vitamin C can cause gastric irritation, flatulence, or diarrhea. With adequate renal function, toxicity is rare. Patients with renal failure, kidney stones, iron overload, or those receiving heparin or warfarin should avoid large doses. Vitamin C can confound common diagnostic tests by causing false-negative results for some fecal occult blood tests and both false-negative and false-positive results for urine glucose.

Dosedĕl M et al. Vitamin C-sources, physiological role, kinetics, deficiency, use, toxicity, and determination. Nutrients. 2021;13:615. [PMID: 33668681]
Nowak D. Vitamin C in human health and disease. Nutrients. 2021;13:1595. [PMID: 34064549]

VITAMIN A DEFICIENCY

Clinical Findings

Vitamin A deficiency is one of the most common vitamin deficiency syndromes, particularly in developing countries. In certain regions, it is the most common cause of blindness. In the United States, it is usually due to fat malabsorption syndromes or mineral oil laxative abuse and occurs most commonly in older adults and patients with malabsorptive conditions.

Night blindness is the earliest symptom. Dryness of the conjunctiva (xerosis) and the development of small white patches on the conjunctiva (Bitot spots) are early signs. Ulceration and necrosis of the cornea (keratomalacia), perforation, endophthalmitis, and blindness are late manifestations. Xerosis and hyperkeratinization of the skin and loss of taste may also occur.

Diagnosis

Abnormalities of dark adaptation are strongly suggestive of vitamin A deficiency. Serum levels below the normal range of 30–65 mg/dL are commonly seen in advanced deficiency.

Treatment

Night blindness, poor wound healing, and other signs of deficiency can be effectively treated with vitamin A 30,000 IU orally daily for 1 week.

VITAMIN A TOXICITY

Excess intake of β-carotene (hypercarotenosis) results in staining of the skin a yellow-orange color but is otherwise benign. Skin changes are most marked on the palms and soles, while sclerae remain white, clearly distinguishing hypercarotenosis from jaundice.

Excessive vitamin A (hypervitaminosis A), on the other hand, can be toxic. Chronic toxicity usually occurs after ingestion of daily doses of over 50,000 IU/day for > 3 months. Early manifestations include dry, scaly skin, hair loss, mouth sores, painful hyperostosis, anorexia, and vomiting. More serious findings include hypercalcemia; increased intracranial pressure with papilledema, headaches, and decreased cognition; and hepatomegaly, which can progress to cirrhosis. Acute toxicity can result from ingestion of excessive doses of vitamin A via medications or supplements. Manifestations include nausea, vomiting, abdominal pain, headache, papilledema, and lethargy.

The diagnosis can be confirmed by elevations of serum retinol levels. The only treatment is withdrawal of vitamin A from the diet. Most symptoms and signs improve rapidly.

Carazo A et al. Vitamin A update: forms, sources, kinetics, detection, function, deficiency, therapeutic use and toxicity. Nutrients. 2021;13:1703. [PMID: 34069881]

VITAMIN D

Vitamin D is reviewed in Chapter 30.

VITAMIN E DEFICIENCY

Clinical Findings

Clinical deficiency of vitamin E is most commonly seen in patients with fat-malabsorptive disorders, such as Crohn disease, cystic fibrosis, compromised biliary function, or resection of the ileum or small intestine. Deficiency may produce spinocerebellar degeneration of the posterior columns of the spinal cord. Manifestations include slurring of speech, sensory loss, areflexia, disturbances of gait, decreased vibration and proprioception, and ophthalmoplegia. (See Chapter 27.)

Diagnosis

Normal plasma vitamin E levels are 0.5–0.7 mg/dL or higher. Since vitamin E is normally transported in lipoproteins, the serum level should be interpreted in relation to plasma cholesterol levels.

Treatment

The optimal therapeutic dose of vitamin E has not been defined; however, the suggested range is 200–2000 mg/day. Large doses, often administered parenterally, can be used to improve the neurologic complications seen in abetalipoproteinemia and cholestatic liver disease. Vitamin E supplementation may also provide benefit in patients with nonalcoholic fatty liver disease.

VITAMIN E TOXICITY

Clinical trials have suggested an increase in all-cause mortality with high-dose (> 400 IU/day) vitamin E supplements. Large doses of vitamin E can also increase the vitamin K requirement and result in bleeding in patients taking oral anticoagulants.

Sherf-Dagan S et al. Vitamin E status among bariatric surgery patients: a systematic review. Surg Obes Relat Dis. 2021;17:816. [PMID: 33323330]

VITAMIN K

Vitamin K is reviewed in Chapter 16.

DIET THERAPY

Specific therapeutic diets can complement the medical management of most common illnesses. Dietary modifications can be difficult to sustain, and patients may benefit from the support of a registered dietitian. Eliciting a dietary recall is a helpful strategy to provide insight into a patient's dietary preferences and restrictions and provides information about nutrient content. Ongoing food tracking can improve dietary adherence.

Therapeutic diets can be divided into three groups: (1) diets that alter food consistency, (2) diets that restrict or modify dietary components, and (3) diets that supplement dietary components.

DIETS THAT ALTER CONSISTENCY

Clear Liquid Diet

This diet provides adequate water, 500–1000 kcal as simple sugar, and some electrolytes. It is fiber-free and requires minimal digestion or intestinal motility.

A clear liquid diet is useful for patients with resolving postoperative ileus, acute gastroenteritis, partial intestinal obstruction, and in preparation for diagnostic GI procedures. It is commonly used as the first diet for patients who have been taking nothing by mouth for a long period. Because of the low calorie and minimal protein content of the clear liquid diet, it is used only for short durations unless it is in addition to other means of nutrition support.

Full Liquid Diet

The full liquid diet provides adequate water and can be designed to provide sufficient calories and protein. Vitamins and minerals may be inadequate and should be provided in the form of supplements. Dairy products, protein shakes, and pureed soups are used to supplement clear liquids.

This diet is low in residue and can be useful for patients with difficulty chewing or swallowing due to orofacial trauma or surgery, with GI partial obstructions, or in preparation for certain diagnostic procedures.

Modified Consistency Diets

Modified consistency diets are designed for patients unable to chew or swallow hard food. Textures range from pureed to easy-to-chew foods. Texture modified diets are commonly used in patients with dysphagia or poor dentition, patients who have undergone head and neck surgery, patients with esophageal strictures, and in postoperative patients to assist in progression from liquid diets to regular diets. Modified consistency diets can be designed to meet all nutritional requirements.

DIETS THAT RESTRICT NUTRIENTS

Diets can be designed to restrict (or eliminate) virtually any nutrient or food component. The most common restricted diets are those that limit sodium, fat, carbohydrate, or protein. Other restrictive diets include gluten restriction for patients with gluten enteropathy, potassium and phosphate reduction in patients with CKD, and elimination of certain allergens for patients with food allergies.

Sodium-Restricted Diets

Low-sodium diets can be useful in the management of patients with hypertension and conditions in which sodium retention and edema are prominent features, particularly HF, liver disease, and CKD. When used in conjunction with diuretics, sodium restriction may allow lower dosages of diuretic medications and may prevent side effects. For example, sodium restriction decreases diuretic-related potassium losses by reducing distal tubule sodium delivery.

Typical American diets contain 4–6 g (175–260 mEq) of sodium per day. A no-added-salt diet contains approximately 3 g (132 mEq) of sodium per day. Further restriction can be achieved with diets of 2 or 1 g of sodium per day. Diets with more severe restriction are difficult to adhere to and are rarely used. National Academies of Sciences, Engineering, and Medicine guidelines recommend 2.3 g of sodium per day (approximately 1 teaspoon of salt).

Dietary sodium includes sodium naturally occurring in foods, sodium added during food processing, and sodium added during cooking and at the table. Approximately 80% of dietary intake in American diets is from processed and pre-prepared foods. Diets designed for 2.3 g of sodium per day require elimination of most processed foods, added salt, and foods with high sodium content. Patients with mild hypertension may achieve significant reductions in blood pressure (approximately 5 mm Hg diastolic) with this degree of sodium restriction.

Fat-Restricted Diets & Low–Saturated Fat Diets

Traditional fat-restricted diets are useful in the treatment of patients with fat malabsorption syndromes and following surgical procedures such as cholecystectomy and pancreatic resection. Such diets may improve the symptoms of diarrhea with steatorrhea independent of the primary physiologic abnormality by limiting the quantity of fatty acids that reach the colon. The degree of fat restriction necessary to control symptoms must be individualized. Patients with severe malabsorption can be limited to 40–60 g of fat per day. Diets containing 60–80 g of fat per day can be designed for patients with less severe abnormalities.

Fat-restricted diets that specifically restrict saturated fats are the mainstay of dietary treatment of hyperlipidemia with elevated LDL cholesterol (see Chapter 33). Similar diets are often recommended for the prevention of CAD (see Chapter 10). The Women's Health Initiative Dietary Modification Trial, however, did not show significant benefit of a low-fat diet for weight control or prevention of CVD or cancer. In contrast, a study of Mediterranean diets, supplemented by nuts or extra-virgin olive oil, demonstrated a reduction in cardiovascular events. Plant-based diets, defined by low consumption of animal products, have been increasingly recommended for their health benefits. Numerous studies have found diets enriched with high-quality plant foods, such as whole grains, fruits, vegetables, and nuts, to be associated with lower cardiovascular risk.

The aim of low-fat diets is to restrict total fat to < 30% of calories and saturated fat to < 7% of calories. More extreme restriction offers little additional advantage in modification of serum lipids. Low-fat diets can be augmented with plant stanols and sterols and with soluble dietary fiber to further reduce serum lipids.

Carbohydrate-Restricted Diets

Low-carbohydrate diets typically restrict carbohydrate intake to 50–180 g/day. Consumption of foods that contain higher protein and fat with lower carbohydrate content has been shown to promote satiety. Carbohydrate-restricted diets, including low-glycemic-index diets (see Chapter 32), can be helpful for patients with type 2 diabetes and other forms of insulin resistance to reduce blood sugar and weight. Several studies investigating the efficacy of low-fat versus low-carbohydrate diets for weight loss show no clear benefit of one versus the other.

Protein-Restricted Diets

Protein-restricted diets are most commonly recommended to patients with advanced CKD in order to slow the progression of early disease and to decrease symptoms of uremia in more severe disease.

Protein restriction is intended to limit the production of nitrogenous waste products. Energy intake must be adequate to facilitate the efficient use of dietary protein. Enough protein (at least 0.6 g/kg/day in most patients) must be provided to meet minimal requirements.

DIETS THAT SUPPLEMENT NUTRIENTS

High-Fiber Diets

Dietary fiber is a diverse group of plant constituents that is resistant to digestion by the human digestive tract. Guidelines suggest that adult men should eat 30–38 g of fiber per day and adult women 21–25 g/day. Typical US diets, however, contain about half of that amount. Epidemiologic evidence suggests that populations consuming greater quantities of fiber may have a lower incidence of certain GI disorders, including diverticulitis, colon cancer, and CVD. A meta-analysis of 22 studies suggested that each 7 g of dietary fiber was associated with a 9% decrease in first cardiovascular event.

Diets high in dietary fiber (21–38 g/day) are commonly recommended to patients with a variety of GI disorders such as irritable bowel syndrome and recurrent diverticulitis. Diets high in fiber, particularly soluble fiber, may also be useful to reduce blood sugar in patients with diabetes and to reduce cholesterol in patients with hypercholesterolemia. Good sources of soluble fiber are oats, nuts, seeds, legumes, and most fruits. Foods with insoluble fiber include whole wheat, brown rice, other whole grains, and most vegetables. For some patients, the addition of psyllium or methylcellulose may be a useful adjunct to increase dietary fiber.

NUTRITIONAL SUPPORT

Nutritional support is the provision of nutrients to patients who cannot meet their nutritional requirements by intake of standard diets alone. Nutrients may be delivered enterally via oral nutrition supplements and feeding tubes, or parenterally using lines or catheters inserted directly into veins. Nutritional support techniques permit adequate nutrition delivery; however, their use should be considered only when likely to improve a patient's outcome.

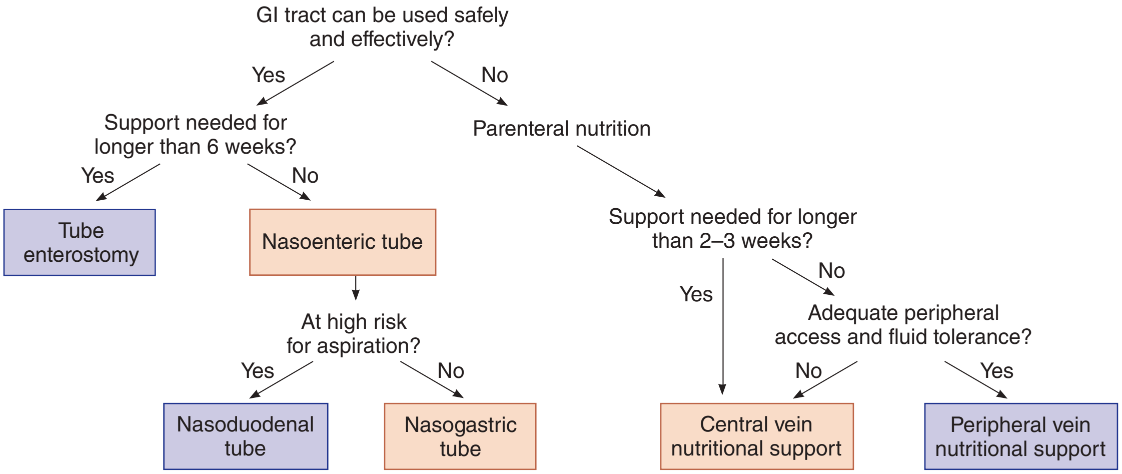
INDICATIONS FOR NUTRITIONAL SUPPORT

Nutritional support is indicated in patients who are malnourished or at risk of malnutrition. Common indications for enteral nutrition include dysphagia, mechanical ventilation or GI obstruction preventing oral intake, high-output fistula, and hypermetabolic disease states, such as burns and trauma. Parenteral nutrition is required when enteral nutrition is contraindicated, or when the GI tract has diminished function due to underlying conditions, including small bowel obstructions, paralytic ileus, short bowel syndrome, and fistulae. In most other conditions, it is difficult to prove the benefit of nutritional support over treatment without such support.

ASPEN has published recommendations for the rational use of nutritional support. These emphasize the need to individualize the decision to begin nutritional support, weighing the risks, benefits, and costs. The guidelines also highlight the need to perform comprehensive nutrition assessments to identify patients who may benefit from aggressive nutrition interventions.

Nutritional Support Methods

Selection of the most appropriate nutritional support method involves consideration of GI function, anticipated duration of nutritional support, and ability of each method to meet the patient's nutritional requirements. The method chosen should meet the patient's nutritional needs with the lowest risk and cost. For most patients, enteral feeding is



GI tract can be used safely and effectively?

safer and less expensive, and it offers significant physiologic advantages. An algorithm for selection of the most appropriate nutritional support method is presented in Figure 34–1.

Prior to initiating specialized enteral nutritional support, efforts should be made to supplement food intake. Attention to patient food preferences, liberalizing diet orders, timing of meals in relation to diagnostic procedures and required medications, and the use of foods brought to the hospital by family and friends can often increase oral intake. Patients unable to eat enough at regular mealtimes to meet nutritional requirements can be given **oral supplements** as snacks or to replace low-calorie beverages. Oral supplements with different nutritional compositions are available to meet the specific needs of various clinical conditions. Formulations vary in fiber and lactose content, caloric density, protein level, and electrolyte concentrations.

Patients with functioning GI tracts who are unable to take adequate oral nutrition or swallow safely are appropriate for enteral nutritional support (tube feeding). Short-term enteral access devices that terminate in the stomach or small bowel can be placed into the nose or mouth. Examples are orogastric, nasogastric, nasoduodenal, and nasojejunal tubes. Bedside placement of short-term enteral access devices is typically successful; however, it may be difficult to achieve post-pyloric placement. Some patients require fluoroscopic or endoscopic guidance to insert the feeding tube distal to the gastric pylorus. Correct feeding tube placement should always be confirmed radiographically prior to initiation of feeding. Long-term enteral access devices that are placed directly into the stomach or small bowel are called tube enterostomies. Percutaneous gastrostomies, jejunostomies, and gastrojejunostomies can be placed by an endoscopist, interventional radiologist, or surgeon.

When selecting the appropriate enteral access device, it is important to consider anticipated duration of use, patient anatomy, aspiration risk, and quality of life. Patients who are at increased risk of aspiration may benefit from small bowel feeding; however, this may not prevent aspiration, particularly if the pylorus is patulous. Patients fed via the stomach can receive bolus, intermittent, or continuous tube feeding. Patients fed via the small bowel require pump-assisted continuous or cycled tube feeding; bolus feeds are generally not well tolerated.

Patients who require nutritional support but whose GI tracts are impaired are candidates for **parenteral nutritional support**. The choice to use parenteral nutrition via central line or peripheral line is based on nutrition status, duration of use, and whether the patient can tolerate large volumes.

Central vein nutritional support is reserved for patients who are malnourished and require nutritional support for > 7–14 days. It is delivered via intravenous catheters placed percutaneously using sterile technique. Proper placement in the superior vena cava is documented radiographically before the solution is infused. Catheters must be carefully maintained by experienced nursing staff to prevent infection and other catheter-related complications.

Peripheral vein nutritional support is most commonly considered in patients who are not malnourished or who require short-term parenteral nutritional support (< 2 weeks). Peripheral vein nutritional support is administered via standard intravenous lines. Serious adverse events are infrequent, but there is a high incidence of phlebitis, infiltration of intravenous lines, and volume overload.

NUTRITIONAL REQUIREMENTS

Prior to initiation of nutritional support, the patient's estimated nutritional requirements are determined. In general, solutions of equal nutrient value can be designed for delivery via enteral and parenteral routes, but differences in absorption should be considered. A complete nutritional support solution must contain water, carbohydrates, amino acids, fat, electrolytes, vitamins, and minerals.

▶ Water

One method for calculating fluid requirements in adults is to allot 1500 mL for the first 20 kg of body weight with the addition of 20 mL for every kilogram above 20 kg. Another way to calculate fluid requirement is 25–35 mL/kg or approximately 1 mL/kcal energy required. It is important to note that patients with certain medical conditions benefit from fluid restriction.

Energy

Indirect calorimetry is considered the gold standard for estimating energy requirements, but it is not available in most clinical settings. In its absence, predictive energy expenditure equations and simple weight-based calculations can be utilized.

The most widely used and validated predictive energy expenditure equations for healthy individuals include the Harris-Benedict Equation and Mifflin-St. Jeor Equation, which calculate RMR with the addition of stress and activity factors. The Penn State Equation is the recommended predictive equation for critically ill patients due to its superior accuracy. This formula calculates RMR combined with dynamic physiological variables such as maximum temperature in a 24-hour period and minute ventilation. Different versions of the equation exist for patients over 60 years of age or with obesity. Actual body weight should be used for all predictive equations.

Energy requirements can also be estimated by multiplying actual body weight in kilograms by 25–35 kcal/kg/day. Although this method is simple and easy to use, its accuracy is of under 50%.

The above methods provide imprecise estimates of actual energy expenditure, especially for markedly underweight, overweight, and critically ill patients who are ideal candidates for indirect calorimetry. Studies using indirect calorimetry have demonstrated that as many as 30–40% of patients have measured expenditures 10% above or below estimated values.

In standard diets and balanced nutritional support solutions, carbohydrates provide the greatest amount of energy compared to the other macronutrients; however, protein and fat are required in optimal amounts to provide the body energy and support other functions.

Protein

Protein and energy requirements are closely related. If adequate calories are provided, stable and non-stressed patients should receive 0.8–1.2 g/kg/day of protein. Patients under moderate to severe stress require at least 1.5 g/kg/day, although patients with trauma and burns may need closer to 2.5 g/kg/day. Actual weight should be used for patients with a healthy weight or underweight while adjusted body weight should be used for patients with obesity.

Patients who receive protein without adequate calories catabolize protein for energy rather than utilize it for protein synthesis. As a result, when energy intake is low, excess protein is needed for nitrogen balance.

Fat

Patients receiving nutritional support should be given 2–4% of their total calories as linoleic acid and 0.25–0.5% as α-linolenic acid to prevent essential fatty acid deficiency (EFAD). Most enteral formulas contain adequate essential fatty acids. Patients receiving parenteral nutrition should be given 250 mL of a 20% soy-based lipid emulsion at least twice weekly to prevent EFAD.

Electrolytes, Minerals, Vitamins, & Trace Elements

Requirements for sodium, potassium, magnesium, calcium, and phosphorus vary widely depending on a patient's cardiovascular, renal, endocrine, and GI status as well as measurements of serum concentration.

Patients receiving enteral nutritional support should receive adequate vitamins and minerals according to recommended daily allowances. Most enteral formulations provide sufficient vitamins, minerals, electrolytes, and trace elements if adequate volumes are administered. Certain formulas, like those intended for patients with renal disease, have a lower electrolyte profile.

Patients receiving parenteral nutritional support typically require 1–2 mEq/kg/day of sodium and potassium, 10–15 mEq/day of calcium, 8–20 mEq/day of magnesium, and 20–40 mmol/day of phosphorus.

Parenteral formulations also contain the trace elements zinc, copper, manganese, selenium, and chromium. Patients with diarrhea may require additional zinc to replace fecal losses. Copper and manganese may be excluded from a parenteral formulation in patients with liver disease due to impaired excretion and risk for toxicity. It is important to note that trace element products do not contain iron, so patients on long-term parenteral nutrition may require external iron supplementation.

Vitamins are provided daily in the parenteral nutrition solution. Injectable multivitamin products for use in adults contain vitamins A, D, E, K, B_1, B_2, B_6, B_{12}, niacinamide, dexpanthenol, biotin, folic acid, and ascorbic acid.

ENTERAL NUTRITIONAL SUPPORT SOLUTIONS

Patients who require enteral nutritional support in an acute care setting receive commercially prepared enteral formulas (Table 34–3). Most enteral formulations have been designed to provide adequate proportions of water, energy, protein, and micronutrients. Some formulas contain less free water for patients who require fluid restriction. Modular products are also available to provide specific macronutrients (eg, protein, carbohydrate, and fat) to supplement commercially available formulas for patients with unique nutrition requirements.

Enteral formulas can generally be classified as standard (polymeric), peptide-based (elemental or semi-elemental) or disease-specific. The classification is based on the overall composition of the formula and its contained macronutrients. Most enteral formulas are lactose-free.

Standard polymeric formulas are typically isotonic, have moderate amounts of intact macronutrients and may contain fiber. Normal digestive and absorptive capacity are needed for the use of polymeric formulas. Isotonic formulas contain 1 kcal/mL, whereas concentrated formulas

Table 34–3. Enteral formulations.

Standard products
- Blenderized commercially prepared (eg, Compleat, Liquid Hope, Real Food Blends)
- Intact protein, lactose-free, low-residue:
  - 1 kcal/mL (eg, Isosource 1.0, Kate Farms Standard 1.0)
  - 1.5 kcal/mL (eg, Isosource 1.5, Osmolite 1.5, Nutren 1.5, Kate Farms 1.4)
  - 2 kcal/mL (eg, TwoCal HN, Nutren 2.0, Resource 2.0)
- Intact protein, lactose-free, high-residue:
  - 1 kcal/mL (eg, Jevity,[1] Nutren with fiber,[1] Fibersource HN)

"Disease-specific" products
- Advanced CKD: with adjusted protein content, fluid concentration, and electrolytes (eg, Nepro, Nepro with Carb Steady, Suplena with Carb Steady, Novosource Renal, Renalcal, Kate Farms Renal Support)
- Type 2 diabetes: with lower carbohydrate content (eg, Glucerna 1.0, 1.2, or 1.5, Nutren Glytrol, Diabetisource AC, Kate Farms Glucose Support 1.2)
- Malabsorption: with partially or fully hydrolyzed nutrients (eg, Peptamen, Peptamen 1.5, Peptamen AF, Peptamen with Prebio, Peptamen Intense VHP, Tolerex, Vital 1.0 and 1.5, Vital AF 1.2, Vital High Protein, Kate Farms Peptide, Vivonex T.E.N., Vivonex RTF, Vivonex Plus)
- Respiratory failure: with > 50% calories from fat (eg, Pulmocare, Nutren Pulmonary, Oxepa)
- Hepatic encephalopathy: with high amounts of branched-chain amino acids (eg, Nutri-Hep)
- Wound healing: with high protein content (eg, Promote, Replete, Perative)

Modular products
- Protein (eg, ProMod, ProStat Sugar Free, Beneprotein, Unjury)
- Carbohydrate (eg, Polycose, SolCarb)
- Fat (eg, MCT Oil, Microlipid)

[1] Isotonic.

contain 1.2–2 kcal/mL. Standard polymeric formulas are well tolerated in most patients.

Semi-elemental and elemental formulas are designed for patients with impaired GI function who have demonstrated malabsorption and maldigestion with standard polymeric formulas. Elemental formulas contain free amino acids, whereas semi-elemental formulas contain partially hydrolyzed oligopeptides. Elemental formulas contain minimal amounts of fat, typically in the form of medium chain triglycerides, which can increase the risk of EFAD when used long-term. Elemental formulas are hypertonic and can result in diarrhea.

Disease-specific enteral formulas have been designed for patients with diabetes, kidney disease, hepatic encephalopathy, and respiratory failure. However, the majority have not been shown to be superior to standard polymeric formulas for most patients.

When initiating enteral nutrition, a continuous pump-infusion is generally preferred. In critically ill patients, enteral nutrition is commonly started at 10–40 mL/hour and advanced to goal rate by 10–20 mL/hour every 8–12 hours. Stable non-critically ill patients can tolerate enteral nutrition at goal rate; however, this is not appropriate in patients at risk for refeeding syndrome who benefit from more conservative initiation and advancement. In patients with long-term enteral access devices, transitioning to bolus feeds or cycled/nocturnal feeds can improve quality of life.

COMPLICATIONS OF ENTERAL NUTRITIONAL SUPPORT

Enteral nutrition is the preferred feeding method in patients with functional GI tracts; however, complications occur in 10–15%. Minor mechanical complications are common and include tube occlusion and dislodgment. Common GI complications include diarrhea, nausea, vomiting, and constipation. GI bleeding from feeding tube placement may occur but is less common. The most common complication is diarrhea, which may be caused by the formula itself (ie, intolerance to a hyperosmotic load or to a specific component in the formula), medications, infections, or a primary disease of the intestine. All possibilities should be considered before attributing diarrhea to the enteral nutrition.

One of the most serious complications of enteral nutritional support is aspiration. Aspiration can be prevented by identifying patients at risk and utilizing protocols to reduce this risk including elevating the head of bed to 30 degrees, checking gastric residual volumes every 4 hours, utilizing promotility agents, and placing post-pyloric feeding tubes, as appropriate.

Metabolic complications during enteral nutritional support are less likely caused by the enteral nutrition itself and more likely related to underlying conditions that predispose patients to metabolic alterations. The most common complications include refeeding syndrome, electrolyte derangements, hyperglycemia, and dehydration.

PARENTERAL NUTRITIONAL SUPPORT SOLUTIONS

The parenteral nutrition formulation is a complex solution containing up to 40 different nutrients. The basic parenteral solution is composed of dextrose, amino acids, lipids, electrolytes, minerals, trace elements, vitamins, and water. Medications can also be added. Most commercial solutions contain the monohydrate form of dextrose that provides 3.4 kcal/g. Crystalline amino acids are used in parenteral nutrition formulations to provide protein, and they provide 4 kcal/g when oxidized. Lipid emulsions are available in 20% and 30% concentrations, which provide 2 kcal/mL and 3 kcal/mL, respectively. The 30% concentration is approved only for compounding within a 3-in-1 admixture.

Parenteral nutrition administered via a central vein allows for administration of hyperosmolar solution (> 1800 mOsm/L) and adequate nutrition delivery. The dextrose, amino acids, and electrolytes contribute to the osmotic load and can be given in higher concentrations as compared to peripheral parenteral nutrition. Lipid emulsions are isotonic and can be given via a central or peripheral vein.

Solutions with lower osmolarities (< 900 mOsm/L) must be administrated via peripheral veins. Solutions for peripheral infusion usually contain 5–10% dextrose and

3% amino acids. These lower osmolarity solutions result in a high incidence of thrombophlebitis and line infiltration. These solutions may provide adequate protein for some patients, but inadequate total energy from dextrose, depending on volume limitations. Additional energy can be provided with lipid emulsions since these solutions are isotonic and well tolerated by peripheral veins.

Lipid emulsions can prevent EFAD and provide energy to patients on parenteral nutrition. There are four lipid emulsion products available for use in the United States. Two formulations are composed of long-chain triglycerides, derived from either 100% soybean oil, or 50% safflower oil and 50% soybean oil. The third formulation, Smoflipid, was created due to concerns about the high content of proinflammatory omega-6 polyunsaturated fatty acids in traditional lipid emulsions. Smoflipid is composed of 30% soybean oil, 30% medium-chain triglycerides, 25% olive oil, and 15% fish oil. The fourth emulsion, Clinolipid, is composed of 80% olive oil and 20% soybean oil. For all lipid emulsions, providers should follow manufacturer dosing recommendations to prevent complications associated with EFAD.

Parenteral nutrition solutions should be initiated at half of the estimated energy requirement, or approximately 100–150 g dextrose for the first 24 hours. They are increased daily as tolerated to prevent hyperglycemia and electrolyte abnormalities in patients at risk for refeeding syndrome. Amino acids and lipid emulsions can be started at target goals.

COMPLICATIONS OF PARENTERAL NUTRITIONAL SUPPORT

Parenteral nutrition is considered a high-risk nutrition therapy, which can result in mechanical, infectious, and metabolic complications, for which patients require close monitoring for prevention, detection, and treatment.

Catheter-related complications can occur during insertion or while the catheter is in place. Pneumothorax, arterial laceration, air emboli, and brachial plexus injury can occur during catheter placement. Radiographic imaging must be performed to confirm proper placement of central venous access prior to initiating parenteral nutrition. Additional catheter-related complications include thrombotic occlusions and non-thrombotic occlusions caused by drug-nutrient interactions, precipitates, and residue.

Catheter-related bloodstream infections are the most serious complications. Patients with indwelling central vein catheters in whom fever develops without an apparent source should have their lines removed or changed immediately, at which time the catheter tip should be cultured, and empiric antibiotics initiated. Quantitative tip cultures and blood cultures narrow antibiotic therapy. Catheter-related sepsis occurs in 2–3% of patients even if optimal efforts are made to prevent infection. "Central line bundles" are evidence-based practices designed to reduce the incidence of central line–associated infections.

Metabolic complications of central vein nutritional support include hyperglycemia, hypoglycemia, EFAD, hypertriglyceridemia, fluid and electrolyte abnormalities, hepatobiliary disorders, and metabolic bone disease. A skilled nutritional support clinician is needed to safely prescribe, monitor, and address potential parenteral nutrition–associated complications. Examples of metabolic complications and suggested solutions are outlined in Table 34–4.

PATIENT MONITORING DURING NUTRITIONAL SUPPORT

Every patient receiving enteral or parenteral nutritional support should be monitored closely. Formal nutritional support teams composed of a physician, a nurse, a dietitian, and a pharmacist have been shown to decrease the rate of complications.

Patients should be monitored both for the adequacy of treatment and to prevent complications or detect them

Table 34–4. Metabolic complications of parenteral nutritional support.

Complication	Common Causes	Possible Solutions
Hyperglycemia	Too rapid infusion of dextrose, "stress," corticosteroids	Decrease glucose infusion; insulin; replacement of dextrose with fat
Hyperosmolar nonketotic dehydration	Severe, undetected hyperglycemia	Insulin, hydration, potassium
Hyperchloremic metabolic acidosis	High chloride administration	Decrease chloride
Azotemia	Excessive protein administration	Decrease amino acid concentration
Hypophosphatemia, hypokalemia, hypomagnesemia	Extracellular to intracellular shifting with refeeding	Increase solution concentration and provide repletion outside of parenteral nutrition bag; do not advance dextrose further
Liver enzyme abnormalities	Lipid trapping in hepatocytes, fatty liver	Decrease dextrose and lipid to a more balanced solution, cycle parenteral nutrition
Acalculous cholecystitis	Biliary stasis	Encourage oral diet or tube feeding as able
Zinc deficiency	Diarrhea, small bowel fistulas	Increase concentration
Copper deficiency	Biliary fistulas	Increase concentration

early when they occur. Because estimates of nutritional requirements are imprecise, frequent reassessment is necessary. Daily intakes should be recorded and compared with estimated requirements. Body weight, hydration status, and overall clinical status should be followed. Patients who do not appear to be responding as anticipated should have an indirect calorimetry study performed if possible, and they should be evaluated for nitrogen balance with the following equation:

$$\text{Nitrogen balance} = \frac{\text{24-hour protein intake (g)}}{6.25} - \left(\text{24-hour urinary nitrogen (g)} + 4\right)$$

Patients who receive calorie prescriptions comparable to the results of the indirect calorimetry study and who have positive nitrogen balances can continue their current regimens, whereas patients not meeting their energy targets or who have negative nitrogen balances should receive moderate increases in calorie and protein before reassessment. Monitoring for metabolic complications includes daily measurements of basic metabolic panels, magnesium, and phosphorus levels. Once the patient is stabilized on the goal nutritional support regimen, laboratory values can be checked 1–2 times per week. Liver function tests and triglyceride levels should be checked weekly. Vitamins and trace elements should be obtained every 3–6 months in patients receiving long-term nutritional support.

Common Problems in Infectious Diseases & Antimicrobial Therapy

Monica Fung, MD, MPH
Katherine Gruenberg, PharmD, MAEd
Peter V. Chin-Hong, MD

COMMON PROBLEMS IN INFECTIOUS DISEASES

FEVER OF UNKNOWN ORIGIN (FUO)

ESSENTIALS OF DIAGNOSIS

- Illness of at least 3 weeks in duration.
- Fever ≥ 38.3°C on at least three occasions.
- Diagnosis has not been made despite a minimum set of diagnostic tests.

General Considerations

The intervals specified in the criteria for the diagnosis of FUO are arbitrary ones intended to exclude patients with protracted but self-limited illnesses and to allow time for the usual radiographic, serologic, and cultural studies to be performed. The criteria for FUO are met when *a diagnosis has not been made despite a minimum standard of diagnostic tests. These include blood tests (CBC with differential, comprehensive metabolic panel including calcium and liver function tests, ESR, CRP, TSH, rheumatoid factor, antineutrophil cytoplasmic antibodies, and ANA), microbiologic tests (three sets of blood cultures, urinalysis, HIV antibody/antigen, and tuberculin skin test or interferon-γ release assay), and imaging (abdominal ultrasound and CXR or CT of the chest/abdomen/pelvis).*

Added categories of FUO include complications of current health care scenarios: (1) **Hospital-associated FUO** refers to the hospitalized patient with fever of 38.3°C or higher on several occasions, due to a process not present or incubating at the time of admission, in whom initial cultures are negative and the diagnosis remains unknown after 1 week of investigation (see Health Care–Associated Infections, below); (2) **Neutropenic FUO** includes patients with fever of 38.3°C or higher on several occasions with < 500 neutrophils per microliter in whom initial cultures are negative and the diagnosis remains uncertain after 3 days (see Chapter 2 and Infections in the Immunocompromised Patient, below); (3) **HIV-associated FUO** pertains to patients with HIV and fever of 38.3°C or higher who have been febrile for 4 weeks or more as an outpatient or 3 days as an inpatient, in whom the diagnosis remains uncertain after 3 days of investigation with at least 2 days for cultures to incubate (see Chapter 36). Although not usually considered separately, **FUO in solid organ transplant recipients** and **FUO in the returning traveler** are common scenarios, each with a unique differential diagnosis, and are also discussed in this chapter.

For a general discussion of fever, see the section on fever and hyperthermia in Chapter 2.

A. Common Causes

Most cases represent unusual manifestations of common diseases and not rare or exotic diseases—eg, tuberculosis, endocarditis, gallbladder disease, and HIV (primary infection or opportunistic infection) are more common causes of FUO than Whipple disease or familial Mediterranean fever.

B. Age of Patient

In adults, infections (25–40% of cases) and cancer (25–40% of cases) account for the majority of FUOs. Autoimmune disorders occur with equal frequency in adults and children (10–20% of cases), but the diseases differ. Juvenile rheumatoid arthritis is common in children, whereas SLE, granulomatosis with polyangiitis, and polyarteritis nodosa are more common in adults. Still disease, giant cell arteritis, and polymyalgia rheumatica occur exclusively in adults. In adults > 65 years of age, multisystem immune-mediated diseases such as temporal arteritis, polymyalgia rheumatica, sarcoidosis, rheumatoid arthritis, and granulomatosis with polyangiitis account for 25–30% of all FUOs.

C. Duration of Fever

The cause of FUO changes dramatically in patients who have been febrile for 6 months or longer. Infection, cancer, and autoimmune disorders combined account for only 20% of FUOs in these patients. Instead, other entities such as granulomatous diseases (granulomatous hepatitis, Crohn disease, ulcerative colitis) and factitious fever become important causes. One-fourth of patients who say they have been febrile for 6 months or longer actually have no true fever or underlying disease. Instead, the usual normal circadian variation in temperature (temperature 0.5–1°C higher in the afternoon than in the morning) is interpreted as abnormal. Patients with **episodic** or **recurrent fever** (ie, those who meet the criteria for FUO but have fever-free periods of 2 weeks or longer) are similar to those with **prolonged fever**. Infection, malignancy, and autoimmune disorders account for only 20–25% of such fevers, whereas various miscellaneous diseases (Crohn disease, familial Mediterranean fever, allergic alveolitis) account for another 25%. *Approximately 50% of cases remain undiagnosed but have a benign course with eventual resolution of symptoms.*

D. Immunologic Status

In the neutropenic patient, fungal infections and occult bacterial infections are important causes of FUO. In the patient taking immunosuppressive medications (particularly organ transplant patients), cytomegalovirus (CMV) infections are a frequent cause of fever, as are fungal infections, nocardiosis, *Pneumocystis jirovecii* pneumonia, and mycobacterial infections.

E. Classification of Causes of FUO

Most patients with FUO will fit into one of five categories.

1. Infection—Both systemic and localized infections can cause FUO. *Tuberculosis and endocarditis are the most common systemic infections associated with FUO*, but mycoses, viral diseases (particularly infection with Epstein-Barr virus and CMV), toxoplasmosis, brucellosis, Q fever, cat-scratch disease, salmonellosis, malaria, and many other less common infections have been implicated. Primary infection with HIV or opportunistic infections associated with AIDS—particularly mycobacterial infections—also can present as FUO. *The most common form of localized infection causing FUO is an occult abscess*. Liver, spleen, kidney, brain, and bone abscesses may be difficult to detect. A collection of pus may form in the peritoneal cavity or in the subdiaphragmatic, subhepatic, paracolic, or other areas. Cholangitis, osteomyelitis, UTI, dental abscess, or paranasal sinusitis may cause prolonged fever.

2. Neoplasms—Many cancers can present as FUO. The most common are lymphoma (both Hodgkin and non-Hodgkin) and leukemia. Posttransplant lymphoproliferative disorders may also present with fever. Other diseases of lymph nodes, such as angioimmunoblastic lymphoma and Castleman disease, can also cause FUO. Primary and metastatic tumors of the liver are frequently associated with fever, as are renal cell carcinomas. Atrial myxoma is an often-forgotten neoplasm that can result in fever. Chronic lymphocytic leukemia and multiple myeloma are rarely associated with fever, and the presence of fever in patients with these diseases should prompt a search for infection.

3. Autoimmune disorders—Still disease, SLE, cryoglobulinemia, and polyarteritis nodosa are the most common causes of autoimmune-associated FUO. Giant cell arteritis and polymyalgia rheumatica are seen almost exclusively in patients > 50 years of age and are nearly always associated with an elevated ESR (> 40 mm/h).

4. Miscellaneous causes—Many other conditions have been associated with FUO but less commonly than the foregoing types of illness. Examples include thyroiditis, sarcoidosis, Whipple disease, familial Mediterranean fever, recurrent pulmonary emboli, alcoholic hepatitis, drug fever, and factitious fever.

5. Undiagnosed FUO—Despite extensive evaluation, the diagnosis remains elusive in about one-half of patients. Of these patients, the fever abates spontaneously in ~75% with no diagnosis; in the remainder, more classic manifestations of the underlying disease appear over time.

▶ Clinical Findings

Because the evaluation of a patient with FUO is costly and time-consuming, it is imperative to first document the presence of fever. This is done by observing the patient while the temperature is being taken to ascertain that fever is not factitious (self-induced). Associated findings that accompany fever include tachycardia, chills, and piloerection. A thorough history—including family, occupational, social (sexual practices, use of injection drugs), dietary (unpasteurized products, raw meat), exposures (animals, chemicals), and travel—may give clues to the diagnosis. Repeated physical examination may reveal subtle, evanescent clinical findings essential to diagnosis.

A. Laboratory Tests

In addition to routine laboratory studies, *three sets of blood cultures should always be obtained*, preferably when the patient has not taken antibiotics for several days, and should be held by the laboratory for 2 weeks to detect slow-growing organisms. Cultures on special media are requested if *Legionella*, *Bartonella*, or nutritionally deficient streptococci are possible pathogens. "Screening tests" with immunologic or microbiologic serologies ("febrile agglutinins") are of low yield and should *not* be done. If the history or physical examination suggests a specific diagnosis, specific serologic tests with an associated fourfold rise or fall in titer may be useful. Because infection is the most common cause of FUO, other body fluids are usually cultured, ie, urine, sputum, stool, CSF, and morning gastric aspirates (if one suspects tuberculosis). Direct examination of blood smears may establish a diagnosis of malaria or relapsing fever (*Borrelia*).

B. Imaging

All patients with FUO should have chest and abdominal imaging—this can be a combination of CXR and abdominal ultrasound or CT of the chest, abdomen, and pelvis if readily available. Studies such as sinus CT, upper GI series with small bowel follow-through, barium enema, proctosigmoidoscopy, and evaluation of gallbladder function are reserved for patients who have symptoms, signs, or a history that suggest disease in these body regions. CT scan of the abdomen and pelvis is also frequently performed and is particularly useful for looking at the liver, spleen, and retroperitoneum. When the CT scan is abnormal, the findings often lead to a specific diagnosis. A normal CT scan is not quite as useful; more invasive procedures such as biopsy or exploratory laparotomy may be needed. The role of MRI in the investigation of FUO has not been evaluated. In general, however, MRI is better than CT for detecting lesions of the nervous system and is useful in diagnosing various vasculitides. Ultrasound is sensitive for detecting lesions of the kidney, pancreas, and biliary tree. Echocardiography should be used if one is considering endocarditis or atrial myxoma. *Transesophageal echocardiography is more sensitive than surface echocardiography for detecting valvular lesions, but even a negative transesophageal study does not exclude endocarditis (10% false-negative rate).* Guidelines currently suggest the use of nuclear medicine studies, particularly fludeoxyglucose-PET/CT (FDG-PET/CT), earlier in the course of FUO. Diagnostic yields of FDG-PET/CT for underlying causes are 84–98%, with patients with infection or malignancy benefiting more. Furthermore, FDG-PET/CT may assist with prognostication with patients with negative studies being five times more likely to experience spontaneous remission.

C. Biopsy

Invasive procedures are often required for diagnosis. Any abnormal finding should be aggressively evaluated: headache calls for lumbar puncture to rule out meningitis; skin rash should be biopsied for cutaneous manifestations of collagen vascular disease or infection; and enlarged lymph nodes should be aspirated or biopsied for neoplasm and sent for culture. Bone marrow aspiration with biopsy is a relatively low-yield procedure (15–25%; except in patients with HIV, in whom mycobacterial infection is a common cause of FUO), but the risk is low and the procedure should be done if other less invasive tests have not yielded a diagnosis, particularly in persons with hematologic abnormalities. Liver biopsy will yield a specific diagnosis in 10–15% of patients with FUO and should be considered in any patient with abnormal liver tests even if the liver is normal in size. CT scanning and MRI have decreased the need for exploratory laparotomy; however, surgical visualization and biopsies should be considered when there is continued deterioration or lack of diagnosis.

Treatment

Although an empiric course of antimicrobials is sometimes considered for FUO, it is rarely helpful and may impact infectious diseases diagnoses (eg, by reducing the sensitivity of blood cultures).

When to Refer

- Any patient with FUO and progressive weight loss and other constitutional signs.
- Any immunocompromised patient (eg, transplant recipients and patients with HIV).
- Infectious diseases specialists may also be able to coordinate and interpret specialized testing (eg, Q fever serologies) with outside agencies, such as the US CDC.

When to Treat Empirically

- Any patient who is hemodynamically unstable with high risk of sepsis.
- If FUO is present in immunocompromised patients, such as those who are neutropenic from recent chemotherapy or those who have undergone transplantation (particularly in the previous 6 months).
- High clinical suspicion for tuberculosis (requires Infectious Diseases consultation).
- Patients with suspected giant cell arteritis with visual complaints.

INFECTIONS IN THE IMMUNOCOMPROMISED PATIENT

ESSENTIALS OF DIAGNOSIS

- Fever and other symptoms may be blunted because of immunosuppression.
- A contaminating organism in an immunocompetent individual may be a pathogen in an immunocompromised one.
- The interval since transplantation and the degree of immunosuppression can narrow the differential diagnosis.
- Empiric broad-spectrum antibiotics may be appropriate in high-risk patients whether or not symptoms are localized.

General Considerations

Immunocompromised patients have defects in their natural defense mechanisms resulting in an increased risk for infection. In addition, infection is often severe, rapidly progressive, and life-threatening. Organisms that are not usually problematic in the immunocompetent person may be important pathogens in the compromised patient (eg, *Staphylococcus epidermidis*, *Bacillus* species). Therefore, culture results must be interpreted with caution, and isolates should not be disregarded as solely contaminants. Although the type of immunodeficiency is associated with specific infectious disease syndromes, *nearly any pathogen can cause infection in any immunosuppressed patient*. Thus, a systematic evaluation is required to identify a causative pathogen, and expert consultation is required to interpret identification of microbiologic organisms.

A. Impaired Humoral Immunity

Defects in humoral immunity are often congenital, although hypogammaglobulinemia can occur in multiple myeloma, chronic lymphocytic leukemia, small lymphocyte lymphoma, and in patients who have undergone splenectomy. Patients with ineffective humoral immunity lack opsonizing antibodies and are *at particular risk for infection with encapsulated organisms*, such as *Haemophilus influenzae*, *Neisseria meningitides*, and *Streptococcus pneumoniae*. Although rituximab is normally thought of as being linked to impaired cellular immunity, it has been associated with the development of *Pneumocystis jirovecii* infection and progressive multifocal leukoencephalopathy (PML) as well as with hepatitis B reactivation.

B. Neutropenia

Neutropenia is common following hematopoietic stem cell transplantation and among patients with solid tumors—as a result of myelosuppressive chemotherapy—and in acute leukemias. *The risk of infection begins to increase when the absolute neutrophil count falls below 1000/mcL, with a dramatic increase in frequency and severity when the neutrophil count falls below 200/mcL.* The infection risk is also increased with a rapid rate of decline of neutrophils and with a prolonged period of neutropenia. Patients with granulocytopenia are particularly susceptible to infections with gram-negative enteric organisms, *Pseudomonas*, gram-positive cocci (particularly *Staphylococcus aureus* and viridans streptococci), *Candida, Aspergillus*, and other fungi such as *Scedosporium*, *Fusarium*, and the mucormycoses.

C. Impaired Cellular Immunity

Patients with cellular immune deficiency encompass a large and heterogeneous group, including patients with HIV infection (see Chapter 36); patients with lymphoreticular malignancies, such as Hodgkin disease; and patients receiving immunosuppressive medications, such as corticosteroids, cyclosporine, tacrolimus, and other cytotoxic medications. This latter group—those who are immunosuppressed because of medications—includes patients who have undergone solid organ transplantation, many patients receiving therapy for solid tumors, and patients receiving prolonged high-dose corticosteroid treatment (eg, for asthma, temporal arteritis, SLE). Patients taking TNF inhibitors, such as etanercept and infliximab, also are included in this category. Patients with cellular immune dysfunction are susceptible to infections by a large number of organisms, particularly ones that replicate intracellularly. Examples include bacteria, such as *Listeria*, *Legionella*, *Salmonella*, and mycobacteria; viruses, such as herpes simplex, varicella, and CMV; fungi, such as *Cryptococcus*, *Coccidioides*, *Histoplasma*, and *Pneumocystis;* and protozoa, such as *Toxoplasma*.

D. Hematopoietic Cell Transplant Recipients

The length of time it takes for complications to occur in hematopoietic cell transplant recipients can be helpful in determining the etiologic agent. In the *early (preengraftment) posttransplant period (days 1–21)*, patients will become severely neutropenic for 7–21 days. Patients are at risk for gram-positive (particularly catheter-related) and gram-negative bacterial infections, as well as herpes simplex virus, respiratory syncytial virus, and fungal infections. In contrast to solid organ transplant recipients, the source of fever is unknown in 60–70% of hematopoietic cell transplant patients. *Between 3 weeks and 3 months posttransplant*, infections with CMV, adenovirus, *Aspergillus*, and *Candida* are most common. *P jirovecii* pneumonia is possible, particularly in patients who receive additional immunosuppression for treatment of graft-versus-host disease. Patients continue to be at risk for infectious complications *beyond 3 months following transplantation*, particularly those who have received allogeneic transplantation and those who are taking immunosuppressive therapy for chronic graft-versus-host disease. Varicella zoster is common, and *Aspergillus* and CMV infections are increasingly seen in this period as well.

E. Solid Organ Transplant Recipients

The length of time it takes for infection to occur following solid organ transplantation can also be helpful in determining the infectious origin. *Immediate postoperative infections* often involve the transplanted organ. Following lung transplantation, pneumonia and mediastinitis are common; following liver transplantation, intra-abdominal abscess, cholangitis, and peritonitis may be seen; after kidney transplantation, UTIs, perinephric abscesses, and infected lymphoceles can occur.

Most infections that occur in the *first 2–4 weeks posttransplant* are related to the operative procedure and to hospitalization itself (wound infection, intravenous catheter infection, UTI from an indwelling urinary catheter) or are related to the transplanted organ. In rare instances, donor-derived infections (eg, West Nile virus, tuberculosis) may present during this time period. Compensated organ transplants obtained abroad through "medical tourism" can introduce additional risk of infections, which vary by country and by transplant setting. Infections that occur *between the first and sixth months* are often related to immunosuppression. During this period, reactivation of viruses, such as herpes simplex, varicella zoster, and CMV is quite common. Opportunistic infections with fungi (eg, *Candida*, *Aspergillus*, *Cryptococcus*, *Pneumocystis*), *Listeria monocytogenes*, *Nocardia*, and *Toxoplasma* also are common. *After 6 months*, if immunosuppression has been reduced to maintenance levels, infections that would be expected in any population occur. Patients with poorly functioning allografts receiving long-term immunosuppression therapy continue to be at risk for opportunistic infections.

F. Tumor Necrosis Factor Inhibitor Recipients

Patients taking TNF inhibitors (infliximab, etanercept, adalimumab, certolizumab pegol, golimumab) have specific defects that increase risk of bacterial, mycobacterial (particularly tuberculosis), viral (HBV reactivation and HCV progression), and fungal infections (*Pneumocystis*, molds, and endemic mycoses). Infection risk may be highest shortly after therapy is initiated (within the first 3 months) and with a higher dose of medications.

G. Recipients of Other Biologics

In addition to TNF inhibitors, other biologics target a variety of immunologic pathways that are involved in immunologic mediated disease and in cancer replication. Disruption of these pathways include, but are not limited to, impact on B cells, T cells, complement, and leukocytes. *This may result in not only serious infections, but the development of autoimmune disease and malignancies as well.* Some medications have been observed to have specific associations with opportunistic infections (eg, natalizumab and PML, or eculizumab and meningococcal disease). Other biologics such as chimeric antigen receptor T (CAR-T) cells also carry infection risks of up to 40% post-infection or may have adverse effects that mimic infection (eg, cytokine release syndrome). Checkpoint inhibitors (eg, anti–PD-1 and CTLA antibodies) used for the treatment of advanced malignancies also may have *effects that mimic infection via immune enhancement*. Prolonged immunosuppression used to treat immune-associated adverse events in CAR-T and checkpoint inhibitor therapy (eg, TNF inhibitors and corticosteroids) can then result in opportunistic and other infections. As more biologics are developed, such as bispecific antibodies, clinicians must remain vigilant for the possibility of serious infectious disease risk.

H. Other Immunocompromised States

A large group of patients who are not specifically immunodeficient are at increased risk for infection due to debilitating injury (eg, burns or severe trauma), invasive procedures (eg, chronic central intravenous catheters, indwelling urinary catheters, dialysis catheters), CNS dysfunction (which predisposes patients to aspiration pneumonia and pressure injuries), obstructing lesions (eg, pneumonia due to an obstructed bronchus, pyelonephritis due to nephrolithiasis, cholangitis secondary to cholelithiasis), and use of broad-spectrum antibiotics. Patients with diabetes mellitus have alterations in cellular immunity, resulting in mucormycosis, emphysematous pyelonephritis, and foot infections.

▶ Clinical Findings

A. Laboratory Findings

Routine evaluation includes CBC with differential, complete metabolic panel, and blood cultures, with a low threshold for cross-sectional imaging; urine and respiratory cultures should be obtained if indicated clinically or radiographically. Any focal symptoms (eg, localized pain, headache, rash) should prompt imaging and cultures appropriate to the site.

Patients who remain febrile without an obvious source should be evaluated for viral infection (serum CMV PCR), abscesses (which usually occur near previous operative sites), candidiasis involving the liver or spleen, or aspergillosis. Serologic evaluation may be helpful if toxoplasmosis or an endemic fungal infection (coccidioidomycosis, histoplasmosis) is a possible cause. Antigen-based assays may be useful for the diagnosis of aspergillosis (detected by galactomannan level in serum or bronchoalveolar lavage fluid), or other invasive fungal disease, including *Pneumocystis* infection (serum β-ᴅ-glucan level).

B. Special Diagnostic Procedures

Special diagnostic procedures should also be considered. The cause of pulmonary infiltrates can be easily determined with simple techniques in some situations—eg, induced sputum yields a diagnosis of *Pneumocystis* pneumonia in 50–80% of patients with AIDS with this infection. In other situations, more invasive procedures may be required (bronchoalveolar lavage, transbronchial biopsy, open lung biopsy). Skin, liver, or bone marrow biopsy may be helpful in establishing a diagnosis. Next-generation DNA-sequencing analysis (eg, of plasma, bronchoalveolar lavage, CSF) is an increasingly used and validated option for diagnosis of infectious diseases in immunocompromised persons.

▶ Differential Diagnosis

Allograft rejection, organ ischemia and necrosis, thrombophlebitis, and malignancy including posttransplant lymphoproliferative disease may all present as fever and must be considered in the differential diagnosis.

▶ Prevention

While prophylactic antimicrobial medications are used commonly, the optimal medications or dosage regimens are debated. *Hand washing is the simplest and most effective means of decreasing hospital-associated infections*, especially in the compromised patient. Invasive devices such as central and peripheral lines and indwelling urinary catheters are potential sources of infection. Some centers use *laminar airflow isolation* or *high-efficiency particulate air (HEPA) filtering* in hematopoietic cell transplant patients. Rates of infection and episodes of febrile neutropenia, but not mortality, are decreased if *colony-stimulating factors* are used (typically in situations where the risk of febrile neutropenia is ≥ 20%) during chemotherapy or during stem cell transplantation.

A. *Pneumocystis* & Herpes Simplex Infections

Trimethoprim-sulfamethoxazole (TMP-SMX), one double-strength tablet orally three times a week, one double-strength tablet twice daily on weekends, or one single-strength tablet daily, can prevent *Pneumocystis* infections. In patients allergic to TMP-SMX, dapsone, 50 mg orally daily or 100 mg three times weekly, is recommended. Glucose-6-phosphate dehydrogenase (G6PD) levels should be assessed before dapsone is instituted.

Acyclovir prevents herpes simplex infections in bone marrow and solid organ transplant recipients and is given to seropositive patients who are not receiving ganciclovir or valganciclovir for CMV prophylaxis. The usual dose is 200 mg orally three times daily for 4 weeks (hematopoietic cell transplants) to 12 weeks (solid organ transplants).

B. CMV

The two approaches to CMV prevention are *universal prophylaxis* or *preemptive therapy*. Among solid organ transplant recipients (liver, kidney, heart, lung), the strategy chosen depends on the serologic status of the donor and recipient and the organ transplanted, which determines the level of immunosuppression sought after transplant. The greatest risk of developing CMV disease is in seronegative recipients who receive organs from seropositive donors. These high-risk patients often receive prophylaxis with oral valganciclovir for 3–6 months, potentially longer in lung transplant recipients. Other solid organ transplant recipients (seropositive recipients) are at lower risk for developing CMV disease but still usually receive either prophylaxis with oral valganciclovir for 3 months or preemptive management in which they are monitored for the presence of CMV by PCR. If CMV is detected, then therapy is instituted with treatment-dose oral valganciclovir for a minimum of 2–3 weeks. The newest agent for refractory or resistant CMV is maribavir. The lowest-risk group for the development of CMV disease is in seronegative patients who receive organs from seronegative donors. Typically, no CMV prophylaxis is used in this group. Ganciclovir and valganciclovir also prevent herpes virus reactivation. Because immunosuppression is increased during periods of rejection, patients treated for rejection either receive CMV prophylaxis or are monitored preemptively during rejection therapy.

Recipients of hematopoietic cell transplants are more severely immunosuppressed than recipients of solid organ transplants, are at greater risk for developing serious CMV infection (usually CMV reactivation), and thus usually receive more aggressive prophylaxis. Like in solid organ transplant recipients, all high-risk patients (seropositive patients who receive allogeneic transplants) receive oral prophylaxis to day 100. Because valganciclovir is associated with significant bone marrow toxicity, letermovir is first line for high-risk hematopoietic cell transplant (HCT) recipients. Moderate- and low-risk hematopoietic cell transplant recipients undergo the preemptive approach over prophylaxis. Other preventive strategies include use of *CMV-negative* or *leukocyte-depleted blood products* for CMV-seronegative recipients.

C. Other Organisms

Routine decontamination of the GI tract to prevent bacteremia in the neutropenic patient is *not* recommended. The use of prophylactic antibiotics in the afebrile, asymptomatic neutropenic patient is debated, although many centers have adopted this strategy. Rates of bacteremia are decreased, but overall mortality is *not* affected and emergence of resistant organisms takes place. Use of intravenous immunoglobulin is reserved for the small number of patients with severe hypogammaglobulinemia following hematopoietic stem cell transplantation and should not be routinely administered to all transplant patients.

Prophylaxis with antifungal agents to prevent invasive mold (primarily *Aspergillus*) and yeast (primarily *Candida*) infections is routinely used, but the optimal agent, dose, and duration are also debated. Lipid-based preparations of amphotericin B as well as systemic fluconazole, voriconazole, or posaconazole are all prophylactic options in the neutropenic patient. Voriconazole and posaconazole are superior to amphotericin for documented *Aspergillus* infections, and posaconazole prophylaxis (compared with fluconazole) results in fewer cases of invasive aspergillosis among allogeneic stem cell transplant recipients with graft-versus-host disease; thus, one approach to prophylaxis is to use oral fluconazole (400 mg/day) for patients at low risk for developing fungal infections (autologous stem cell transplants) and oral voriconazole (200 mg twice daily) or oral posaconazole (200 mg suspension three times daily or 300 mg [three 100-mg tablets] sustained-release tablets once daily) for those at high risk (allogeneic transplants, graft-versus-host disease) at least until engraftment (usually 30 days). In solid organ transplant recipients, the risk of invasive fungal infection varies considerably (1–2% in liver, pancreas, and kidney transplants and 6–8% in heart and lung transplants). Whether universal prophylaxis or observation with preemptive therapy is the best approach has not been determined. Although fluconazole is effective in preventing yeast infections, emergence of fluconazole-resistant *Candida* and molds (*Fusarium*, *Aspergillus*, *Mucor*) has raised concerns about its routine use as a prophylactic agent in the general solid organ transplant population. However, liver transplant recipients with additional risk factors, such as having undergone a choledochojejunostomy, having had a high transfusion requirement, or having developed kidney disease, may benefit from abbreviated postoperative *Candida* prophylaxis.

Given the high risk of reactivation of tuberculosis in patients taking TNF inhibitors, all patients should be screened for latent tuberculosis infection (LTBI) with a tuberculin skin test or an interferon-γ release assay prior to the start of therapy. If LTBI is diagnosed, treatment with the TNF inhibitors should be delayed until treatment for LTBI is completed. There is also a marked risk of reactivation of hepatitis B and hepatitis C in patients taking TNF inhibitors; patients should also be screened for these viruses when TNF inhibitor treatment is being considered. Providers should also ensure that patients' vaccinations are up to date before starting TNF inhibitor therapy.

Treatment

A. General Measures

Because infections in the immunocompromised patient can be rapidly progressive and life-threatening, diagnostic procedures must be performed promptly, and empiric therapy is usually instituted.

While reduction or discontinuation of immunosuppressive medication may risk rejection of the transplanted organ or worsening of underlying disease, this measure may be necessary if the infection is life-threatening. Hematopoietic growth factors (granulocyte and granulocyte-macrophage colony-stimulating factors) stimulate proliferation of bone marrow stem cells, resulting in an increase in peripheral leukocytes. These agents shorten the period of neutropenia and have been associated with reduction in infection.

B. Specific Measures

Antimicrobial medication therapy ultimately should be tailored to culture results. While combinations of antimicrobials are used with the intent of providing synergy or preventing resistance, the primary reason for empiric combination therapy is broad-spectrum coverage of all likely pathogens.

Empiric therapy is often instituted at the earliest sign of infection in the immunosuppressed patient because prompt therapy favorably affects outcome, particularly in febrile neutropenia. The antibiotic or combination of antibiotics used depends on the degree of immune compromise and the site of infection. For example, in the *high-risk febrile neutropenic patient, an algorithmic approach to therapy is often used*. Febrile neutropenic patients should be empirically treated with broad-spectrum agents active against selected gram-positive bacteria, *Pseudomonas aeruginosa*, and other aerobic gram-negative bacilli (such as cefepime 2 g every 8 hours intravenously). The addition of vancomycin, 10–15 mg/kg/dose intravenously every 12 hours, should be considered in those patients with suspected infection due to methicillin-resistant *S aureus* (MRSA). Continued neutropenic fever in an unstable patient necessitates broadening of antibacterial coverage from cefepime to agents such as meropenem 1 g every 8 hours intravenously along with an additional gram-negative agent (ciprofloxacin or tobramycin) if patient is critically ill. Antifungal agents (such as voriconazole, 200 mg intravenously or orally every 12 hours) should be added if fevers continue after 5–7 days of broad-spectrum antibacterial therapy. *While the traditional approach was to continue antibiotics until resolution of neutropenia, practice has shifted to earlier discontinuation of antibiotics in the neutropenic patient who becomes afebrile for 72 hours if no signs or symptoms of infection persist.*

Patients with fever and *low-risk neutropenia* (neutropenia expected to persist for < 10 days, no comorbid complications requiring hospitalization, and cancer adequately treated) can be treated with oral antibiotic regimens, such as ciprofloxacin, 750 mg every 12 hours, plus amoxicillin-clavulanic acid, 500 mg every 8 hours. *Antibiotics are usually continued as long as the patient is neutropenic even if a source is not identified.* In the organ transplant patient with interstitial infiltrates, the main concern is infection with *Pneumocystis* or *Legionella* species, so that empiric treatment with a macrolide or fluoroquinolone (*Legionella*) and TMP-SMX, 15 mg/kg/day orally or intravenously (*Pneumocystis*), would be reasonable in those patients not receiving TMP-SMX prophylaxis. If the patient does not respond to empiric treatment, a decision must be made to add more antimicrobial agents or perform invasive procedures to make a specific diagnosis. By making a definite diagnosis, therapy can be specific, thereby reducing selection pressure for resistance and superinfection.

When to Refer

- Any immunocompromised patient with an opportunistic infection.
- Patients with potential drug toxicities and drug interactions related to antimicrobials where alternative agents are sought.
- Patients with latent tuberculosis, HBV, and HCV infection in whom therapy with TNF inhibitors is planned.

When to Admit

Immunocompromised patients who are febrile, or those without fevers in whom an infection is suspected, particularly in the following groups: solid organ or hematopoietic stem cell transplant recipient (particularly in the first 6 months), neutropenic patients, patients receiving TNF inhibitors, and transplant recipients who have had recent rejection episodes (including graft-versus-host disease).

HEALTH CARE–ASSOCIATED INFECTIONS

ESSENTIALS OF DIAGNOSIS

- Acquired during the course of receiving health care treatment for other conditions.
- Most cases are preventable.
- Hospital-associated infections are defined as not being present or incubating at the time of hospital admission and developing ≥ 48 hours after admission.
- Hand washing is the most effective prevention and should be done routinely even when gloves are worn.

General Considerations

Worldwide, approximately 10% of patients acquire a health care–associated infection, resulting in prolongation of the hospital stay, increase in cost of care, and significant morbidity and mortality. The most common infections are UTIs, usually associated with indwelling urinary catheters or urologic procedures; bloodstream infections, most commonly from indwelling catheters but also from secondary sites, such as surgical wounds, abscesses, pneumonia, the genitourinary tract, and the GI tract; pneumonia in intubated patients or those with altered levels of consciousness; surgical wound infections; MRSA infections; and *Clostridioides difficile* infection. There has been hospital-associated transmission of respiratory viruses.

Some general principles are helpful in preventing, diagnosing, and treating health care–associated infections:

1. Many infections are a direct result of the use of *invasive devices* for monitoring or therapy, such as intravenous catheters, indwelling urinary catheters, shunts, surgical drains, catheters placed by interventional radiology for drainage, nasogastric tubes, and orotracheal or nasotracheal tubes for ventilatory support. *Early removal of such devices reduces the possibility of infection.*
2. Patients in whom health care–associated infections develop are often critically ill, have been hospitalized for extended periods, and have received several courses of broad-spectrum antibiotic therapy. As a result, *health care–associated infections are often due to multidrug-resistant pathogens and differ from those encountered in community-acquired infections.* For example, *S aureus* and *S epidermidis* (a frequent cause of prosthetic device infection) are often resistant to methicillin and require vancomycin for therapy; *Enterococcus faecium* is often resistant to ampicillin and vancomycin; gram-negative infections caused by *Pseudomonas, Citrobacter, Enterobacter, Acinetobacter*, *Stenotrophomonas*, extended-spectrum β-lactamase (ESBL)–producing *E coli*, *Klebsiella*, and carbapenem-resistant Enterobacteriaceae may be resistant to most antibacterials. When choosing antibiotics to treat the seriously ill patient with a health care–associated infection, the individual patient's prior infection history and local antibiogram (antimicrobial resistance patterns) must be considered. In the most seriously ill patients, broad-spectrum coverage with vancomycin and a carbapenem with or without an aminoglycoside is recommended. Once a pathogen is isolated and susceptibilities are known, the most narrow-spectrum, least toxic, most cost-effective regimen should be used.

Widespread use of antimicrobial medications contributes to the selection of drug-resistant organisms; thus, *every effort should be made to limit the spectrum of coverage and unnecessary duration*. All too often, unreliable or uninterpretable specimens are obtained for culture that result in unnecessary use of antibiotics. The best example of this principle is the diagnosis of line-related or bloodstream infection in the febrile patient. To avoid unnecessary use of antibiotics, thoughtful consideration of culture results is mandatory. A positive wound culture without signs of inflammation or infection, a positive sputum culture without pulmonary infiltrates on CXR, or a positive urine culture in a catheterized patient without symptoms or signs of pyelonephritis are all likely to represent *colonization*, not infection.

Clinical Findings

A. Symptoms and Signs

Catheter-associated infections have a variable presentation, depending on the type of catheter used (peripheral or central venous catheters, nontunneled or tunneled). Local signs of infection may be present at the insertion site, with pain, erythema, and purulence. Fever is often absent in uncomplicated infections and, if present, may indicate more disseminated disease such as bacteremia, cellulitis and septic thrombophlebitis. Often signs of infection at the insertion site are absent.

1. Fever in an ICU patient—Fever complicates up to 70% of patients in ICUs, and the etiology of the fever may be infectious or noninfectious. Common infectious causes include catheter-associated infections, hospital-acquired and ventilator-associated pneumonia (see Chapter 9), surgical site infections, UTIs, and sepsis. Clinically relevant sinusitis is relatively uncommon in the patient in the ICU.

An important noninfectious cause is thromboembolic disease. Fever in conjunction with refractory hypotension and shock may suggest sepsis; however, adrenal insufficiency, thyroid storm, and transfusion reaction may have a similar clinical presentation. Drug fever is difficult to diagnose and is usually a diagnosis of exclusion unless there are other signs of hypersensitivity, such as a typical maculopapular rash (most common with β-lactams).

2. Fever in the postoperative patient—Postoperative fever is common and noninfectious fever resolves spontaneously. Timing of the onset of the fever in relation to the surgical procedure may be of diagnostic benefit.

A. IMMEDIATE FEVER (IN THE FIRST FEW HOURS AFTER SURGERY)—Immediate fever can be due to medications that were given perioperatively, to surgical trauma, or to infections that were present before surgery. Necrotizing fasciitis due to group A streptococci or mixed organisms may present in this period. **Malignant hyperthermia** is rare and presents 30 minutes to several hours following inhalational anesthesia and is characterized by extreme hyperthermia, muscle rigidity, rhabdomyolysis, electrolyte abnormalities, and hypotension. Aggressive cooling and dantrolene are the mainstays of therapy. Aspiration of acidic gastric contents during surgery can result in a chemical pneumonitis (**Mendelson syndrome**) that develops rapidly, is transient, and does not require antibiotics. Fever due to surgical trauma usually resolves in 2–3 days; however, it may be longer in more complicated operative cases and in patients with head trauma.

B. ACUTE FEVER (WITHIN 1 WEEK OF SURGERY)—Acute fever is usually due to common causes of hospital-associated infections, such as ventilator-associated pneumonia (including aspiration pneumonia in patients with decreased gag reflex) and line infections. Noninfectious causes include alcohol withdrawal, gout, PE, and pancreatitis.

Atelectasis following surgery is commonly invoked as a cause of postoperative fever, but there is no good evidence to support a causal association between the presence or degree of atelectasis and fever.

c. Subacute fever (at least 1 week after surgery)—Surgical site infections commonly present at least 1 week after surgery. The type of surgery that was performed predicts specific infectious etiologies. Patients undergoing cardiothoracic surgery may be at higher risk for pneumonia and deep and superficial sternal wound infections. Meningitis without typical signs of meningismus may complicate neurosurgical procedures. Postoperative deep abdominal abscesses may require drainage.

B. Laboratory Findings

Blood cultures are universally recommended, and CXRs are frequently obtained. A properly prepared sputum Gram stain and sputum cultures may be useful in selected patients where there is a high pretest probability of pneumonia but multiple exclusion criteria probably limit generalizability in most patients, such as immunocompromised patients and those with drug resistance. Other diagnostic strategies will be dictated by the clinical context (eg, transesophageal echocardiogram in a patient with *S aureus* bacteremia).

Any fever in a patient with a central venous catheter should prompt the collection of blood. The best method to evaluate bacteremia is to gather *at least two peripherally obtained blood cultures.* Blood cultures from unidentified sites, a single blood culture from any site, or a blood culture through an existing line will often be positive for coagulase-positive staphylococci, particularly *S epidermidis*, often resulting in the inappropriate use of vancomycin. *Unless two separate venipuncture cultures are obtained—not through catheters—interpretation of results is impossible*, and unnecessary therapy often results with resulting increase in bacterial resistance pressure, laboratory costs, antibiotic use, and length of stay. Microbiologic evaluation of the removed catheter can sometimes be helpful, but only in addition to (not instead of) blood cultures drawn from peripheral sites. The *differential time to positivity* measures the difference in time that cultures simultaneously drawn through a catheter and a peripheral site become positive. A positive test (central blood culture positive ≥ 120 minutes before peripheral blood culture) supports a catheter-related bloodstream infection, while a negative test suggests catheters may be retained.

Complications

Complications such as septic thrombophlebitis, endocarditis, or metastatic foci of infection (particularly with *S aureus*) may be suspected in patients with persistent bacteremia and fever despite removal of the infected catheter. Additional studies such as venous Doppler studies, transesophageal echocardiogram, and CXRs may be indicated, and 4–6 weeks of antibiotics may be needed. In the case of septic thrombophlebitis, anticoagulation with heparin is also recommended if there are no contraindications.

Differential Diagnosis

Although most fevers are due to infections, about 25% of patients will have fever of noninfectious origin, including drug fever, nonspecific postoperative fevers (tissue damage or necrosis), hematoma, pancreatitis, PE, MI, and ischemic bowel disease.

Prevention

The concept of ***universal precautions*** *emphasizes that all patients are treated as though they have a potential bloodborne transmissible disease, and thus all body secretions are handled with care to prevent spread of disease.* Body substance isolation requires use of gloves whenever a health care worker anticipates contact with blood or other body secretions. *Even though gloves are worn, health care workers should routinely wash their hands, since it is the easiest and most effective means of preventing hospital-associated infections.* Application of a *rapid drying, alcohol-based antiseptic* is simple, takes less time than traditional hand washing with soap and water, is more effective at reducing hand colonization, and promotes compliance with hand decontamination. *For prevention of transmission of C difficile infection, hand washing is more effective than alcohol-based antiseptics.* Consequently, even after removing gloves, providers should always wash hands in cases of proven or suspected *C difficile* infection.

Peripheral intravenous lines should be replaced no more frequently than every 3–4 days. Some clinicians replace only when clinically indicated or if the line was put in emergently. Arterial lines and lines in the central venous circulation (including those placed peripherally) can be left in place indefinitely and are changed or removed when they are clinically suspected of being infected, when they are nonfunctional, or when they are no longer needed. Using sterile barrier precautions (including cap, mask, gown, gloves, and drape) is recommended while inserting central venous catheters. *Antibiotic-impregnated (minocycline plus rifampin or chlorhexidine plus silver sulfadiazine) venous catheters* reduce line infections. *Silver alloy–impregnated indwelling urinary catheters* reduce the incidence of catheter-associated bacteriuria, but not consistently catheter-associated UTIs. Best practices to prevent ventilator-associated pneumonia include avoiding intubation if possible, minimizing and daily interruption of sedation, pooling/draining of subglottic secretions above the tube cuff, and elevating the head of the bed. Silver-coated endotracheal tubes may reduce the incidence of ventilator-associated pneumonia but have limited impact on hospital stay duration or mortality, so they are not generally recommended. *Catheter-related UTIs and intravenous catheter-associated infections are not Medicare-reimbursable conditions in the United States. Preoperative skin preparation* with chlorhexidine and alcohol (versus povidone-iodine) reduces the incidence of infection following surgery. Another strategy that can prevent surgical site infections is the *identification and treatment of S aureus nasal carriers* with 2% mupirocin nasal ointment and chlorhexidine soap. *Daily bathing of ICU patients* with chlorhexidine-impregnated washcloths versus soap and water results in lower incidence of health care–associated infections and colonization. Selective decontamination of the digestive tract with nonabsorbable or parenteral antibiotics, or both, may prevent hospital-acquired pneumonia and decrease mortality but is in limited use because of the concern of the development of antibiotic resistance. *Prevention bundles* (implementing more than one intervention concomitantly) are commonly used as a practical strategy to enhance care.

Attentive nursing care (positioning to prevent pressure injuries, wound care, elevating the head during tube feedings to prevent aspiration) is critical in preventing hospital-associated infections. In addition, monitoring of high-risk areas by hospital epidemiologists is critical in the prevention of infection. Some guidelines advocate rapid screening (active surveillance cultures) for MRSA on admission to acute care facilities among certain subpopulations of patients (eg, those recently hospitalized, admission to the ICU, patients undergoing hemodialysis). However, outside the setting of an MRSA outbreak, it is not clear whether this strategy decreases the incidence of hospital-associated MRSA infections.

Vaccines, including hepatitis A, hepatitis B, and the varicella, pneumococcal, influenza, and SARS-CoV-2 vaccinations, are important adjuncts. (See Immunization Against Infectious Diseases, below.)

Treatment

A. Fever in an ICU Patient

Unless the patient has a central neurologic injury with elevated intracranial pressure or has a temperature > 41°C, there is less physiologic need to maintain euthermia. *Empiric broad-spectrum antibiotics (see* Table 35–1*) are recommended for neutropenic and other immunocompromised patients and in patients who are clinically unstable.*

B. Catheter-Associated Infections

Factors that inform treatment decisions include the type of catheter, the causative pathogen, the availability of alternate catheter access sites, the need for ongoing intravascular access, and the severity of disease.

In general, catheters should be removed if there is purulence at the exit site; if the organism is *S aureus*, gram-negative rods, or *Candida* species; if there is persistent bacteremia (> 48 hours while receiving antibiotics); or if complications, such as septic thrombophlebitis, endocarditis, or other metastatic disease, exist. Central venous catheters may be exchanged over a guidewire provided there is no erythema or purulence at the exit site and the patient does not appear to be septic. Methicillin-resistant, coagulase-negative staphylococci are the most common pathogens; thus, empiric therapy with vancomycin, 15 mg/kg/dose intravenously twice daily, should be given assuming normal kidney function. Empiric gram-negative coverage should be used in patients who are immunocompromised or who are critically ill (see Table 35–1).

Antibiotic treatment duration depends on the pathogen and the extent of disease. For uncomplicated bacteremia, 5–7 days of therapy is usually sufficient for coagulase-negative staphylococci, even if the original catheter is retained. Fourteen days of therapy are generally recommended for uncomplicated bacteremia caused by gram-negative rods, *Candida* species, and *S aureus*. *Antibiotic lock therapy* involves the instillation of supratherapeutic concentrations of antibiotics with heparin in the lumen of catheters. The purpose is to achieve adequate concentrations of antibiotics to kill microbes in the biofilm. Antibiotic lock therapy can be used for catheter-related bloodstream infections caused by both gram-positive and gram-negative bacterial pathogens and when the catheter is being retained in a salvage situation.

When to Refer

- Any patient with multidrug-resistant infection.
- Any patient with fungemia, *S aureus* bacteremia, or persistent bacteremia of any organism.
- Patients whose catheters cannot be removed.
- Patients with multisite infections.
- Patients with impaired or fluctuating kidney function for assistance with dosing of antimicrobials.
- Patients with refractory or recurrent *C difficile* infection.

INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

ESSENTIALS OF DIAGNOSIS

- CNS infection is a medical emergency.
- Symptoms and signs common to all CNS infections include headache, fever, sensorial disturbances, neck and back stiffness, positive Kernig and Brudzinski signs, and CSF abnormalities.

General Considerations

Infections of the CNS can be caused by almost any infectious agent, including bacteria, mycobacteria, fungi, spirochetes, protozoa, helminths, and viruses.

Table 35–1. Examples of initial antimicrobial therapy for acutely ill, hospitalized adults pending identification of causative organism (listed in alphabetical order by suspected clinical diagnosis).

Suspected Clinical Diagnosis	Likely Etiologic Diagnosis	Medication of Choice
Brain abscess	*Staphylococcus aureus*, gram-negative bacilli, streptococci, mixed anaerobes	Ceftriaxone, 2 g intravenously every 12 hours **plus** metronidazole, 500 mg orally/intravenous every 8 hours, **plus** vancomycin, 15–20 mg/kg intravenously every 8–12 hours[1]
Endocarditis, acute	*S aureus*, *Enterococcus faecalis*, viridans streptococci	Vancomycin, 15–20 mg/kg/dose intravenously every 8–12 hours[1]
Fever in neutropenic patient receiving cancer chemotherapy	*S aureus*, *Pseudomonas*, *Klebsiella*, *Escherichia coli*	Cefepime, 2 g intravenously every 8 hours. If concerned for MRSA infection, add vancomycin 15–20 mg/kg intravenously every 8–12 hours[1]
Intra-abdominal sepsis (eg, postoperative, peritonitis, cholecystitis)	Gram-negative bacteria, anaerobic bacteria (ie, *Bacteroides*), enterococcus	Piperacillin-tazobactam, 4.5 g intravenously every 6–8 hours, **or** ertapenem, 1 g every 24 hours
Meningitis, bacterial, age 18–50 years, community-acquired	Pneumococcus,[3] meningococcus	Ceftriaxone, 2 g intravenously every 12 hours,[3] **plus** vancomycin, 15–20 mg/kg intravenously every 8–12 hours[1]
Meningitis, bacterial, age > 50 years, community-acquired	*Streptococcus pneumoniae* (pneumococcus), *Neisseria meningitidis* (meningococcus), *Listeria monocytogenes*,[2] gram-negative bacilli, group B streptococcus	Ampicillin, 2 g intravenously every 4 hours, **plus** ceftriaxone, 2 g intravenously every 12 hours, **plus** vancomycin, 15–20 mg/kg intravenously every 8–12 hours[1]
Meningitis, postoperative (or posttraumatic)	*S aureus*, gram-negative bacilli, coagulase-negative staphylococci, diphtheroids (eg, *Cutibacterium acnes*)	Vancomycin, 15–20 mg/kg intravenously every 8–12 hours,[1] **plus** cefepime, 2 g intravenously every 8 hours
Osteomyelitis	*S aureus*, secondarily gram-negative aerobes	Vancomycin 15–20 mg/kg intravenously every 8–12 hours,[1] **plus** ceftriaxone 2 g intravenously every 24 hours
Pneumonia, community-acquired, non-ICU hospital admission	Pneumococci, *Haemophilus influenzae*, *Mycoplasma pneumoniae*, *Legionella*, *Chlamydia pneumoniae*	Ceftriaxone, 1 g intravenously every 24 hours or ampicillin-sulbactam 1.5–3 g intravenously every 6 hours) **plus** azithromycin, 500 mg intravenously every 24 hours; **or** a respiratory fluoroquinolone[4] alone
Pneumonia, postoperative or nosocomial	*S aureus*, gram-negative bacilli	Cefepime, 2 g intravenously every 8 hours; **or** ceftazidime, 2 g intravenously every 8 hours; **or** piperacillin-tazobactam, 4.5 g intravenously every 6–8 hours; **or** imipenem, 500 mg intravenously every 6 hours; **or** meropenem, 1 g intravenously every 8 hours **plus** vancomycin, 15–20 mg/kg/dose intravenously every 8–12 hours[1] Empiric combination therapy for gram-negative bacilli may be considered based on local susceptibility patterns. Secondary agents include ciprofloxacin, 400 mg intravenously every 8 hours **or** tobramycin, 5–7 mg/kg intravenously every 24 hours
Pyelonephritis with flank pain and fever	*E coli*, *Klebsiella*, *Proteus*	Ceftriaxone, 1 g intravenously every 24 hours; **or** if culture results confirm susceptibility, ciprofloxacin, 400 mg intravenously every 12 hours (500 mg orally); **or** levofloxacin, 500 mg once daily (intravenously/orally)
Septic arthritis	*S aureus*, *Neisseria gonorrhoeae*	Ceftriaxone, 1–2 g intravenously every 24 hours **plus** vancomycin 15–20 mg/kg/dose intravenously every 8–12 hours[1]
Septic thrombophlebitis	*S aureus*, gram-negative aerobic bacteria	Vancomycin, 15–20 mg/kg/dose intravenously every 8–12 hours,[1] **plus** ceftriaxone, 1 g intravenously every 24 hours

[1] Vancomycin serum levels should be monitored. Select drug interval based on estimated kidney function and dose rounded to nearest 250 mg.

[2] TMP-SMX can be used to treat *Listeria monocytogenes* in patients allergic to penicillin in a dosage of 15–20 mg/kg/day of TMP in three or four divided doses. Dose reduction is necessary for patients with reduced kidney function.

[3] Including penicillin-resistant isolates.

[4] Levofloxacin 750 mg/day, moxifloxacin 400 mg/day.

Table 35–2. Typical CSF findings in various CNS diseases (listed in alphabetical order after "Normal").

Diagnosis	Cells/mcL	Glucose (mg/dL)	Protein (mg/dL)	Opening Pressure
Normal	0–5 lymphocytes	45–85[1]	15–45	70–180 mm H_2O
Aseptic meningitis, viral meningitis, or meningoencephalitis[2]	25–2000 (0.025–2.0 × 10^9/L), mostly lymphocytes[3]	Normal or low	High (> 50)	Slightly elevated
Granulomatous meningitis (mycobacterial, fungal)[3]	100–1000 (0.1–1.0 × 10^9/L), mostly lymphocytes[3]	Low (< 45)	High (> 50)	Moderately elevated
"Neighborhood reaction"[4]	Variably increased	Normal	Normal or high	Variable
Purulent meningitis (bacterial)[5] community-acquired	200–20,000 (0.2–20 × 10^9/L) polymorphonuclear neutrophils	Low (< 45)	High (> 50)	Markedly elevated
Spirochetal meningitis	100–1000 (0.1–1.0 × 10^9/L), mostly lymphocytes[3]	Normal	High (> 50)	Normal to slightly elevated

[1] CSF glucose must be considered in relation to blood glucose level. Normally, CSF glucose is 20–30 mg/dL lower than blood glucose, or 50–70% of the normal value of blood glucose.

[2] Viral isolation from CSF early; antibody titer rise in paired specimens of serum; PCR for herpesvirus.

[3] Polymorphonuclear neutrophils may predominate early.

[4] May occur in mastoiditis, brain abscess, epidural abscess, sinusitis, septic thrombus, brain tumor. CSF culture results usually negative.

[5] Organisms in smear or culture of CSF; counterimmunoelectrophoresis or latex agglutination may be diagnostic.

Etiologic Classification

CNS infections can be divided into several categories that usually can be readily distinguished from each other by CSF examination as the first step toward etiologic diagnosis (Table 35–2).

A. Purulent Meningitis

Patients with bacterial meningitis usually seek medical attention within hours or 1–2 days after onset of symptoms. The organisms responsible depend primarily on the age of the patient as summarized in Table 35–3. The diagnosis is usually based on the Gram stain (positive in 60–90%) or culture (positive in > 90%) of the CSF.

B. Chronic Meningitis

The presentation of chronic meningitis is less acute than purulent meningitis. Patients with chronic meningitis usually have a history of symptoms lasting weeks to months. The most common pathogens are *Mycobacterium*

Table 35–3. Initial antimicrobial therapy for purulent meningitis of unknown cause.

Population	Usual Microorganisms	Standard Therapy
18–50 years	*Streptococcus pneumoniae, Neisseria meningitidis*	Vancomycin[1] **plus** ceftriaxone[2]
Over 50 years	*S pneumoniae, N meningitidis, Listeria monocytogenes*, enteric gram-negative bacilli, group B streptococcus	Vancomycin[1] **plus** ampicillin,[3] **plus** ceftriaxone[2]
Impaired cellular immunity	*L monocytogenes*, gram-negative bacilli, *S pneumoniae*	Vancomycin[1] **plus** ampicillin,[3] **plus** cefepime[4]
Postsurgical or posttraumatic	*Staphylococcus aureus, S pneumoniae*, aerobic gram-negative bacilli, coagulase-negative staphylococci,[5] diphtheroids (eg, *Cutibacterium acnes*)[5] (uncommon)	Vancomycin[1] **plus** cefepime[4]

[1] Given to cover highly penicillin- or cephalosporin-resistant pneumococci. The dose of vancomycin is 15–20 mg/kg intravenously every 8–12 hours. Doses should be adjusted to achieve a target area under the curve (AUC) between 400 and 600 mg*h/L for confirmed methicillin-resistant *Staphylococcus aureus* (MRSA) or target trough 15–20 mcg/mL for non-MRSA infections. Vancomycin should be stopped if the causative organism is susceptible to ceftriaxone.

[2] Ceftriaxone 2 g intravenously every 12 hours can often be used safely in most patients with a history of low-risk (eg, not IgE-mediated) penicillin allergy. Aztreonam, dosed at 2 g intravenously every 6–8 hours, can be considered for empiric coverage of gram-negative bacilli in patients with type 1 IgE-mediated (anaphylactic) penicillin and cephalosporin allergy. If the organism is susceptible to penicillin, then penicillin 4 million units intravenously every 4 hours is given.

[3] In severely ill patients, ampicillin 2 g intravenously every 4 hours is used when *L monocytogenes* infection is a consideration. For confirmed infection due to *L monocytogenes*, gentamicin is sometimes added to ampicillin. (For patients with type 1 IgE-mediated penicillin allergy, trimethoprim-sulfamethoxazole [TMP-SMX] in a dosage of 15–20 mg/kg/day of TMP in three or four divided doses can be considered.)

[4] Cefepime is given in a dose of 2 g intravenously every 8 hours.

[5] Primarily associated with presence of hardware.

tuberculosis, atypical mycobacteria, fungi (*Cryptococcus*, *Coccidioides*, *Histoplasma*), and spirochetes (*Treponema pallidum* and *Borrelia burgdorferi*). The diagnosis is made by culture or in some cases by serologic tests (cryptococcosis, coccidioidomycosis, syphilis, Lyme disease).

C. Aseptic Meningitis

Aseptic meningitis—a more benign and self-limited syndrome than purulent meningitis—is *caused principally by viruses*, especially herpes simplex virus and the enterovirus group (including coxsackieviruses and echoviruses). Infectious mononucleosis may be accompanied by aseptic meningitis. Leptospiral infection is also usually placed in the aseptic group because of the lymphocytic cellular response and its relatively benign course. This type of meningitis also occurs during secondary syphilis and disseminated Lyme disease. Prior to the routine administration of measles-mumps-rubella (MMR) vaccines, mumps was the most common cause of viral meningitis. Drug-induced aseptic meningitis has been reported with NSAIDs, sulfonamides, and certain monoclonal antibodies.

D. Encephalitis

Encephalitis (due to herpesviruses, arboviruses, rabies virus, flaviviruses [West Nile encephalitis, Japanese encephalitis], and many others) produces disturbances of the sensorium, seizures, and many other manifestations. Patients are more ill than those with aseptic meningitis. CSF may be entirely normal or may show some lymphocytes and, in some instances (eg, herpes simplex), red cells as well. Influenza has been associated with encephalitis, but the relationship is not clear. An autoimmune form of encephalitis associated with *N*-methyl-D-aspartate receptor antibodies should be suspected in younger patients with encephalitis and associated seizures, movement disorders, and psychosis.

E. Partially Treated Bacterial Meningitis

Previous effective antibiotic therapy given for 12–24 hours will decrease the rate of positive CSF Gram stain results by 20% and culture by 30–40% but will have little effect on cell count, protein, or glucose. Occasionally, previous antibiotic therapy will change a predominantly polymorphonuclear response to a lymphocytic pleocytosis, and some of the CSF findings may be similar to those seen in aseptic meningitis.

F. Neighborhood Reaction

As noted in Table 35–2, this term denotes a purulent infectious process in close proximity to the CNS that spills some of the products of the inflammatory process—WBCs or protein—into the CSF. Such an infection might be a brain abscess, osteomyelitis of the vertebrae, epidural abscess, subdural empyema, or bacterial sinusitis or mastoiditis.

G. Noninfectious Meningeal Irritation

Carcinomatous meningitis, sarcoidosis, SLE, chemical meningitis, and certain medications—NSAIDs, OKT3, TMP-SMX, and others—can also produce symptoms and signs of meningeal irritation with associated CSF pleocytosis, increased protein, and low or normal glucose. Meningismus with normal CSF findings occurs in the presence of other infections such as pneumonia and shigellosis.

H. Brain Abscess

Brain abscess presents as a space-occupying lesion; symptoms may include vomiting, fever, change of mental status, or focal neurologic manifestations. When brain abscess is suspected, a CT scan should be performed. If positive, lumbar puncture should *not* be performed since results rarely provide clinically useful information and herniation can occur. The bacteriology of brain abscess is usually polymicrobial and includes *S aureus*, gram-negative bacilli, streptococci, and mouth anaerobes (including anaerobic streptococci and *Prevotella* species).

I. Health Care–Associated Meningitis

This infection may arise as a result of invasive neurosurgical procedures (eg, craniotomy, internal or external ventricular catheters, external lumbar catheters), complicated head trauma, or hospital-acquired bloodstream infections. Outbreaks have been associated with contaminated epidural or paraspinal corticosteroid injections. In general, the microbiology is distinct from community-acquired meningitis, with gram-negative organisms (eg, *Pseudomonas*), *S aureus*, and coagulase-negative staphylococci and, in the outbreaks associated with contaminated corticosteroids, mold and fungi (*Exserohilum rostratum* and *Aspergillus fumigatus*) playing a larger role.

▶ Clinical Findings

A. Symptoms and Signs

The classic triad of fever, stiff neck, and altered mental status has a low sensitivity (44%) for bacterial meningitis. However, *nearly all patients with bacterial meningitis have at least two of the following symptoms—fever, headache, stiff neck, or altered mental status.*

B. Laboratory Tests

Evaluation of a patient with suspected meningitis includes a blood count, blood culture, lumbar puncture followed by careful study and culture of the CSF, and a CXR. The fluid must be examined for cell count, glucose, and protein, and a smear stained for bacteria (and acid-fast organisms when appropriate) and cultured for pyogenic organisms and for mycobacteria and fungi when indicated. Latex agglutination tests can detect antigens of encapsulated organisms (*S pneumoniae, H influenzae*, *N meningitidis*, and *Cryptococcus neoformans*) but are rarely used except for detection of *Cryptococcus* or in partially treated patients. PCR testing of CSF has been used to detect bacteria (*S pneumoniae*, *H influenzae*, *N meningitidis*, *M tuberculosis*, *B burgdorferi*, and *Tropheryma whipplei*) and viruses (herpes simplex, varicella zoster, CMV, Epstein-Barr virus, and enteroviruses) in patients with meningitis. The greatest experience is with PCR for herpes simplex, varicella zoster, and JC virus. These tests are very sensitive (> 95%) and specific. In addition to its use in meningitis, molecular methods such as PCR and next-generation sequencing are being used increasingly for the diagnosis of encephalitis, transverse myelitis, and brain abscess. In general, molecular diagnostic tests may provide a more sensitive and rapid alternative to traditional culture and serology methods. However, it is difficult to ascertain the true sensitivity of many molecular tests for CNS infections given the absence of a gold standard. In some cases, tests to detect several organisms may not be any more sensitive than culture (or serology), but the *real value is the rapidity* with which results are available, ie, hours compared with days or weeks.

C. Lumbar Puncture and Imaging

Since performing a lumbar puncture in the presence of a space-occupying lesion (brain abscess, subdural hematoma, subdural empyema, necrotic temporal lobe from herpes encephalitis) may result in brainstem herniation, *a CT scan is performed prior to lumbar puncture if a space-occupying lesion is suspected on the basis of papilledema, seizures, or focal neurologic findings.* Other indications for CT scan are an immunocompromised patient or moderately to severely impaired level of consciousness. If delays are encountered in obtaining a CT scan and bacterial meningitis is suspected, blood cultures should be drawn and antibiotics and corticosteroids administered even before CSF is obtained for culture to avoid delay in treatment (Table 35–2). *Antibiotics given within 4 hours before obtaining CSF probably do not affect culture results.* MRI with contrast of the epidural injection site and surrounding areas is recommended (sometimes repeatedly) for those with symptoms following a possibly contaminated corticosteroid injection to exclude epidural abscess, phlegmon, vertebral osteomyelitis, discitis, or arachnoiditis.

▶ Treatment

Although it is difficult to prove with existing clinical data that early antibiotic therapy improves outcome in bacterial meningitis, *prompt therapy is still recommended.* In purulent meningitis, the identity of the causative microorganism may remain unknown or doubtful for a few days and initial antibiotic treatment as set forth in Table 35–3 should be directed against the microorganisms most common for each age group.

The duration of therapy for bacterial meningitis varies depending on the etiologic agent: *H influenzae*, 7 days; *N meningitidis*, 3–7 days; *S pneumoniae*, 10–14 days; *L monocytogenes*, 14–21 days; and gram-negative bacilli, 21 days.

For adults with pneumococcal meningitis, dexamethasone 10 mg administered intravenously 15–20 minutes before or simultaneously with the first dose of antibiotics and continued every 6 hours for 4 days decreases morbidity and mortality. Patients most likely to benefit from corticosteroids are those infected with gram-positive organisms (*S pneumoniae* or *S suis*), and those who are HIV negative. It is unknown whether patients with meningitis due to *N meningitidis* and other bacterial pathogens benefit from the use of adjunctive corticosteroids. Increased intracranial pressure due to brain edema often requires therapeutic attention. Hyperventilation, mannitol (25–50 g intravenously as a bolus), and even drainage of CSF by repeated lumbar punctures or by placement of intraventricular catheters have been used to control cerebral edema and increased intracranial pressure. Dexamethasone (4 mg intravenously every 4–6 hours) also may decrease cerebral edema.

Therapy of brain abscess consists of drainage (excision or aspiration) in addition to 3–4 weeks of systemic antibiotics directed against isolated organisms. An empiric regimen often includes metronidazole, 500 mg intravenously or orally every 8 hours, plus ceftriaxone, 2 g intravenously every 12 hours (CNS dosing), with or without vancomycin, 10–15 mg/kg/dose intravenously every 12 hours. Vancomycin trough serum levels should be > 15 mcg/mL in such patients; however, achievement of an area under the curve/minimal inhibitory concentration (AUC/MIC) ratio of 400–600 is a better predictor of outcome and should be used in confirmed MRSA abscesses. In cases where abscesses are smaller than 2 cm, where there are multiple abscesses that cannot be drained, or if an abscess is located in an area where significant neurologic sequelae would result from drainage, antibiotics for 6–8 weeks can be used without drainage.

In addition to antibiotics, in cases of health care–associated meningitis associated with an external intraventricular catheter, the probability of cure is increased if the catheter is removed. In infections associated with internal ventricular catheters, removal of the internal components and insertion of an external drain is recommended. After collecting CSF, epidural aspirate, or other specimens for culture, routine empiric treatment for other pathogens (as above) is recommended until the specific cause of the patient's CNS or parameningeal infection has been identified. In addition, early consultation with a neurosurgeon is recommended for those found to have an epidural abscess, phlegmon, vertebral osteomyelitis, discitis, or arachnoiditis to discuss possible surgical management (eg, debridement).

Therapy of other types of meningitis is discussed elsewhere in this book (fungal meningitis, Chapter 41; syphilis and Lyme borreliosis, Chapter 39; tuberculous meningitis, Chapter 38; herpes encephalitis, Chapter 37).

▶ When to Refer

- Patients with acute meningitis, particularly if culture negative or atypical (eg, fungi, syphilis, Lyme disease, *M tuberculosis*), or if hospital-acquired, associated with an intraventricular catheter, or if the patient is immunosuppressed.
- Patients with chronic meningitis.
- All patients with brain abscesses and encephalitis.
- Patients with suspected hospital-acquired meningitis (eg, in patients who have undergone recent neurosurgery or epidural or paraspinal corticosteroid injection).
- Patients with recurrent meningitis.

When to Admit

- Patients with suspected acute meningitis, encephalitis, and brain or paraspinous abscess should be admitted for urgent evaluation and treatment.
- There is less urgency to admit patients with chronic meningitis; these patients may be admitted to expedite diagnostic procedures and coordinate care, particularly if no diagnosis has been made in the outpatient setting.

ANIMAL & HUMAN BITE WOUNDS

ESSENTIALS OF DIAGNOSIS

- Cat and human bites have higher rates of infection than dog bites.
- Hand bites are particularly concerning for the possibility of closed-space infection.
- Antibiotic prophylaxis indicated for noninfected bites of the hand and hospitalization required for infected hand bites.
- All infected wounds need to be cultured to direct therapy.

General Considerations

About 1000 dog bite injuries require emergency department attention each day in the United States, most often in urban areas. Dog bites occur most commonly in the summer months. Biting animals are usually known by their victims, and most biting incidents are *provoked* (ie, bites occur while playing with the animal or after surprising the animal while eating or waking it abruptly from sleep). *Failure to elicit a history of provocation is important because an unprovoked attack raises the possibility of rabies.* Human bites are usually inflicted by children while playing or fighting; in adults, bites are associated with alcohol use and closed-fist injuries that occur during fights.

The animal inflicting the bite, the location of the bite, and the type of injury inflicted are all important determinants of whether they become infected. *Cat bites are more likely to become infected than human bites*—between 30% and 50% of all cat bites become infected. Infections following human bites are variable. Bites inflicted by children rarely become infected because they are superficial, and bites by adults become infected in 15–30% of cases, with a high rate of infection in closed-fist injuries. Dog bites, for unclear reasons, become infected only 5% of the time. Bites of the head, face, and neck are less likely to become infected than bites on the extremities. “Through and through” bites (eg, involving the mucosa and the skin) have an infection rate similar to closed-fist injuries. Puncture wounds become infected more frequently than lacerations, probably because the latter are easier to irrigate and debride.

The bacteriology of bite infections is polymicrobial. Following dog and cat bites, > 50% of infections are caused by aerobes and anaerobes and 36% are due to aerobes alone. Pure anaerobic infections are rare. *Pasteurella* species are the single most common isolate (75% of infections caused by cat bites and 50% of infections caused by dog bites). Other common aerobic isolates include streptococci, staphylococci, *Moraxella*, and *Neisseria;* the most common anaerobes are *Fusobacterium*, *Bacteroides*, *Porphyromonas*, and *Prevotella*. The median number of isolates following human bites is four (three aerobes and one anaerobe). Like dog and cat bites, infections caused by most human bites are a mixture of aerobes and anaerobes (54%) or are due to aerobes alone (44%). Streptococci and *S aureus* are the most common aerobes. *Eikenella corrodens* (found in up to 30% of patients), *Prevotella*, and *Fusobacterium* are the most common anaerobes. Although the organisms noted are the most common, innumerable others have been isolated—including *Capnocytophaga* (dog and cat), *Pseudomonas*, and *Haemophilus*—emphasizing the point that *all infected bites should be cultured to define the microbiology.*

HIV can be transmitted from bites (either from biting or receiving a bite from a patient with HIV) but has rarely been reported.

Treatment

A. Local Care

Vigorous cleansing and irrigation of the wound as well as debridement of necrotic material are the most important factors in decreasing the incidence of infections. Radiographs should be obtained to look for fractures and the presence of foreign bodies. Careful examination to assess the extent of the injury (tendon laceration, joint space penetration) is critical to appropriate care.

B. Suturing

If wounds require closure for cosmetic or mechanical reasons, suturing can be done. However, *one should never suture an infected wound, and wounds of the hand should generally not be sutured since a closed-space infection of the hand can result in loss of function.*

C. Prophylactic Antibiotics

Prophylaxis is indicated in high-risk bites and in high-risk patients. *Cat bites in any location and hand bites by any* *animal, including humans, should receive prophylaxis*. Individuals with certain comorbidities (diabetes, liver disease) are at increased risk for severe complications and should receive prophylaxis even for low-risk bites, as should patients without functional spleens who are at increased risk for overwhelming sepsis (primarily with *Capnocytophaga* species). Amoxicillin-clavulanate (Augmentin) 500 mg orally three times daily for 5–7 days is the regimen of choice. For patients with serious allergy to penicillin, a combination of clindamycin 300 mg orally three times daily together with one of the following is recommended for 5–7 days: doxycycline 100 mg orally twice daily, or double-strength TMP-SMX orally twice daily, or a fluoroquinolone (ciprofloxacin 500 mg orally twice daily or levofloxacin 500–750 mg orally once daily). Moxifloxacin, a fluoroquinolone with good aerobic and anaerobic activity, may be suitable as monotherapy at 400 mg orally once daily for 5–7 days. Agents such as dicloxacillin, cephalexin, macrolides, and clindamycin should *not be used alone* because they lack activity against *Pasteurella* species. TMP-SMX has poor activity against anaerobes and should be used only in combination with clindamycin.

Because the risk of HIV transmission is so low following a bite, routine postexposure prophylaxis is not recommended. Each case should be evaluated individually and consideration for prophylaxis should be given to those who present within 72 hours of the incident, the source is known to be HIV infected, and the exposure is high risk.

D. Antibiotics for Documented Infection

For wounds that are infected, antibiotics are clearly indicated. How they are given (orally or intravenously) and the need for hospitalization are individualized clinical decisions. The most commonly encountered pathogens require treatment with ampicillin-sulbactam (Unasyn), 1.5–3.0 g intravenously every 6–8 hours; or amoxicillin-clavulanate (Augmentin), 500 mg orally three times daily; or ertapenem, 1 g intravenously daily. For the patient with severe penicillin allergy, a combination of clindamycin, 600–900 mg intravenously every 8 hours, plus a fluoroquinolone (ciprofloxacin, 400 mg intravenously every 12 hours; levofloxacin, 500–750 mg intravenously once daily) is indicated. Duration of therapy is usually 2–3 weeks unless complications such as septic arthritis or osteomyelitis are present; if these complications are present, therapy should be extended to 4 and 6 weeks, respectively.

E. Tetanus and Rabies

All patients must be evaluated for the need for tetanus (see Chapter 38) and rabies (see Chapter 37) prophylaxis.

When to Refer

- If septic arthritis or osteomyelitis is suspected.
- For exposure to bites by dogs, cats, reptiles, amphibians, and rodents.
- When rabies is a possibility.

When to Admit

- Patients with infected hand bites.
- Deep bites, particularly if over joints.

SEXUALLY TRANSMITTED INFECTIONS

ESSENTIALS OF DIAGNOSIS

- All sexually transmitted infections (STIs), also known as sexually transmitted diseases (STDs), have subclinical or latent periods, and patients may be asymptomatic.
- Simultaneous infection with several organisms is common.
- All patients who seek STI testing should be screened for syphilis and HIV.
- Partner notification and treatment are important to prevent further transmission and reinfection of the index case.

General Considerations

The rate of STIs is on the rise, particularly after disruptions in testing and treatment during the COVID-19 pandemic. The most common STIs are gonorrhea,* syphilis,* HPV-associated condyloma acuminatum, chlamydial genital infections,* herpesvirus genital infections, trichomonas vaginitis, chancroid,* granuloma inguinale, scabies, louse infestation, and bacterial vaginosis (among women who have sex with women). However, shigellosis;* hepatitis A, B, and C;* amebiasis; giardiasis;* cryptosporidiosis;* salmonellosis;* campylobacteriosis; dermatophytes (tinea); and mpox may also be transmitted by sexual (oral–anal) contact, especially in men who have sex with men. Ebola virus and Zika virus have both been associated with sexual transmission. Both homosexual and heterosexual contact are risk factors for the transmission of HIV (see Chapter 36). All STIs have *subclinical* or *latent phases* that play an important role in long-term persistence of the infection or in its transmission from infected (but largely asymptomatic) persons to other contacts. *Simultaneous infection by several different agents is common.*

Infections typically present in one of several ways, each of which has a defined differential diagnosis, which should prompt appropriate diagnostic tests.

---

*Reportable to public health authorities.

A. Genital Ulcers

Common etiologies include herpes simplex virus, primary syphilis, and chancroid. Other possibilities include lymphogranuloma venereum (see Chapter 38), granuloma inguinale caused by *Klebsiella granulomatis* (see Chapter 38), mpox, and lesions caused by infection with Epstein-Barr virus and HIV. Noninfectious causes are Behçet disease (see Chapter 23), neoplasm, trauma, drugs, and irritants.

B. Urethritis With or Without Urethral Discharge

The most common infections causing urethral discharge are *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. *N gonorrhoeae* and *C trachomatis* are also frequent causes of prostatitis among sexually active men. Other STIs that can cause urethritis include *Mycoplasma genitalium* and, less commonly, *Ureaplasma urealyticum* and *Trichomonas vaginalis*. Noninfectious causes of urethritis include reactive arthritis with associated urethritis.

C. Vaginal Discharge

Common causes of vaginitis are bacterial vaginosis (caused by overgrowth of anaerobes such as *Gardnerella vaginalis*), candidiasis, and *T vaginalis* (see Chapter 21). Less common infectious causes of vaginitis include HPV-associated condylomata acuminata and group A streptococcus. Noninfectious causes are physiologic changes related to the menstrual cycle, irritants, and lichen planus. Even though *N gonorrhoeae* and *C trachomatis* are frequent causes of cervicitis, they *rarely* produce vaginal discharge.

▶ Screening & Prevention

All persons who seek STI testing should undergo routine screening for HIV infection, using rapid HIV testing (if patients may not follow-up for results obtained by standard methods) or nucleic acid amplification followed by confirmatory serology (if primary HIV infection may be a possibility) as indicated. *Most algorithms now start with an antigen/antibody combination HIV-1/2 immunoassay with a confirmatory HIV-1/HIV-2 antibody differentiation immunoassay.* Patients in whom certain STIs have been diagnosed and treated (chlamydia or gonorrhea, and trichomonas in women) are at a high risk for reinfection and should be encouraged to be rescreened for STIs at 3 months following the initial STI diagnosis.

Asymptomatic patients often request STI screening at the time of initiating a new sexual relationship. Routine HIV testing and hepatitis B serology testing should be offered to all such patients. In sexually active women who have not been recently screened, cervical Papanicolaou testing and nucleic acid amplification testing of a urine specimen for gonorrhea and chlamydia are recommended. Among men who have sex with men, additional screening is recommended for syphilis; hepatitis A; urethral, pharyngeal, and rectal gonorrhea; as well as urethral and rectal chlamydia. Nucleic acid amplification testing is recommended for gonorrhea or chlamydia. There are no recommendations to screen heterosexual men for urethral chlamydia, but this could be considered in STI clinics, adolescent clinics, or correctional facilities. The periodicity of screening thereafter depends on sexual risk, but most screening should be offered at least annually to sexually active adults (particularly to those 25 years old and under). Clinicians should also evaluate transgender persons for STI screening, based on current anatomy and behaviors practiced. If not immune, *hepatitis B vaccination is recommended for all sexually active adults*, and hepatitis A vaccination in men who have sex with men. Persons between the ages of 9 and 26 should be routinely offered vaccination against HPV (9-valent).

The risk of developing an STI following a sexual assault is difficult to accurately ascertain given high rates of baseline infections and poor follow-up. People who have been sexually assaulted have a high baseline rate of infection (*N gonorrhoeae*, 6%; *C trachomatis*, 10%; *T vaginalis*, 15%; and bacterial vaginosis, 34%), and the risk of acquiring infection as a result of the assault is significant but often lower than the preexisting rate (*N gonorrhoeae*, 6–12%; *C trachomatis*, 4–17%; *T vaginalis*, 12%; syphilis, 0.5–3%; and bacterial vaginosis, 19%). Patients should be evaluated within 24 hours of the assault, and nucleic acid amplification tests for *N gonorrhoeae* and *C trachomatis* should be performed. Vaginal secretions are obtained for *Trichomonas* wet mount and culture, or point-of-care testing. If a discharge is present, if there is itching, or if secretions are malodorous, a wet mount should be examined for *Candida* and bacterial vaginosis. In addition, a blood sample should be obtained for immediate serologic testing for syphilis, hepatitis B, and HIV. Follow-up examination for STIs should be repeated within 1–2 weeks, since concentrations of infecting organisms may not have been sufficient to produce a positive test at the time of initial examination. If prophylactic treatment was given (may include postexposure hepatitis B vaccination without hepatitis B immune globulin; treatment for chlamydial, gonorrheal, or trichomonal infection; and emergency contraception), tests should be repeated only if the patient has symptoms. If prophylaxis was not administered, the individual should be seen in 1 week so that any positive tests can be treated. Follow-up serologic testing for syphilis and HIV infection should be performed in 6, 12, and 24 weeks if the initial tests are negative. The usefulness of presumptive therapy is controversial, with some feeling that all patients should receive it and others that it should be limited to those in whom follow-up cannot be ensured or to patients who request it.

Although seroconversion to HIV has been reported following sexual assault when this was the only known risk, this risk is believed to be low. The likelihood of HIV transmission from vaginal or anal receptive intercourse when the source is known to be HIV positive is 1 per 1000 and 5 per 1000, respectively. Although prophylactic antiretroviral therapy has not been studied in this setting, the Department of Health and Human Services recommends the *prompt institution of postexposure prophylaxis with antiretroviral therapy if the person seeks care within 72 hours of the assault, the source is known to be HIV positive, and the exposure presents a substantial risk of transmission.*

In addition to screening asymptomatic patients with STIs, other strategies for preventing further transmission include evaluating sex partners and administering preexposure prophylaxis of preventable STIs to individuals at risk; additional strategies include the consistent use of male and female condoms and male circumcision. Adult male circumcision has been shown to decrease the transmission of HIV by 50%, and of herpes simplex virus and HPV by 30% in heterosexual couples in sub-Saharan Africa. Note that vaginal spermicides and condoms containing nonoxynol-9 provide *no* additional protection against STIs. Among persons with HIV, viral suppression with antiretroviral therapy can prevent HIV acquisition in an uninfected sex partner. Also, preexposure prophylaxis with either a once-daily or on-demand pill containing emtricitabine plus tenofovir or long-acting injectable cabotegravir has been shown to be effective in preventing HIV infection among high-risk men who have sex with men, heterosexual women and men, transgender women, and persons who inject drugs. Postexposure prophylaxis with doxycycline appears to reduce bacterial STIs among individuals disproportionately affected by STIs. Antiviral suppression of HSV can decrease risk of transition to an uninfected sex partner. For each patient with an STI, there are one or more sexual contacts who require diagnosis and treatment. Prompt treatment of contacts by giving antibiotics to the index case to distribute to all sexual contacts (*patient-delivered therapy*) is an important strategy for preventing further transmission and to prevent reinfection of the index case.

When to Refer

- Patients with a new diagnosis of HIV.
- Patients with persistent, refractory, or recurrent STIs, particularly when drug resistance is suspected.

INFECTIONS IN PERSONS WHO INJECT DRUGS

ESSENTIALS OF DIAGNOSIS

- Common infections that occur with greater frequency in persons who inject drugs include:
  - Skin infections, aspiration pneumonia, tuberculosis.
  - Hepatitis A, B, C, D; STIs; HIV/AIDS.
  - Pulmonary septic emboli, infective endocarditis.
  - Osteomyelitis and septic arthritis.

General Considerations

There is a high incidence of infection among persons with opioid use disorder, particularly among people who inject drugs. Increased risk of infection is likely associated with poor hygiene and colonization with potentially pathogenic organisms, contamination of drugs and equipment, increased sexual risk behaviors, and impaired immune defenses. The use of parenterally administered recreational drugs has increased enormously in recent years, fueled in part by an epidemic of prescription opioid misuse and abuse. More than 3 million persons in North America are estimated to have used injection drugs in the past year, with opioid deaths increasing during the COVID-19 pandemic particularly in low-income urban neighborhoods.

Skin infections are associated with poor hygiene and use of nonsterile technique when injecting drugs. *S aureus* (including community-acquired methicillin-resistant strains) and oral flora (streptococci, *Eikenella, Fusobacterium, Peptostreptococcus*) are the most common organisms, with enteric gram-negatives generally more likely seen in those who inject into the groin. Cellulitis and subcutaneous abscesses occur most commonly, particularly in association with subcutaneous ("skin-popping") or intramuscular injections and the use of cocaine and heroin mixtures (probably due to ischemia). Myositis, clostridial myonecrosis, and necrotizing fasciitis occur infrequently but are life-threatening. Wound botulism in association with black tar heroin occurs sporadically but often in clusters.

Aspiration pneumonia and its complications (lung abscess, empyema, brain abscess) result from altered consciousness associated with drug use. Mixed aerobic and anaerobic mouth flora are usually involved.

Tuberculosis also occurs in persons who use drugs, and infection with HIV has fostered the spread of tuberculosis in this population. Morbidity and mortality rates are increased in individuals with HIV and tuberculosis. Classic radiographic findings are often absent; tuberculosis is suspected in any patient with infiltrates who does not respond to antibiotics.

Hepatitis is common among persons who inject drugs and is transmissible both by the parenteral (hepatitis B, C, and D) and by the fecal-oral route (hepatitis A). Multiple episodes of hepatitis with different agents can occur. Hepatitis C has also been associated with noninjection heroin use as well as intranasal use of other drugs, likely secondary to blood on shared straws.

Pulmonary septic emboli may originate from venous thrombi or right-sided endocarditis.

STIs are not directly related to drug use, but the practice of exchanging sex for drugs has resulted in an increased frequency of STIs. Syphilis, gonorrhea, and chancroid are the most common.

HIV/AIDS has a high incidence among persons who inject drugs and their sexual contacts and among the offspring of infected women (see Chapter 36).

Infective endocarditis in persons who inject drugs is most commonly caused by *S aureus*, *Candida* (usually *C albicans* or *C parapsilosis*), *Enterococcus faecalis*, other streptococci, and gram-negative bacteria (especially *Pseudomonas* and *Serratia marcescens*). See Chapter 38.

Other vascular infections include septic thrombophlebitis and mycotic aneurysms. Mycotic aneurysms resulting from direct trauma to a vessel with secondary infection most commonly occur in femoral arteries and less commonly in arteries of the neck. Aneurysms resulting from hematogenous spread of organisms frequently involve intracerebral vessels and thus are seen in association with endocarditis.

Osteomyelitis and *septic arthritis* involving vertebral bodies, sternoclavicular joints, the pubic symphysis, the sacroiliac joints, and other sites usually results from hematogenous distribution of injected organisms or septic venous thrombi. Pain and fever precede radiographic changes, sometimes by several weeks. While *S aureus*—often methicillin-resistant—is most common, *Serratia, Pseudomonas, Candida* (often not *C albicans*), and other pathogens rarely encountered in spontaneous bone or joint disease are found in persons who inject drugs.

Treatment

A common and difficult clinical problem is management of a person known to inject drugs who presents with fever. In general, after obtaining appropriate cultures (blood, urine, and sputum if the CXR is abnormal), empiric therapy is begun. If the CXR is suggestive of a community-acquired pneumonia (consolidation), therapy for outpatient pneumonia is begun with ceftriaxone, 1 g intravenously every 24 hours, plus either azithromycin (500 mg orally or intravenously every 24 hours) or doxycycline (100 mg orally or intravenously twice daily). If the CXR is suggestive of septic emboli (nodular infiltrates), therapy for presumed endocarditis is initiated, usually with vancomycin 15 mg/kg/dose every 12 hours intravenously (due to the high prevalence of MRSA and the possibility of enterococcus). If the CXR is normal and no focal site of infection can be found, *endocarditis is presumed*. While awaiting the results of blood cultures, empiric treatment with vancomycin is started. If blood cultures are positive for organisms that frequently cause endocarditis in drug users (see above), endocarditis is presumed to be present and treated accordingly. In the instance of confirmed methicillin-susceptible *S aureus* infection, vancomycin should be discontinued and treatment initiated with cefazolin or an antistaphylococcal penicillin. If blood cultures are positive for an organism that is an unusual cause of endocarditis, evaluation for an occult source of infection should go forward. In this setting, a transesophageal echocardiogram may be quite helpful since it is 90% sensitive in detecting vegetations and a negative study is strong evidence against endocarditis. If blood cultures are negative and the patient responds to antibiotics, therapy should be continued for 7–14 days (oral therapy can be given once an initial response has occurred). In every patient, careful examination for an occult source of infection (eg, genitourinary, dental, sinus, gallbladder) should be done. *Clinicians also can have a significant role to play in integrating treatment of opioid use disorder when patients present with infectious disease complications.* This includes screening for opioid use disorder, undergoing specific training for and prescribing opioid use disorder medications, treatment of withdrawal symptoms, and linkage to community-based treatment after hospital discharge.

When to Refer

- Any patient with suspected or proven infective endocarditis.
- Patients with persistent bacteremia.

When to Admit

- Persons who inject drugs with fever.
- Patients with abscesses or progressive skin and soft tissue infections that require debridement.

ACUTE INFECTIOUS DIARRHEA

ESSENTIALS OF DIAGNOSIS

- Acute diarrhea: lasts < 2 weeks.
- Chronic diarrhea: lasts > 2 weeks.
- Mild diarrhea: ≤ 3 stools per day.
- Moderate diarrhea: ≥ 4 stools per day with local symptoms (abdominal cramps, nausea, tenesmus).
- Severe diarrhea: ≥ 4 stools per day with systemic symptoms (fever, chills, dehydration).

General Considerations

Acute diarrhea can be caused by a number of different factors, including emotional stress, food intolerance, inorganic agents (eg, sodium nitrite), organic substances (eg, mushrooms, shellfish), medications, and infectious agents (including viruses, bacteria, and protozoa) (Table 35–4). From a diagnostic and therapeutic standpoint, it is helpful to classify infectious diarrhea into syndromes that produce inflammatory or bloody diarrhea and those that are noninflammatory, nonbloody, or watery. In general, the term *inflammatory diarrhea* suggests colonic involvement by invasive bacteria or parasites or by toxin production. Patients report frequent bloody, small-volume stools, often associated with fever, abdominal cramps, tenesmus, and fecal urgency. Common causes of this syndrome include

Table 35–4. Acute bacterial diarrheas and "food poisoning" (listed in alphabetical order by organism).

Organism	Incubation Period	Vomiting	Diarrhea	Fever	Associated Foods	Diagnosis	Clinical Features and Treatment
Bacillus cereus (diarrheal toxin)	10–16 hours	±	+++	–	Toxin in meats, stews, and gravy.	Clinical. Food and stool can be tested for toxin.	Abdominal cramps, watery diarrhea, and nausea lasting 24–48 hours. Treatment: Supportive care.
Bacillus cereus (preformed toxin)	1–8 hours	+++	±	–	Reheated fried rice causes vomiting or diarrhea.	Clinical. Food and stool can be tested for toxin.	Acute onset, severe nausea and vomiting lasting 24 hours. Treatment: Supportive care.
Campylobacter jejuni	2–5 days	±	+++	+	Raw or undercooked poultry, unpasteurized milk, water.	Stool culture on special medium.	Fever, diarrhea that can be bloody, cramps. Usually self-limited in 2–10 days. May be associated with Guillain-Barré syndrome. Treatment: Azithromycin. Fluoroquinolones can be used if susceptibility is confirmed.
Clostridioides difficile	Usually occurs after 7–10 days of antibiotics. Can occur after a single dose or several weeks after completion of antibiotics.	–	+++	++	Associated with antibacterial drugs; clindamycin and β-lactams most commonly implicated. Fluoroquinolones associated with hypervirulent strains.	Stool tested for toxin.	Abrupt onset of diarrhea that may be bloody; fever. Treatment: fidaxomicin or oral vancomycin.
Clostridium botulinum	12–72 hours	±	–	–	Clostridia grow in anaerobic acidic environment, eg, canned foods, fermented fish, foods held warm for extended periods.	Stool, serum, and food can be tested for toxin. Stool and food can be cultured.	Diplopia, dysphagia, dysphonia, respiratory embarrassment. Symptoms can last for days to months. Treatment: clear airway, ventilation, and intravenous polyvalent antitoxin.
Clostridium perfringens	8–16 hours	±	+++	–	Clostridia grow in rewarmed meat and poultry dishes and produce an enterotoxin.	Stools can be tested for enterotoxin or cultured.	Abrupt onset of profuse diarrhea, abdominal cramps, nausea; vomiting occasionally. Treatment: Recovery usually without treatment in 24–48 hours. Supportive care; antibiotics not needed.
Enterohemorrhagic *Escherichia coli*, including STEC	1–8 days	+	+++	–	Undercooked beef, especially hamburger; unpasteurized milk and juice; raw fruits and vegetables.	STEC can be cultured on special medium. Other toxins can be detected in stool.	Usually abrupt onset of diarrhea, often bloody; abdominal pain. In adults, it is usually self-limited to 5–10 days. In children, it is associated with HUS. Treatment: Antibiotic therapy may increase risk of HUS. Plasma exchange may help patients with STEC-associated HUS.
Enterotoxigenic *E coli*	1–3 days	±	+++	±	Water, food contaminated with feces.	Stool culture. Special tests required to identify toxin-producing strains.	Watery diarrhea and abdominal cramps, usually lasting 3–7 days. Treatment: In travelers, fluoroquinolones shorten disease.

(*continued*)

Table 35–4. Acute bacterial diarrheas and "food poisoning" (listed in alphabetical order by organism). (continued)

Organism	Incubation Period	Vomiting	Diarrhea	Fever	Associated Foods	Diagnosis	Clinical Features and Treatment
Noroviruses and other caliciviruses	12–48 hours	++	+++	+	Shellfish and fecally contaminated foods touched by infected food handlers.	Clinical diagnosis with negative stool cultures. PCR available on stool.	Nausea, vomiting (more common in children), diarrhea (more common in adults), fever, myalgias, abdominal cramps. Lasts 12–60 hours. Treatment: Supportive care.
Rotavirus	1–3 days	++	+++	+	Fecally contaminated foods touched by infected food handlers.	Immunoassay on stool.	Acute onset, vomiting, watery diarrhea that lasts 4–8 days. Treatment: Supportive care.
Salmonella species	1–3 days	–	++	+	Eggs, poultry, unpasteurized milk, cheese, juices, raw fruits and vegetables.	Routine stool culture.	Gradual or abrupt onset of diarrhea and low-grade fever. Treatment: No antimicrobials unless high risk (ie, immunosuppressed persons), systemic dissemination is suspected, or isolation of *Salmonella enterica* serotype Typhi or Paratyphi. If susceptibility is confirmed, treatment with ceftriaxone, ciprofloxacin, TMP-SMX, or amoxicillin is recommended. Prolonged carriage can occur.
Shigella species (mild cases)	24–48 hours	±	+	+	Food or water contaminated with human feces. Person to person spread.	Routine stool culture.	Abrupt onset of diarrhea, often with blood and pus in stools, cramps, tenesmus, and lethargy. Stool cultures are positive. Treatment: Azithromycin, ciprofloxacin, and ceftriaxone are drugs of choice. Avoid fluoroquinolones if the ciprofloxacin MIC is 0.12 mcg/mL or greater even if the laboratory report identifies the isolate as susceptible. Do not give opioids. Often mild and self-limited.
Staphylococcus (preformed toxin)	1–8 hours	+++	±	±	Staphylococci grow in meats, dairy, and bakery products and produce enterotoxin.	Clinical. Food and stool can be tested for toxin.	Abrupt onset, intense nausea and vomiting for up to 24 hours, recovery in 24–48 hours. Treatment: Supportive care.
Vibrio cholerae	24–72 hours	+	+++	–	Contaminated water, fish, shellfish, street vendor food.	Stool culture on special medium.	Abrupt onset of liquid diarrhea in endemic area. Treatment: Prompt intravenous or oral replacement of fluids and electrolytes. Doxycycline is drug of choice if antibiotics are indicated. Ciprofloxacin, azithromycin, or ceftriaxone are alternatives.
Vibrio parahaemolyticus	2–48 hours	+	+	±	Undercooked or raw seafood.	Stool culture on special medium.	Abrupt onset of watery diarrhea, abdominal cramps, nausea and vomiting. Treatment: Supportive; recovery is usually complete in 2–5 days.
Yersinia enterocolitica	24–48 hours	±	+	+	Undercooked pork, contaminated water, unpasteurized milk, tofu.	Stool culture on special medium.	Severe abdominal pain (appendicitis-like symptoms), diarrhea, fever. Polyarthritis, erythema nodosum in children. Treatment: If severe, give TMP-SMX. Alternatives are cefotaxime and ciprofloxacin. Without treatment, self-limited in 1–3 weeks.

HUS, hemolytic-uremic syndrome; MIC, minimum inhibitory concentration; STEC, Shiga-toxin–producing *E coli* strains; TMP-SMX, trimethoprim-sulfamethoxazole.

Shigella, *Salmonella*, *Campylobacter*, *Yersinia*, invasive strains of *Escherichia coli*, and other Shiga-toxin–producing strains of *E coli* (STEC), *Entamoeba histolytica*, and *C difficile*. Tests for fecal leukocytes or the neutrophil marker lactoferrin are frequently positive, and definitive etiologic diagnosis requires stool culture. *Noninflammatory diarrhea* is generally milder and is caused by viruses or toxins that affect the small intestine and interfere with salt and water balance, resulting in large-volume watery diarrhea, often with nausea, vomiting, and cramps. Common causes of this syndrome include viruses (eg, rotavirus, norovirus, astrovirus, enteric adenoviruses), vibriones (*Vibrio cholerae*, *Vibrio parahaemolyticus*), enterotoxin-producing *E coli*, *Giardia lamblia*, cryptosporidia, and agents that can cause food-borne gastroenteritis. In developed countries, viruses (particularly norovirus) are an important cause of hospitalizations due to acute gastroenteritis among adults.

The term *food poisoning* denotes diseases caused by toxins present in consumed foods. When the incubation period is short (1–6 hours after consumption), the *toxin is usually preformed.* Vomiting is usually a major symptom, and fever is usually absent. Examples include intoxication from *S aureus* or *Bacillus cereus*, and toxin can be detected in the food. When the incubation period is longer—between 8 hours and 16 hours—the organism is present in the food and *produces toxin after being ingested.* Vomiting is less prominent, abdominal cramping is frequent, and fever is often absent. The best example of this disease is that due to *Clostridium perfringens*. Toxin can be detected in food or stool specimens.

The inflammatory and noninflammatory diarrheas discussed above can also be transmitted by food and water and usually have incubation periods between 12 and 72 hours. *Cyclospora*, cryptosporidia, and *Isospora* are protozoans capable of causing disease in both immunocompetent and immunocompromised patients. Characteristics of disease include profuse watery diarrhea that is prolonged but usually self-limited (1–2 weeks) in the immunocompetent patient but can be chronic in the compromised host. Epidemiologic features may be helpful in determining etiology. Recent hospitalization or antibiotic use suggests *C difficile*; recent foreign travel suggests *Salmonella*, *Shigella*, *Campylobacter*, *E coli*, or *V cholerae;* undercooked hamburger suggests STEC; outbreak in long-term care facility, school, or cruise ship suggests norovirus (including newly identified strains, eg, GII.4 Sydney); and fried rice consumption is associated with *B cereus* toxin. Prominent features of some of these causes of diarrhea are listed in Table 35–4.

Treatment

A. General Measures

In general, *most cases of acute gastroenteritis are self-limited and do not require therapy other than supportive measures.* Treatment usually consists of replacement of fluids and electrolytes and, rarely, management of hypovolemic shock and respiratory compromise. In mild diarrhea, increasing ingestion of juices and clear soups is adequate. In more severe cases of dehydration (postural light-headedness, decreased urination), oral glucose-based rehydration solutions can be used (Ceralyte, Pedialyte).

B. Specific Measures

In immunocompetent adults, empiric antimicrobial therapy for bloody diarrhea while waiting for results is recommended only with the following circumstances: (1) documented fever, abdominal pain, bloody diarrhea, and **bacillary dysentery** (frequent scant bloody stools, fever, abdominal cramps, tenesmus) presumptively due to *Shigella*; and (2) returning travelers with a temperature of at least 38.5°C or signs of sepsis.

Either a fluoroquinolone or azithromycin should be used as empiric antimicrobial therapy for bloody diarrhea. Empiric antibacterial treatment should be considered in immunocompromised people with severe illness and bloody diarrhea. Loperamide may be given to immunocompetent adults with acute watery diarrhea but should be avoided with *Shigella* infection or in suspected or proven toxic megacolon. Therapeutic recommendations for specific agents can be found elsewhere in this book.

INFECTIOUS DISEASES IN THE RETURNING TRAVELER

ESSENTIALS OF DIAGNOSIS

- Most infections are common and self-limited.
- Identify patients with transmissible diseases that require isolation.
- The incubation period may be helpful in diagnosis.
  - Less than 3 weeks following exposure may suggest dengue, leptospirosis, and yellow fever.
  - More than 3 weeks suggests typhoid fever, malaria, and tuberculosis.

General Considerations

The differential diagnosis of fever in the returning traveler is broad, ranging from self-limited viral infections to life-threatening illness. *The evaluation is best done by identifying whether a particular syndrome is present, then refining the differential diagnosis based on an exposure history*. The travel history should include directed questions regarding geography (rural versus urban, specific country and region visited), time of year, animal or arthropod contact, unprotected sexual intercourse, ingestion of untreated water or raw foods, historical or pretravel immunizations, and adherence to malaria prophylaxis.

Etiologies

The most common infectious causes of fever—excluding simple causes such as upper respiratory infections, bacterial pneumonia and UTIs—in returning travelers are malaria (see Chapter 40), diarrhea (see next section), and dengue (see Chapter 37). Others include mononucleosis (associated with Epstein-Barr virus or cytomegalovirus), respiratory infections, including seasonal influenza, influenza A/H1N1 “swine” influenza, and influenza A/H5N1 or A/H7N9 “avian” influenza (see Chapter 37); leptospirosis (see Chapter 39); typhoid fever (see Chapter 38); and rickettsial infections (see Chapter 37). Coronaviruses cause regional and global outbreaks of various sizes (SARS-CoV, MERS-CoV, and the massive global pandemic from SARS-CoV-2). Foreign travel is increasingly recognized as a risk factor for colonization and disease with resistant pathogens, such as ESBL-producing gram-negative organisms. Systemic febrile illnesses without a diagnosis also occur commonly, particularly in travelers returning from sub-Saharan Africa or Southeast Asia.

A. Fever and Rash

Potential etiologies include dengue, Ebola, Chikungunya, and Zika viruses, viral hemorrhagic fever, leptospirosis, meningococcemia, yellow fever, typhus, *Salmonella typhi*, and acute HIV infection.

B. Pulmonary Infiltrates

Tuberculosis, *Ascaris*, *Paragonimus*, and *Strongyloides* can all cause pulmonary infiltrates.

C. Meningoencephalitis

Etiologies include *N meningitidis*, leptospirosis, arboviruses, rabies, and (cerebral) malaria.

D. Jaundice

Consider hepatitis A, yellow fever, hemorrhagic fever, leptospirosis, and malaria.

E. Fever Without Localizing Symptoms or Signs

Malaria, typhoid fever, acute HIV infection, rickettsial illness, visceral leishmaniasis, trypanosomiasis, and dengue are possible etiologies.

F. Traveler’s Diarrhea

See next section.

Clinical Findings

Fever and rash in the returning traveler should prompt blood cultures and serologic tests based on the exposure history. The workup of a pulmonary infiltrate should include the placement of a PPD or use of an interferon-γ release assay, examination of sputum for acid-fast bacilli and possibly for ova and parasites. Patients with evidence of meningoencephalitis should receive lumbar puncture, blood cultures, thick/thin smears of peripheral blood, history-guided serologies, and a nape biopsy (if rabies is suspected). Jaundice in a returning traveler should be evaluated for hemolysis (for malaria), and the following tests should be performed: liver biochemical tests, thick/thin smears of peripheral blood, and directed serologic testing. The workup of traveler’s diarrhea is presented in the following section. Finally, patients with fever but no localizing signs or symptoms should have blood cultures performed. Routine laboratory studies usually include CBC with differential, electrolytes, liver biochemical tests, UA, and blood cultures. Thick and thin peripheral blood smears should be done (and repeated in 12–24 hours if clinical suspicion remains high) for malaria if there has been travel to endemic areas. Other studies are directed by the results of history, physical examination, and initial laboratory tests. They may include stool for ova and parasites, CXR, HIV test, and specific serologies (eg, dengue, leptospirosis, rickettsial disease, schistosomiasis, *Strongyloides*). Bone marrow biopsy to diagnose typhoid fever could be helpful in the appropriate patient. Increasingly, next-generation sequencing of plasma or body fluids such as CSF is used as an adjunctive modality for diagnosis when traditional methods have not yielded a diagnosis.

When to Refer

Travelers with fever, particularly if immunocompromised.

When to Admit

Any evidence of hemorrhage, respiratory distress, hemodynamic instability, and neurologic deficits.

TRAVELER’S DIARRHEA

ESSENTIALS OF DIAGNOSIS

- Usually a benign, self-limited disease occurring about 1 week into travel.
- Prophylaxis *not* recommended unless there is a comorbid disease (inflammatory bowel syndrome, HIV, immunosuppressive medication).
- Single-dose therapy of a fluoroquinolone usually effective if significant symptoms develop.

General Considerations

Whenever a person travels from one country to another—particularly if the change involves a marked difference in climate, social conditions, or sanitation standards and facilities—diarrhea may develop within 2–10 days. Bacteria cause 80% of cases of traveler's diarrhea, with enterotoxigenic *E coli*, *Shigella* species, and *Campylobacter jejuni* being the most common pathogens. Less common are *Aeromonas*, *Salmonella*, noncholera vibriones, *E histolytica*, and *G lamblia*. Contributory causes include unusual food and drink, change in living habits, occasional viral infections (adenoviruses or rotaviruses), and change in bowel flora. Chronic watery diarrhea may be due to amebiasis or giardiasis or, rarely, tropical sprue.

Clinical Findings

A. Symptoms and Signs

There may be up to 10 or even more loose stools per day, often accompanied by abdominal cramps and nausea, occasionally by vomiting, and rarely by fever. The stools are usually watery and not associated with fever when caused by enterotoxigenic *E coli*. With invasive bacterial pathogens (*Shigella*, *Campylobacter*, *Salmonella*), stools can be bloody and fever may be present. The illness usually subsides spontaneously within 1–5 days, although 10% remain symptomatic for 1 week or longer, and symptoms persist for longer than 1 month in 2%. Traveler's diarrhea is also a significant risk factor for developing irritable bowel syndrome.

B. Laboratory Findings

In patients with fever and bloody diarrhea, stool culture is indicated, but *in most cases, cultures are reserved for those who do not respond to antibiotics.*

Prevention

A. General Measures

Avoidance of fresh foods and water sources that are likely to be contaminated is recommended for travelers to developing countries, where infectious diarrheal illnesses are endemic.

B. Specific Measures

Because not all travelers will have diarrhea and because most episodes are brief and self-limited, the recommended approach is to *provide the traveler with a supply of antimicrobials. Prophylaxis* is recommended for those with significant underlying disease (IBD, AIDS, diabetes mellitus, heart disease in older adults, conditions requiring immunosuppressive medications) and for those whose full activity status during the trip is so essential that even short periods of diarrhea would be unacceptable.

Prophylaxis is started upon entry into the destination country and is continued for 1 or 2 days after leaving. For stays of > 3 weeks, prophylaxis is not recommended because of the cost and increased toxicity. For prophylaxis, several oral antimicrobial once-daily regimens are effective, such as ciprofloxacin, 500 mg, or rifaximin, 200 mg. Bismuth subsalicylate is effective but turns the tongue and the stools black and can interfere with doxycycline absorption, which may be needed for malaria prophylaxis; it is rarely used.

Treatment

For most individuals, the affliction is short-lived, and symptomatic therapy with loperamide is all that is required, provided the patient is not systemically ill (fever 39°C or higher) and does not have dysentery (bloody stools), in which case antimotility agents should be avoided. Packages of oral rehydration salts to treat dehydration are available over the counter in the United States (Infalyte, Pedialyte, others) and in many foreign countries.

When treatment is necessary, in areas where toxin-producing bacteria are the major cause of diarrhea (Latin America and Africa), loperamide (4 mg oral loading dose, then 2 mg after each loose stool to a maximum of 16 mg/day) with a single oral dose of ciprofloxacin (750 mg), levofloxacin (500 mg), or ofloxacin (200 mg) cures most cases of traveler's diarrhea. If diarrhea is associated with bloody stools or persists despite a single dose of a fluoroquinolone, 1000 mg of azithromycin should be taken. In pregnant women and in areas where invasive bacteria more commonly cause diarrhea (Indian subcontinent, Asia, especially Thailand where fluoroquinolone-resistant *Campylobacter* is prevalent), azithromycin is the medication of choice. Rifaximin, a nonabsorbable agent, is also approved for therapy of traveler's diarrhea at a dose of 200 mg orally three times per day or 400 mg twice a day for 3 days. Because luminal concentrations are high, but tissue levels are insufficient, it should not be used in situations where there is a high likelihood of invasive disease (eg, fever, systemic toxicity, or bloody stools).

When to Refer

- Cases refractory to treatment.
- Persistent infection.
- Immunocompromised patient.

When to Admit

Patients who are severely dehydrated or hemodynamically unstable should be admitted to the hospital.

ANTIMICROBIAL THERAPY

SELECTED PRINCIPLES OF ANTIMICROBIAL THERAPY

Specific steps (outlined below) are required when considering antibiotic therapy for patients. Medications within classes, medications of first choice, and alternative medications are presented in Table 35–5.

Table 35–5. Medication of choice for suspected or documented microbial pathogens (listed in alphabetical order, within classes).

Suspected or Proved Etiologic Agent	Medication(s) of First Choice	Alternative Medication(s)
Gram-Negative Cocci		
Moraxella catarrhalis	Cefuroxime axetil, amoxicillin-clavulanic acid	Ceftriaxone, a fluoroquinolone,[1] a macrolide,[2] a tetracycline,[3] TMP-SMX[4]
Neisseria gonorrhoeae (gonococcus)	Ceftriaxone ± doxycycline[5]	Gentamicin + azithromycin or cefixime ± doxycycline[5]
Neisseria meningitidis (meningococcus)	Penicillin[6]	Ceftriaxone, ampicillin
Gram-Positive Cocci		
Enterococcus faecalis	Ampicillin ± gentamicin[7] Ampicillin ± ceftriaxone	Vancomycin ± gentamicin
Enterococcus faecium	Vancomycin ± gentamicin[7]	Linezolid,[8] daptomycin,[8] tigecycline,[8] tedizolid,[8] oritavancin[8]
Staphylococcus, methicillin-resistant	Vancomycin	TMP-SMX,[4] doxycycline, minocycline, linezolid,[8] tedizolid,[8] daptomycin,[8] televancin,[8] dalbavancin,[8] oritavancin,[8] ceftaroline, delafloxacin
Staphylococcus, methicillin-susceptible	Cefazolin or Penicillinase-resistant penicillin[9]	Vancomycin, a cephalosporin,[10] clindamycin, amoxicillin-clavulanic acid, ampicillin-sulbactam
Streptococcus, hemolytic, groups A, B, C, G	Penicillin[6]	Macrolide,[2] a cephalosporin,[10] vancomycin, clindamycin
Streptococcus pneumoniae[11] (pneumococcus)	Penicillin[6]	A cephalosporin,[10] vancomycin, clindamycin, a tetracycline,[3] respiratory fluoroquinolones[1]
Viridans streptococci	Penicillin[6]	Cephalosporin,[10] vancomycin
Gram-Negative Rods		
Acinetobacter	Imipenem, meropenem, ampicillin-sulbactam	Tigecycline, minocycline, aminoglycosides,[12] polymyxin B, cefiderocol, sulbactam/durlobactam
Bacteroides, GI strains	Metronidazole	Ampicillin-sulbactam, piperacillin-tazobactam, ertapenem
Brucella	Doxycycline + rifampin	TMP-SMX[4] ± gentamicin; ciprofloxacin + rifampin
Burkholderia pseudomallei (melioidosis) and *Burkholderia mallei* (glanders)	Ceftazidime initially followed by TMP-SMX[4]	Meropenem initially followed by amoxicillin-clavulanic acid
Campylobacter jejuni	Azithromycin	A fluoroquinolone[1]
Enterobacter	Ertapenem, imipenem, meropenem, cefepime	Aminoglycoside, a fluoroquinolone,[1] TMP-SMX[4]
Escherichia coli (complicated, hospitalized)[13]	Ceftriaxone if high local susceptibility rates, otherwise select an alternative	Ertapenem,[13] aminoglycosides,[12] aztreonam, piperacillin-tazobactam, ceftazidime-avibactam,[13,14] ceftolozane-tazobactam,[13] meropenem/vaborbactam,[14] imipenem/cilastatin-relebactam[13,14]
Escherichia coli (uncomplicated outpatient UTI)	Nitrofurantoin	Fluoroquinolones,[1] fosfomycin, TMP-SMX,[4] oral cephalosporin
Haemophilus (respiratory infections, otitis)	Amoxicillin-clavulanate	Doxycycline, azithromycin, ceftriaxone, cefuroxime sodium, cefuroxime axetil, TMP-SMX[4]
Haemophilus (serious infection)	Ceftriaxone	Aztreonam
Helicobacter pylori	PPI, clarithromycin, amoxicillin, and metronidazole if high local susceptibility rates, otherwise select an alternative	PPI, bismuth subsalicylate, tetracycline, and metronidazole
Klebsiella[13]	Ceftriaxone if high local susceptibility rates, otherwise select an alternative	Cefepime, TMP-SMX,[4] aminoglycoside,[12] ertapenem,[13] fluoroquinolone,[1] aztreonam, piperacillin-tazobactam, ceftazidime-avibactam,[13] ceftolozane-tazobactam,[13] meropenem/vaborbactam,[14] imipenem/cilastatin-relebactam[13,14]

(*continued*)

Table 35–5. Medication of choice for suspected or documented microbial pathogens (listed in alphabetical order, within classes). (continued)

Suspected or Proved Etiologic Agent	Medication(s) of First Choice	Alternative Medication(s)
Legionella species (pneumonia)	Azithromycin, or fluoroquinolones[1] ± rifampin	Doxycycline ± rifampin
Prevotella, oropharyngeal strains	Clindamycin	Metronidazole
Proteus mirabilis	Ampicillin	TMP-SMX,[4] a fluoroquinolone,[1] a cephalosporin,[10] ertapenem or meropenem[13]
Proteus vulgaris and other species (*Morganella*, *Providencia*)	Ceftriaxone	Ertapenem or meropenem, TMP-SMX,[4] a fluoroquinolone[1]
Pseudomonas aeruginosa	Piperacillin-tazobactam or ceftazidime or cefepime, or imipenem or meropenem or doripenem or aztreonam	Ceftazidime-avibactam[13,15]; ceftolozane-tazobactam,[13,15] cefiderocol,[15] imipenem/cilastatin-relebactam[15]
Salmonella (bacteremia)	Ceftriaxone	A fluoroquinolone[1]
Serratia	Ceftriaxone, piperacillin-tazobactam	TMP-SMX,[4] a fluoroquinolone,[1] a carbapenem
Shigella	Azithromycin, ciprofloxacin, or ceftriaxone	TMP-SMX[4]
Vibrio (cholera, sepsis)	A tetracycline[3]	Azithromycin, a fluoroquinolone,[1] ceftriaxone
Yersinia pestis (plague)	A fluoroquinolone,[1] or streptomycin, or gentamicin	TMP-SMX,[5] tetracycline[3]
Gram-Positive Rods		
Actinomyces	Penicillin[6]	Tetracycline,[3] clindamycin
Bacillus (including anthrax)	Penicillin[6]	A macrolide,[2] a fluoroquinolone[1]
Clostridium (eg, gas gangrene, tetanus)	Penicillin[6]	Metronidazole, clindamycin, imipenem, or meropenem
Corynebacterium diphtheria	Macrolide[2]	Penicillin[6]
Corynebacterium jeikeium	Vancomycin	Linezolid
Listeria	Ampicillin ± aminoglycoside[12]	TMP-SMX[4]
Acid-Fast Rods		
Mycobacterium avium complex	Clarithromycin or azithromycin + ethambutol, ± rifabutin	Amikacin, ciprofloxacin
Mycobacterium fortuitum-chelonae	Cefoxitin + clarithromycin	Amikacin, rifampin, sulfonamide, doxycycline, linezolid
Mycobacterium kansasii	INH + rifampin ± ethambutol	Clarithromycin, azithromycin, ethionamide, cycloserine
Mycobacterium leprae	Dapsone + rifampin ± clofazimine	Minocycline, ofloxacin, clarithromycin
Mycobacterium tuberculosis[16]	Isoniazid (INH) + rifampin + pyrazinamide ± ethambutol	Other antituberculous drugs (see Chapter 9)
Nocardia	TMP-SMX[4]	Minocycline, imipenem or meropenem, linezolid
Spirochetes		
Borrelia burgdorferi (Lyme disease)	Doxycycline, amoxicillin, cefuroxime axetil	Ceftriaxone, penicillin, azithromycin
Borrelia recurrentis (relapsing fever)	Doxycycline[3]	Penicillin[6]
Leptospira	Penicillin[6]	Doxycycline,[3] ceftriaxone
Treponema pallidum (syphilis)	Penicillin[6]	Doxycycline
Treponema pertenue (yaws)	Penicillin[6]	Doxycycline

(continued)

Table 35–5. Medication of choice for suspected or documented microbial pathogens (listed in alphabetical order, within classes). (continued)

Suspected or Proved Etiologic Agent	Medication(s) of First Choice	Alternative Medication(s)
Mycoplasmas	**Azithromycin or doxycycline**	**A fluoroquinolone**[1]
Chlamydiae		
C pneumoniae	Doxycycline[3]	Azithromycin, a fluoroquinolone[1,17]
C psittaci	Doxycycline	Azithromycin, clarithromycin
C trachomatis (urethritis or pelvic inflammatory disease)	Doxycycline	Azithromycin, levofloxacin
Rickettsiae	**Doxycycline**[3]	**A fluoroquinolone**[1]

[1] Fluoroquinolones include ciprofloxacin, levofloxacin, moxifloxacin, and others. Levofloxacin, and moxifloxacin, the respiratory fluoroquinolones, demonstrate the most reliable activity against penicillin-resistant *S pneumoniae* and other respiratory infection pathogens. Delafloxacin is predictably active against methicillin-resistant *S aureus* (MRSA).

[2] Azithromycin is the preferred macrolide due to increased safety profile and minimal drug interaction potential.

[3] All tetracyclines have similar activity against most microorganisms. Minocycline (the most active tetracycline) and doxycycline are more active than tetracycline against *S aureus*.

[4] TMP-SMX is a mixture of 1 part trimethoprim and 5 parts sulfamethoxazole.

[5] Add doxycycline if *Chlamydia* has not been ruled out.

[6] Penicillin G is preferred for parenteral injection, penicillin V for oral administration.

[7] Addition of gentamicin indicated only for severe enterococcal infections (eg, endocarditis, meningitis).

[8] Linezolid, tedizolid, tigecycline, daptomycin, telavancin, dalbavancin, and oritavancin should be reserved for the treatment of vancomycin-resistant isolates or in patients intolerant of vancomycin.

[9] Parenteral nafcillin or oxacillin; oral dicloxacillin, cloxacillin, or oxacillin.

[10] Most intravenous cephalosporins (with the exception of ceftazidime) are active against streptococci and methicillin-susceptible staphylococci.

[11] Infections caused by isolates with intermediate resistance may respond to high-dose penicillin or ceftriaxone or the respiratory fluoroquinolones (levofloxacin and moxifloxacin). Infections caused by highly penicillin-resistant isolates should be treated with vancomycin. Penicillin-resistant pneumococci are often resistant to macrolides, tetracyclines, and TMP-SMX.

[12] Aminoglycosides—gentamicin, tobramycin, amikacin, plazomicin—should be chosen on the basis of local patterns of susceptibility.

[13] Extended β-lactamase–producing (ESBL) isolates should be treated with a carbapenem. If a carbapenem cannot be used, ceftazidime-avibactam or possibly ceftolozane-tazobactam or imipenem/cilastatin-relebactam can be considered.

[14] Consider in cases of infection due to carbapenemase-producing *Enterobacterales*.

[15] Ceftolozane-tazobactam, cefiderocol, imipenem/cilastatin-relebactam and occasionally ceftazidime-avibactam may be active against multidrug-resistant *P aeruginosa*.

[16] Resistance is common and susceptibility testing must be performed.

[17] Ciprofloxacin has inferior antichlamydial activity compared with levofloxacin or ofloxacin.

±, alone or combined with.

A. Etiologic Diagnosis

Based on the organ system involved, the organism causing infection can often be predicted. See Table 35–1 and Table 35–6.

B. "Best Guess"

Select an empiric regimen that is likely to be effective against the suspected pathogens.

C. Laboratory Control

Specimens for laboratory examination should be obtained before institution of therapy to determine susceptibility.

D. Clinical Response

Based on clinical response and other data, the laboratory reports are evaluated and then the desirability of changing the regimen is considered. If the specimen was obtained from a normally sterile site (eg, blood, CSF, pleural fluid, joint fluid), the recovery of a microorganism in significant amounts is meaningful even if the organism recovered is different from the clinically suspected agent, and this may force a change in treatment. Isolation of unexpected microorganisms from the respiratory tract, GI tract, or surface lesions (sites that have a complex flora) may represent colonization or contamination, and cultures must be critically evaluated before medications are abandoned that were judiciously selected on a "best guess" basis.

E. Drug Susceptibility Tests

Some microorganisms are predictably inhibited by certain medications; if such organisms are isolated, they need not be tested for drug susceptibility. For example, all group A hemolytic streptococci are inhibited by penicillin. Other organisms (eg, enteric gram-negative rods) are variably susceptible and generally require susceptibility testing whenever they are isolated. Organisms that once had predictable susceptibility patterns are associated with

Table 35–6. Examples of empiric choices of antimicrobials for adult outpatient infections (listed in alphabetical order, except for syphilis).

Suspected Clinical Diagnosis	Likely Etiologic Agents	Medications of Choice	Alternative Medications
Acute sinusitis	*Streptococcus pneumoniae, Haemophilus influenzae, Moraxella catarrhalis*	Amoxicillin-clavulanate,[1] 875 mg orally twice daily for 5–7 days	For patients allergic to penicillin, doxycycline, 100 mg twice daily for 5–7 days
Aspiration pneumonia	Mixed oropharyngeal flora, including anaerobes	Amoxicillin-clavulanate 875 mg orally twice daily for 5–7 days	Levofloxacin 750 mg orally once daily or moxifloxacin 400 mg orally once daily for 5–7 days
Cystitis (uncomplicated)	*Escherichia coli, Staphylococcus saprophyticus, Klebsiella pneumoniae, Proteus* species, other gram-negative rods or enterococci	Nitrofurantoin monohydrate macrocrystals 100 mg twice daily for 5–7 days (unless pregnant); fosfomycin 3 g orally as a single dose	Cephalexin, 500 mg orally four times daily for 7 days, for uncomplicated cystitis. Due to increasing bacterial resistance, TMP-SMX and fluoroquinolones are *not* recommended as first-line therapy for empiric treatment.
Erysipelas, impetigo, nonpurulent cellulitis, ascending lymphangitis	Group A streptococcus	Penicillin V, 250–500 mg orally four times daily for 5–7 days	Cephalexin, 500 mg orally four times daily for 5–7 days
Furuncle with surrounding cellulitis	*Staphylococcus aureus*	Dicloxacillin, 500 mg orally four times daily for 5–7 days for MSSA. For CA-MRSA: TMP-SMX[2] one to two double-strength tablet twice daily for 5–7 days; **or** clindamycin 300 mg orally three to four times daily for 5–7 days	Cephalexin, 500 mg orally four times daily for 5–7 days for MSSA. For CA-MRSA, doxycycline, 100 mg orally twice daily, is a reasonable alternative.
Gastroenteritis	*Salmonella, Shigella, Campylobacter, Entamoeba histolytica*	See footnote 3	
Otitis media	*S pneumoniae, H influenzae, M catarrhalis*	Amoxicillin-clavulanate[1] 875 mg orally twice daily for 7–10 days	Cefuroxime, 500 mg orally twice daily; **or** cefpodoxime, 200–400 mg daily; **or** doxycycline, 100 mg twice daily
Pelvic inflammatory disease	*Neisseria gonorrhoeae, Chlamydia trachomatis*, anaerobes, gram-negative rods	Ceftriaxone 500 mg intramuscularly once plus doxycycline 100 mg orally twice daily for 14 days **plus** metronidazole 500 mg orally twice daily for 14 days; **or** cefoxitin 2 g intramuscularly once **plus** probenecid 1 g orally once, **plus** doxycycline 100 mg orally twice daily for 14 days **plus** metronidazole 500 mg orally twice daily for 14 days	Cefotaxime **plus** doxycycline 100 mg orally twice daily for 14 days **plus** metronidazole 500 mg orally twice daily for 14 days
Pharyngitis	Group A streptococcus	Penicillin V, 500 mg orally four times daily, **or** amoxicillin, 500 mg–1 g orally three times daily for 10 days	For patients with history of mild penicillin allergy, cephalexin, 500 mg orally four times daily for 10 days; for patients with IgE-mediated reaction, clindamycin, 300 mg orally four times daily for 10 days; **or** azithromycin, 500 mg on day 1 and 250 mg on days 2–5
Pneumonia	*S pneumoniae, Mycoplasma pneumoniae, Legionella pneumophila, Chlamydia pneumoniae*	Amoxicillin, 1 g three times daily **or** Doxycycline, 100 mg orally twice daily	For patients at high risk for infection due to resistant pneumococci: amoxicillin-clavulanate **or** cefpodoxime **or** cefuroxime + macrolide **or** doxycycline **or** monotherapy with a respiratory fluoroquinolone[4]

(*continued*)

Table 35–6. Examples of empiric choices of antimicrobials for adult outpatient infections (listed in alphabetical order, except for syphilis). (continued)

Suspected Clinical Diagnosis	Likely Etiologic Agents	Medications of Choice	Alternative Medications
Pyelonephritis	*E coli, K pneumoniae, Proteus* species, *S saprophyticus*	Fluoroquinolones[5] for 7 days if prevalence of resistance among uropathogens is < 10%	TMP-SMX,[2] one to two double-strength tablets twice daily for 7–14 days for susceptible pathogens. Oral β-lactams are less effective than fluoroquinolones or TMP-SMX
Urethritis, epididymitis	*N gonorrhoeae, C trachomatis*	Ceftriaxone, 500 mg intramuscularly once for *N gonorrhoeae*; doxycycline, 100 mg orally twice daily for 7 days, for *C trachomatis*	Gentamicin 240 mg intramuscularly once **or** cefixime 800 mg orally once for *N gonorrhoeae*[6] Alternatives for *C trachomatis* include azithromycin 1 g orally once **or** levofloxacin 500 mg orally once daily for 7 days
Syphilis			
Early syphilis (primary, secondary, or latent of < 1 year's duration)	*Treponema pallidum*	Benzathine penicillin G, 2.4 million units intramuscularly once	Doxycycline, 100 mg orally twice daily for 2 weeks. Ceftriaxone, 1 g intravenously or intramuscularly once daily for 10 days
Latent syphilis of > 1 year's duration or cardiovascular syphilis	*T pallidum*	Benzathine penicillin G, 2.4 million units intramuscularly once a week for 3 weeks (total: 7.2 million units)	Doxycycline, 100 mg orally twice daily for 28 days
Neurosyphilis	*T pallidum*	Aqueous penicillin G, 18–24 million units/day intravenously divided every 4 hours for 10–14 days	Procaine penicillin G 2.4 million units intramuscularly once daily + probenecid 500 mg orally four times daily for 10–14 days

[1] Amoxicillin-clavulante is available as a combination of amoxicillin, 250 mg, 500 mg, or 875 mg, plus 125 mg of clavulanic acid. Augmentin XR is a combination of amoxicillin 1 g and clavulanic acid 62.5 mg.

[2] TMP-SMX is a fixed combination of 1 part trimethoprim and 5 parts sulfamethoxazole. Single-strength tablets: 80 mg TMP, 400 mg SMX; double-strength tablets: 160 mg TMP, 800 mg SMX.

[3] The diagnosis should be confirmed by culture before therapy. *Salmonella* gastroenteritis generally does not require therapy. For susceptible *Shigella* isolates, give ciprofloxacin, 500 mg orally twice daily for 5 days. For *Campylobacter* infection, give azithromycin, 1 g orally for one dose, or ciprofloxacin, 500 mg orally twice daily for 5 days. For *E histolytica* infection, give metronidazole, 750 mg orally three times daily for 5–10 days, followed by an intraluminally active drug such as paromomycin 10 mg/kg orally three times daily for 7 days.

[4] Fluoroquinolones with activity against *S pneumoniae*, including penicillin-resistant isolates, include levofloxacin (500–750 mg orally once daily) or moxifloxacin (400 mg orally once daily). Use fluoroquinolones as medication of choice if recent non-fluoroquinolone antibiotic use within 3 months.

[5] Fluoroquinolones and dosages include ciprofloxacin, 500 mg orally twice daily; ofloxacin, 400 mg orally twice daily; and levofloxacin, 500 mg orally daily.

[6] Test of cure recommended if ceftriaxone is not used.

CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus*; MRSA, methicillin-resistant *S aureus*; MSSA, methicillin-susceptible *S aureus;* TMP-SMX, trimethoprim-sulfamethoxazole.

resistance and require testing. Examples include the pneumococci, which may be resistant to multiple medications (including penicillin, macrolides, and tetracyclines); the enterococci, which may be resistant to penicillin, aminoglycosides, and vancomycin; and ESBL-producing *E coli* resistant to third-generation cephalosporins, aminoglycosides, and fluoroquinolones.

When culture and susceptibility results have been finalized, clinicians must use the most narrow-spectrum agent and the shortest duration possible to decrease the selection pressure for antibacterial resistance.

Antimicrobial drug susceptibility tests may be performed on solid media as disk diffusion tests, in broth, in tubes, in wells of microdilution plates, or as E-tests (strips with increasing concentration of antibiotic). The latter three methods yield results expressed as MIC. In most infections, the MIC is the appropriate in vitro test to guide selection of an antibacterial agent. When there appear to be marked discrepancies between susceptibility testing and clinical response, the following possibilities must be considered:

1. Selection of an inappropriate medication, medication dosage, or route of administration.
2. Failure to drain a collection of pus or to remove a foreign body.

3. Failure of a poorly diffusing drug to reach the site of infection (eg, CNS) or to reach intracellular phagocytosed bacteria.
4. Superinfection in the course of prolonged chemotherapy.
5. Emergence of drug resistance in the original pathogen or superinfection with a new more resistant organism.
6. Participation of two or more microorganisms in the infectious process, of which only one was originally detected and used for medication selection.
7. Inadequate host defenses, including immunodeficiencies and diabetes mellitus.
8. Noninfectious causes, including drug fever, malignancy, and autoimmune disease.

F. Promptness of Response

Response depends on a number of factors, including the patient (immunocompromised patients respond slower than immunocompetent patients), the site of infection (deep-seated infections such as osteomyelitis and endocarditis respond more slowly than superficial infections such as cystitis or cellulitis), the pathogen (virulent organisms such as *S aureus* respond more slowly than viridans streptococci; mycobacterial and fungal infections respond slower than bacterial infections), and the duration of illness (in general, the longer the symptoms are present, the longer it takes to respond). Thus, depending on the clinical situation, persistent fever and leukocytosis several days after initiation of therapy may not indicate improper choice of antibiotics but may be due to the natural history of the disease being treated. In most infections, either a bacteriostatic or a bactericidal agent can be used. *In some infections (eg, infective endocarditis and meningitis), a bactericidal agent should be used.* When potentially toxic medications (eg, aminoglycosides, flucytosine) are used, serum levels of the medication are measured to minimize toxicity and ensure appropriate dosage. In patients with altered renal or hepatic clearance of medications, the dosage or frequency of administration must be adjusted; it is best to measure levels in older adults, in patients with morbid obesity, or in those with altered kidney function when possible and adjust therapy accordingly.

G. Duration of Antimicrobial Therapy

Generally, effective antimicrobial treatment results in reversal of the clinical and laboratory parameters of active infection and marked clinical improvement. However, varying periods of treatment may be required for cure. Key factors include (1) the type of infecting organism (bacterial infections generally can be cured more rapidly than fungal or mycobacterial ones), (2) the location of the process (eg, endocarditis and osteomyelitis require prolonged therapy), and (3) the immunocompetence of the patient.

H. Adverse Reactions and Toxicity

These include hypersensitivity reactions, direct toxicity, superinfection by drug-resistant microorganisms, and drug interactions. If the infection is life-threatening and treatment cannot be stopped, the reactions are managed symptomatically or another medication is chosen that does not cross-react with the offending one (Table 35–5). If the infection is less serious, it may be possible to stop all antimicrobials and monitor the patient closely.

I. Route of Administration

Intravenous therapy is preferred for acutely ill patients with serious infections (eg, endocarditis, meningitis, sepsis, severe pneumonia) when dependable levels of antibiotics are required for successful therapy. Certain medications (eg, doxycycline, fluconazole, voriconazole, rifampin, metronidazole, TMP-SMX, and fluoroquinolones) are so well absorbed that they generally can be administered orally in seriously ill—but not hemodynamically unstable—patients.

Food does not significantly influence the bioavailability of most oral antimicrobial agents. However, the tetracyclines (particularly tetracycline) and the quinolones chelate multivalent cations resulting in decreased oral bioavailability.

A major complication of intravenous antibiotic therapy is infection due to the manipulation of the intravenous catheter. Peripheral catheters are changed every 48–72 hours to decrease the likelihood of catheter-associated infection, and antimicrobial-coated central venous catheters (minocycline and rifampin, chlorhexidine and sulfadiazine) have been associated with a decreased incidence of these infections. Most of these infections present with local signs of infection (erythema, tenderness) at the insertion site. *In a patient with fever who is receiving intravenous therapy, the catheter must always be considered a potential source.* Small-gauge (20–23F) peripherally inserted silicone or polyurethane catheters (Per-Q-Cath, A-Cath, Ven-A-Cath, and others) are associated with a low infection rate and can be maintained for 3–6 months without replacement. Such catheters are ideal for long-term outpatient antibiotic therapy.

J. Cost of Antibiotics

The cost of these agents can be substantial. In addition to acquisition costs and monitoring costs (drug levels, liver biochemical tests, electrolytes, etc), the cost of treating adverse reactions, the cost of treatment failure and superinfection, and the costs associated with drug administration must be considered.

K. Antimicrobial Stewardship

Antimicrobial stewardship is a critically important tool intended to optimize clinical outcomes while minimizing unintended consequences of antimicrobial use. These consequences include drug toxicity, superinfection, emergence of bacterial resistance, and impact upon the human microbiome. *The Infectious Diseases Society of America recommends establishment of an antimicrobial stewardship team at all acute care facilities.* The core members of a stewardship team should include an infectious diseases physician and a clinical pharmacist with infectious diseases training. If possible, the addition of a clinical microbiologist, an information system specialist, an infection control professional, and a hospital epidemiologist would be preferable. Key strategies for a stewardship team, as well as the individual prescriber, should include questions associated with the "Four Moments of Antibiotic Decision Making": (1) Does this patient have an infection that requires antibiotics? (2) Have the appropriate cultures been ordered before starting antibiotics? (3) After a few days of empiric antibiotics have passed, can antibiotics be stopped? Can therapy be narrowed? Can therapy be switched from intravenous to oral? (4) What duration of antibiotic therapy is necessary for this patient's diagnosis? Stewardship interventions centered upon one or more of the above questions have been demonstrated to decrease the risk of *C difficile* and *Candida* superinfection as well as attenuate the negative impact of antibiotics on the human microbiome.

HYPERSENSITIVITY

Penicillin Allergy

All penicillins are cross-sensitizing and cross-reacting. Skin tests using penicilloyl-polylysine and undegraded penicillin can identify most individuals with IgE-mediated reactions (eg, hives, bronchospasm). In those patients with positive reaction to skin tests, the incidence of subsequent immediate severe reactions associated with penicillin administration is high. *A history of a penicillin reaction in the past is often not reliable*. Only a small proportion (< 5%) of patients with a stated history of penicillin allergy experience an adverse reaction when challenged with the medication. The decision to administer penicillin or related medications (other β-lactams) to patients with an allergic history depends on the severity of the reported reaction, the severity of the infection being treated, and the availability of alternative medications. For patients with a history of severe reaction (anaphylaxis), alternative medications should be used. In the rare situations when there is a strong indication for using penicillin (eg, syphilis in pregnancy) in allergic patients, desensitization can be performed. If the reaction is mild (nonurticarial rash), the patient may be rechallenged with penicillin or may be given another β-lactam antibiotic.

Allergic reactions include anaphylaxis, serum sickness (urticaria, fever, joint swelling, angioedema 7–12 days after exposure), skin rashes, fever, interstitial nephritis, eosinophilia, hemolytic anemia, other hematologic disturbances, and vasculitis. The incidence of hypersensitivity to penicillin is estimated to be 1–5% among adults in the United States. *Life-threatening anaphylactic reactions are rare (0.05%)*. Ampicillin produces maculopapular skin rashes more frequently than other penicillins, but many ampicillin (and other β-lactam) rashes are not allergic in origin. The nonallergic ampicillin rash usually occurs after 3–4 days of therapy, is maculopapular, is more common in patients with coexisting viral illness (especially Epstein-Barr infection), and resolves with continued therapy. The maculopapular rash may or may not reappear with rechallenge. β-Lactams can induce nephritis with primary tubular lesions associated with anti–basement membrane antibodies.

If the intradermal test described below is negative, desensitization is not necessary, and a full dose of penicillin may be given. If the test is positive, alternative medications should be strongly considered. If that is not feasible, desensitization is necessary.

Patients with a history of allergy to penicillin are also at an increased risk for having a reaction to cephalosporins or carbapenems. A common approach to these patients is to assess the severity of the reaction. If an IgE-mediated reaction to penicillin can be excluded by history, cephalosporin can be administered. When the history justifies concern about an immediate-type reaction, penicillin skin testing should be performed. If the test is negative, cephalosporin or carbapenem can be given. If the test is positive, there is a *5–10% chance of cross-reactivity* with cephalosporins, and the decision whether to use cephalosporins depends on the availability of alternative agents and the severity of the infection. While carbapenems were considered highly cross-reactive with penicillins, the cross-reactivity appears to be minimal (1%).

IMMUNIZATION AGAINST INFECTIOUS DISEASES

RECOMMENDED IMMUNIZATION FOR ADULTS

Immunization is one of the most important tools (along with sanitation) used to prevent morbidity and mortality from infectious diseases. *Passive immunization* occurs when preformed antibodies are given (eg, immune globulin from pooled serum), resulting in temporary protection. However, the administration of most vaccinations induces a durable antibody response (*active immunity*). The two variants of active immunization are *live attenuated vaccines* (which are believed to result in an immunologic response more like natural infection) and *inactivated or killed vaccines.*

The schedule of vaccinations varies based on the risk of the disease being prevented by vaccination, whether a vaccine has been given previously, the immune status of the patient (probability of responding to vaccine) and safety of the vaccine (live versus killed product, as well as implications for the fetus in pregnant women). Recommendations for healthy adults as well as special populations based on medical conditions are summarized in Table 35–7, which can be accessed online at https://www.cdc.gov/vaccines/. Recommendations for SARS-CoV-2 vaccinations and boosters are being updated regularly.

1. Healthy Adults

Vaccination recommendations are made by the Advisory Committee on Immunization Practices (ACIP) of the US CDC (Table 35–7). Characteristics of selected COVID-19 vaccines can be found online and in Chapter 37.

2. Pregnant Women

Given the uncertainty of risks to the fetus, *vaccination during pregnancy is generally avoided* with the following exceptions: tetanus (transfer of maternal antibodies across the placenta is important to prevent neonatal tetanus), diphtheria, and influenza. Live vaccines are avoided during pregnancy.

Influenza can be a serious infection if acquired in pregnancy, and *all pregnant women should be offered influenza (inactivated) vaccination.* The live attenuated (intranasal) influenza vaccine is *not* recommended during pregnancy.

3. Adults with HIV

Patients with HIV have impaired cellular and B-cell responses. Inactivated or killed vaccinations can generally be given without any consequence, but the recipient may not be able to mount an adequate antibody response. Live or attenuated vaccines are generally avoided with some exceptions (ie, in patients with $CD4^+$ T lymphocytes > 200 cells/mcL [0.2×10^9/L]). Guidelines for vaccinating patients with HIV have been issued jointly by the CDC, the US National Institutes of Health, and the HIV Medical Association of the IDSA. Timing of vaccination is important to optimize response. If possible, vaccination should be given early in the course of HIV disease or following immune reconstitution.

4. Hematopoietic Cell Transplant Recipients

HCT recipients have varying rates of immune reconstitution following transplantation, depending on (1) the type of chemotherapy or radiotherapy used pretransplant (in autologous HCT), (2) the preparative regimen used for the transplant, (3) whether graft-versus-host disease is present, and (4) the type of immunosuppression used posttransplantation (in allogeneic HCT). Vaccines may not work immediately in the posttransplant period. B cells may take 3–12 months to return to normal posttransplant, and naïve T cells that can respond to new antigens appear only 6–12 months posttransplant. B cells of posttransplant patients treated with rituximab may take up to 6 months to fully recover after the last dose of the medication. Vaccines are therefore administered 6–12 months following transplantation with a minimum of 1 month between doses to maximize the probability of response.

5. Solid Organ Transplant Recipients

Solid organ transplant recipients demonstrate a broad spectrum of immunosuppression, depending on the reason for and type of organ transplantation and the nature of the immunosuppression (including T cell–depleting agents during treatment of organ rejection). These factors affect the propensity for infection posttransplantation and the ability to develop antibody responses to vaccination. In many cases, the time between placing a patient on a transplant list and undergoing the transplantation takes months or years. Providers should take this opportunity to ensure that indicated *vaccines are given during this pretransplant period to optimize antibody responses*. If this is not possible, most experts give vaccines 3–6 months following transplantation. Live vaccines are contraindicated in the posttransplant period.

RECOMMENDED IMMUNIZATIONS FOR TRAVELERS

Individuals traveling to other countries frequently require immunizations in addition to those routinely recommended and may benefit from chemoprophylaxis against various diseases. Vaccinations against yellow fever and meningococcus are the only ones required by certain countries. These and other travel-specific vaccines are listed at http://wwwnc.cdc.gov/travel/destinations/list.

Various vaccines can be given simultaneously at different sites. Some, such as cholera, plague, and typhoid vaccine, cause significant discomfort and are best given at different times. In general, live attenuated vaccines (measles, mumps, rubella, yellow fever, and oral typhoid vaccine) should *not* be given to immunosuppressed individuals or household members of immunosuppressed people or to pregnant persons. Immunoglobulin should not be given for 3 months before or at least 2 weeks after live virus vaccines, because it may attenuate the antibody response.

Chemoprophylaxis of malaria is discussed in Chapter 40.

VACCINE SAFETY

Most vaccines are safe to administer. *In general, it is recommended that the use of live vaccines be avoided in immunocompromised patients, including pregnant women*. Vaccines are generally not contraindicated in the following situations: mild, acute illness with low-grade fevers (< 40.5°C); concurrent antibiotic therapy; soreness or redness at the site; and family history of adverse reactions to vaccinations. Absolute contraindications to vaccines are rare (Table 35–8).

Table 35–7. Recommended adult immunization schedule—United States, 2025.

Vaccine	19–26 years	27–49 years	50–64 years	≥65 years

- 🟨 Recommended for all adults who lack documentation of vaccination, **OR** lack evidence of immunity
- 🟪 Not recommended for all adults, but recommended for some adults based on either age **OR** increased risk for or severe outcomes from disease
- 🟦 Recommended vaccination based on shared clinical decision–making
- 🟫 Recommended for all adults, and additional doses may be necessary based on medical condition or other indications. See Notes.
- 🟧 Precaution: Might be indicated if benefit of protection outweighs risk of adverse reaction
- 🟥 Contraindicated or not recommended *Vaccinate after pregnancy, if indicated
- ⬜ No Guidance/ Not Applicable

a. Precaution for LAIV3 does not apply to alcoholism. b. See notes for influenza; hepatitis B; measles, mumps, and rubella; and varicella vaccinations. c. Hematopoietic stem cell transplant.

(*continued*)

Table 35–7. Recommended adult immunization schedule—United States, 2025. (continued)

NOTES

For vaccination recommendations for persons ages 18 years or younger, see the Recommended Child and Adolescent Immunization Schedule, 2025: www.cdc.gov/vaccines/hcp/imz-schedules/child-adolescent-age.html

Additional Information

- For calculating intervals between doses, 4 weeks = 28 days. Intervals of ≥4 months are determined by calendar months.
- Within a number range (e.g., 12–18), a dash (–) should be read as "through."
- Vaccine doses administered ≤4 days before the minimum age or interval are considered valid. Doses of any vaccine administered ≥5 days earlier than the minimum age or minimum interval should not be counted as valid and should be repeated. **The repeat dose should be spaced after the invalid dose by the recommended minimum interval.** For further details, see Table 3–2, Recommended and minimum ages and intervals between vaccine doses, in *General Best Practice Guidelines for Immunization* at www.cdc.gov/vaccines/hcp/acip–recs/general–recs/timing.html.
- Information on travel vaccination requirements and recommendations is available at www.cdc.gov/travel/.
- For vaccination of persons with immunodeficiencies, see Table 8–1, Vaccination of persons with primary and secondary immunodeficiencies, in *General Best Practice Guidelines for Immunization* at https://www.cdc.gov/vaccines/hcp/imz-best-practices/altered-immunocompetence.html?CDC_AAref_Val=https://www.cdc.gov/vaccines/hcp/acip-recs/general-recs/immunocompetence.html
- For information about vaccination in the setting of a vaccine–preventable disease outbreak, contact your state or local health department.
- The National Vaccine Injury Compensation Program (VICP) is a no–fault alternative to the traditional legal system for resolving vaccine injury claims. All vaccines included in the adult immunization schedule except PPSV23, RSV, RZV, Mpox, and COVID–19 vaccines are covered by the National Vaccine Injury Compensation Program (VICP). Mpox and COVID–19 vaccines are covered by the Countermeasures Injury Compensation Program (CICP). For more information, see www.hrsa.gov/vaccinecompensation or www.hrsa.gov/cicp.

COVID–19 vaccination

Routine vaccination

Age 19–64 years

- **Unvaccinated:**
  - 1 dose 2024–25 Moderna or Pfizer-BioNTech
  - 2 doses 2024–25 Novavax at 0, 3–8 weeks
- **Previously vaccinated before 2024–25 vaccine with:**
  - **1 or more doses Moderna or Pfizer-BioNTech:** 1 dose 2024–25 Moderna or Novavax or Pfizer-BioNTech at least 8 weeks after the most recent dose.
  - **1 dose Novavax:** 1 dose 2024–25 Novavax 3–8 weeks after most recent dose. If more than 8 weeks after most recent dose, administer 1 dose 2024–25 Moderna or Novavax or Pfizer-BioNTech.
  - **2 or more doses Novavax:** 1 dose 2024–25 Moderna or Novavax or Pfizer-BioNTech at least 8 weeks after the most recent dose.
  - **1 or more doses Janssen:** 1 dose 2024–25 Moderna or Novavax or Pfizer-BioNTech.

Age 65 years and older

- **Unvaccinated:** follow recommendations above for unvaccinated persons ages 19–64 years **and** administer dose 2 of 2024–25 Moderna or Novavax or Pfizer-BioNTech 6 months later (minimum interval 2 months).
- **Previously vaccinated before 2024–25 vaccine:** follow recommendations above for previously vaccinated persons ages 19–64 years **and** administer dose 2 of 2024–25 Moderna or Novavax or Pfizer-BioNTech 6 months later (minimum interval 2 months).

Special situations

Persons who are moderately or severely immunocompromised. Use vaccine from the same manufacturer for all doses in the initial vaccination series.

- **Unvaccinated:**
  - 4 doses (**3-dose initial series 2024–25 Moderna** at 0, 4 weeks, and at least 4 weeks after dose 2, followed by 1 dose 2024–25 Moderna or Novavax or Pfizer-BioNTech 6 months later [minimum interval 2 months]). May administer additional doses.*
  - 4 doses (**3-dose initial series 2024–25 Pfizer-BioNTech** at 0, 3 weeks, and at least 4 weeks after dose 2, followed by 1 dose 2024–25 Moderna or Novavax or Pfizer-BioNTech 6 months later [minimum interval 2 months]). May administer additional doses.*
  - 3 doses (**2-dose initial series 2024–25 Novavax** at 0, 3 weeks, followed by 1 dose Moderna or Novavax or Pfizer-BioNTech 6 months later [minimum interval 2 months]). May administer additional doses.*
- **Incomplete initial vaccination series before 2024–25 vaccine:**
  - **Previous vaccination with Moderna**

    1 dose Moderna: complete initial series with 2 doses 2024–25 Moderna at least 4 weeks apart (administer dose 1 4 weeks after most recent dose), followed by 1 dose 2024–25 Moderna or Novavax or Pfizer-BioNTech 6 months later (minimum interval 2 months). May administer additional doses.*

    2 doses Moderna: complete initial series with 1 dose 2024–25 Moderna at least 4 weeks after most recent dose, followed by 1 dose 2024–25 Moderna or Novavax or Pfizer-BioNTech 6 months later (minimum interval 2 months). May administer additional doses.*

  - **Previous vaccination with Pfizer-BioNTech**
    1 dose Pfizer-BioNTech: complete initial series with 2 doses 2024–25 Pfizer-BioNTech at least 4 weeks apart (administer dose 1 3 weeks after most recent dose), followed by 1 dose 2024–25 Moderna or Novavax or Pfizer-BioNTech 6 months later (minimum interval 2 months). May administer additional doses.*
    2 doses Pfizer-BioNTech: complete initial series with 1 dose 2024–25 Pfizer-BioNTech at least 4 weeks after most recent dose, followed by 1 dose 2024–25 Moderna or Novavax or Pfizer-BioNTech 6 months later (minimum interval 2 months). May administer additional doses.*
  - **Previous vaccination with Novavax**
    1 dose Novavax: complete initial series with 1 dose 2024–25 Novavax at least 3 weeks after most recent dose, followed by 1 dose 2024–25 Moderna or Novavax or Pfizer-BioNTech 6 months later (minimum interval 2 months). May administer additional doses.*
- **Completed the initial vaccination series before 2024–25 vaccine with:**
  - **3 or more doses Moderna or 3 or more doses Pfizer-BioNTech:** 2 doses 2024–25 Moderna or Novavax or Pfizer-BioNTech 6 months apart (minimum interval 2 months). Administer dose 1 at least 8 weeks after the most recent dose. May administer additional doses.*
  - **2 or more doses Novavax:** 2 doses 2024–25 Moderna or Novavax or Pfizer-BioNTech 6 months apart (minimum interval 2 months). Administer dose 1 at least 8 weeks after the most recent dose. May administer additional doses.*

***Additional doses of 2024–25 COVID-19 vaccine for moderately or severely immunocompromised:** based on shared clinical decision-making and administered at least 2 months after the most recent dose (see Table 2 at www.cdc.gov/vaccines/covid-19/clinical-considerations/interim-considerations-us.html#table-02.). For description of moderate and severe immunocompromising conditions and treatment, see www.cdc.gov/vaccines/covid-19/clinical-considerations/interim-considerations-us.html#immunocompromising-conditions-treatment.

Unvaccinated persons have never received any COVID-19 vaccine doses. There is no preferential recommendation for the use of one COVID-19 vaccine over another when more than one recommended age-appropriate vaccine is available. Administer an age-appropriate COVID-19 vaccine product for each dose.

For information about interchangeability of COVID-19 vaccines, see wcms-wp.cdc.gov/vaccines/covid-19/clinical-considerations/interim-considerations-us.html#Interchangeability.

Current COVID-19 schedule and dosage formulation available at www.cdc.gov/covidschedule. For more information on Emergency Use Authorization (EUA) indications for COVID-19 vaccines, see https://www.fda.gov/emergency-preparedness-and-response/coronavirus-disease-2019-covid-19/covid-19-vaccines-2024-2025.

***Haemophilus influenzae* type b vaccination**

Special situations

- **Anatomical or functional asplenia (including sickle cell disease):** 1 dose if previously did not receive Hib vaccine
  - **Elective splenectomy:** 1 dose preferably at least 14 days before splenectomy
- **Hematopoietic stem cell transplant (HSCT):** 3-dose series 4 weeks apart starting 6–12 months after successful transplant, regardless of Hib vaccination history

Hepatitis A vaccination

Routine vaccination

- **Any person who is not fully vaccinated and requests vaccination** (identification of risk factor not required): complete 2-dose series HepA (Havrix 6–12 months apart or Vaqta 6–18 months apart [minimum interval: 6 months]) or 3-dose series HepA–HepB (Twinrix at 0, 1, 6 months [minimum intervals: dose 1 to dose 2 = 4 weeks; dose 2 to dose 3 = 5 months])

Special situations

- **Any person who is not fully vaccinated and who is at risk for hepatitis A virus infection or severe disease from hepatitis A virus infection:** complete 2-dose series HepA or 3-dose series HepA–HepB as above. Risk factors include:
  - **Chronic liver disease** including persons with hepatitis B, hepatitis C, cirrhosis, fatty liver disease, alcoholic liver disease, autoimmune hepatitis, alanine aminotransferase (ALT) or aspartate aminotransferase (AST) level greater than twice the upper limit of normal.
  - **HIV infection**
  - **Men who have sex with men**
  - **Injection or noninjection drug use**
  - **Persons experiencing homelessness**
  - **Work with hepatitis A virus** in research laboratory or with nonhuman primates with hepatitis A virus infection
  - **Travel in countries with high or intermediate endemic hepatitis A:** HepA–HepB (Twinrix) may be administered on an accelerated schedule of 3 doses at 0, 7, and 21–30 days, followed by a booster dose at 12 months.
  - **Close, personal contact with international adoptee** (e.g., household or regular babysitting) in first 60 days after arrival from country with high or intermediate endemic hepatitis A: dose 1 as soon as adoption is planned; preferably at least 2 weeks before adoptee's arrival.
  - **Pregnancy** if at risk for infection or severe outcome from infection during pregnancy
  - **Settings for exposure,** including health care setting serving persons who use injection or noninjection drugs, or group homes and nonresidential day care facilities for developmentally disabled persons (individual risk factor screening not required)

(*continued*)

Table 35–7. Recommended adult immunization schedule—United States, 2025. (continued)

Hepatitis B vaccination
Routine vaccination

- **Age 19 through 59 years:** complete a 2- or 3- or 4-dose series
  - 2-dose series only applies when 2 doses of Heplisav–B are used at least 4 weeks apart
  - 3-dose series Engerix–B, PreHevbrio*, or Recombivax HB at 0, 1, 6 months (minimum intervals: dose 1 to dose 2 = 4 weeks; dose 2 to dose 3 = 8 weeks; dose 1 to dose 3 = 16 weeks)
  - 3-dose series HepA–HepB (Twinrix) at 0, 1, 6 months (minimum intervals: dose 1 to dose 2 = 4 weeks; dose 2 to dose 3 = 5 months)
  - 4-dose series HepA–HepB (Twinrix) accelerated schedule of 3 doses at 0, 7, and 21–30 days, followed by a booster dose at 12 months

***Note:** PreHevbrio is not recommended in pregnancy due to lack of safety data in pregnant women.

- **Age 60 years or older without** known risk factors for hepatitis B virus infection **may** receive a HepB vaccine series.
- **Age 60 years or older with** known risk factors for hepatitis B virus infection **should** receive a HepB vaccine series.
- **Any adult age 60 years of age or older** who requests HepB vaccination **should** receive a HepB vaccine series.
  - **Risk factors for hepatitis B virus infection include:**
    - **Chronic liver disease** including persons with hepatitis C, cirrhosis, fatty liver disease, alcoholic liver disease, autoimmune hepatitis, alanine aminotransferase (ALT) or aspartate aminotransferase (AST) level greater than twice the upper limit of normal.
    - **HIV infection**
    - **Sexual exposure risk** e.g., sex partners of hepatitis B surface antigen (HBsAg)–positive persons, sexually active persons not in mutually monogamous relationships, persons seeking evaluation or treatment for a sexually transmitted infection, men who have sex with men
    - **Current or recent injection drug use**
    - **Percutaneous or mucosal risk for exposure to blood** e.g., household contacts of HBsAg–positive persons, residents and staff of facilities for developmentally disabled persons, health care and public safety personnel with reasonably anticipated risk for exposure to blood or blood–contaminated body fluids, persons on maintenance dialysis (including in–center or home hemodialysis and peritoneal dialysis), persons who are predialysis, and patients with diabetes**
    - **Incarceration**
    - **Travel in countries with high or intermediate endemic hepatitis B**

****Age 60 years or older with diabetes:** Based on shared clinical decision making, 2-, 3-, or 4-dose series as above.

Special situations

- **Patients on dialysis:** complete a 3- or 4-dose series
  - 3-dose series Recombivax HB at 0, 1, 6 months (Note: Use Dialysis Formulation 1 mL = 40 mcg)
  - 4-dose series Engerix–B at 0, 1, 2, and 6 months (Note: Use 2 mL dose instead of the normal adult dose of 1 mL)
- **Age 20 years or older with an immunocompromising condition:** complete a 2- or 3- or 4-dose series.
  - 3-dose series Recombivax HB at 0, 1, 6 months (Note: Use Dialysis Formulation 1 ml = 40 mcg)
  - 4-dose series Engerix–B at 0, 1, 2, and 6 months (Note: Use 2mL dose instead of the normal adult dose of 1mL)
  - 2-dose series Heplisav–B at 0, 1 months
  - 3-dose series PreHevbrio* at 0, 1, 6 months

Human papillomavirus vaccination
Routine vaccination

- **All persons through age 26 years:** complete 2– or 3-dose series depending on age at initial vaccination or condition.
  - **Age 9–14 years at initial vaccination and received 1 dose or 2 doses less than 5 months apart:** 1 additional dose
  - **Age 9–14 years at initial vaccination and received 2 doses at least 5 months apart:** HPV vaccination series complete, no additional dose needed
  - **Age 15 years or older at initial vaccination:** 3-dose series at 0, 1–2 months, 6 months (minimum intervals: dose 1 to dose 2 = 4 weeks; dose 2 to dose 3 = 12 weeks; dose 1 to dose 3 = 5 months; repeat dose if administered too soon)
- No additional dose recommended when any HPV vaccine series of any valency has been completed using the recommended dosing intervals.

Shared clinical decision–making

- **Adults age 27–45 years:** Based on shared clinical decision–making, complete a 2-dose series (if initiated age 9–14 years) or 3-dose series (if initiated ≥15 years).

For additional information on shared clinical decision–making for HPV; see www.cdc.gov/vaccines/hcp/admin/downloads/isd–job–aid–scdm–hpv–shared–clinical–decision–making–hpv.pdf

Special situations

- **Age ranges recommended above for routine and catch–up vaccination or shared clinical decision–making also apply in special situations**
  - **Immunocompromising conditions, including HIV infection**: complete 3-dose series, even for those who initiate vaccination at age 9 through 14 years.
  - **Pregnancy**: Pregnancy testing is not needed before vaccination. HPV vaccination is not recommended until after pregnancy. No intervention needed if inadvertently vaccinated while pregnant.

Influenza vaccination

Routine vaccination

- **Age 19 years or older:** 1 dose any influenza vaccine appropriate for age and health status annually
  - **Solid organ transplant recipients aged 19 through 64 years receiving immunosuppressive medications:** HD–IIV3 and aIIV3 are acceptable options. No preference over other age–appropriate IIV3 or RIV3.
  - **Age 65 years or older:** Any one of HD-IIV3, RIV3, or aIIV3 is preferred. If none of these three vaccines is available, then any other age–appropriate influenza vaccine should be used.
- For the 2024–25 season, see www.cdc.gov/mmwr/volumes/73/rr/rr7305a1.htm
- For the 2025–26 season, see the 2025–26 ACIP influenza vaccine recommendations.

Special situations

- **Close contacts (e.g., caregivers, healthcare workers) of severely immunosuppressed persons who require a protected environment:** should not receive LAIV3. If LAIV3 is given, they should avoid contact with/caring for such immunosuppressed persons for 7 days after vaccination.

Note: Persons with an egg allergy can receive any influenza vaccine (egg-based or non–egg based) appropriate for age and health status.

Measles, mumps, and rubella vaccination

Routine vaccination

- **No evidence of immunity to measles, mumps, or rubella:** 1 dose
  - **Evidence of immunity:** Born before 1957 (except for health care personnel, see below), documentation of receipt of MMR vaccine, laboratory evidence of immunity or disease (diagnosis of disease without laboratory confirmation is not evidence of immunity)

Special situations

- **Pregnancy with no evidence of immunity to rubella:** MMR contraindicated during pregnancy; after pregnancy (before discharge from health care facility): 1 dose
- **Nonpregnant women of childbearing age with no evidence of immunity to rubella:** 1 dose
- **HIV infection with CD4 percentages ≥15% and CD4 count ≥200 cells/mm3 for at least 6 months and no evidence of immunity to measles, mumps, or rubella:** complete 2-dose series at least 4 weeks apart; MMR contraindicated for HIV infection with CD4 percentage <15% or CD4 count <200 cells/mm^3
- **Severe immunocompromising conditions:** MMR contraindicated
- **Students in postsecondary educational institutions, international travelers, and household or close, personal contacts of immunocompromised persons with no evidence of immunity to measles, mumps, or rubella:** complete 2-dose series at least 4 weeks apart if previously did not receive any doses of MMR or 1 dose if previously received 1 dose MMR
- **In mumps outbreak settings,** for information about additional doses of MMR (including 3rd dose of MMR), see www.cdc.gov/mmwr/volumes/67/wr/mm6701a7.htm
- **Health care personnel:**
  - **Born before 1957 with no evidence of immunity to measles, mumps, or rubella:** Consider 2-dose series at least 4 weeks apart for protection against measles or mumps or 1 dose for protection against rubella.
  - **Born in 1957 or later with no evidence of immunity to measles, mumps, or rubella:** complete 2-dose series at least 4 weeks apart for protection against measles or mumps or at least 1 dose for protection against rubella.

Meningococcal vaccination

Special situations for MenACWY

- **Anatomical or functional asplenia (including sickle cell disease), HIV infection, persistent complement component deficiency, complement inhibitor (e.g., eculizumab, ravulizumab) use:** 2-dose primary series Menveo or MenQuadfi at least 8 weeks apart; 1 booster dose 5 years after primary series and every 5 years if risk remains
- **Travel in countries with hyperendemic or epidemic meningococcal disease, or for microbiologists routinely exposed to *Neisseria meningitidis*:** 1 dose Menveo or MenQuadfi; 1 booster dose 5 years after primary series and every 5 years if risk remains
- **First–year college students who live in residential housing (if not previously vaccinated at age 16 years or older) or military recruits:** 1 dose Menveo or MenQuadfi

For MenACWY recommendations **in outbreak setting** (e.g., in community or organizational settings, or among men who have sex with men) and **additional meningococcal vaccination** information, see www.cdc.gov/mmwr/volumes/69/rr/rr6909a1.htm

Shared clinical decision–making for MenB

- **Adolescents and young adults age 16–23 years (age 16–18 years preferred)* not at increased risk for meningococcal disease:** based on shared clinical decision–making
  - **Bexsero or Trumenba (use same brand for all doses):** 2-dose series at least 6 months apart (if dose 2 is administered earlier than 6 months, administer dose 3 at least 4 months after dose 2)

*To optimize rapid protection (e.g., for students starting college in less than 6 months), a 3-dose series (0, 1–2, 6 months) may be administered.

For additional information on shared clinical decision–making for MenB, see https://www.cdc.gov/vaccines/media/pdfs/2025/03/2024-isd-job-aid-scdm-menb-508-remediated.pdf?CDC_AAref_Val=https://www.cdc.gov/vaccines/hcp/admin/downloads/isd-job-aid-scdm-mening-b-shared-clinical-decision-making.pdf

Special situations for MenB

- **Anatomical or functional asplenia (including sickle cell disease), persistent complement component deficiency, complement inhibitor (e.g., eculizumab, ravulizumab) use, or microbiologists routinely exposed to *Neisseria meningitidis*.**
  - **Bexsero or Trumenba (use same brand for all doses including booster doses):** 3-dose primary series at 0, 1–2, 6 months (if dose 2 was administered at least 6 months after dose 1, dose 3 not needed; if dose 3 is administered earlier than 4 months after dose 2, a 4th dose should be administered at least 4 months after dose 3).
  - **Booster doses:** 1 booster dose one year after primary series and every 2–3 years if risk remains

---

(*continued*)

Table 35–7. Recommended adult immunization schedule—United States, 2025. (continued)

- **Pregnancy:** Delay MenB until after pregnancy due to lack of safety data in pregnant women. May administer if at increased risk and vaccination benefits outweigh potential risks.

For MenB recommendations **in outbreak setting** (e.g., in community or organizational settings, or among men who have sex with men) and **additional meningococcal vaccination** information, see www.cdc.gov/mmwr/volumes/69/rr/rr6909a1.htm.

Note: MenB vaccines may be administered simultaneously with MenACWY vaccines if indicated, but at a different anatomic site, if feasible.
Adults may receive a single dose of Penbraya (MenACWY–TT/MenB–FHbp) as an alternative to separate administration of MenACWY and MenB when both vaccines would be given on the same clinic day. For adults not at increased risk, if Penbraya is used for dose 1 MenB, then MenB–FHbp (Trumenba) should be administered for dose 2 MenB. For adults at increased risk of meningococcal disease, Penbraya may be used for additional MenACWY and MenB doses (including booster doses) if both would be given on the same clinic day **and** at least 6 months have elapsed since most recent Penbraya dose.

Mpox vaccination
Special situations

- **Any person at risk for mpox infection:** complete 2-dose series, 28 days apart.
  Risk factors for mpox infection include:
  - Gay, bisexual, or other MSM, or a person who has sex with gay, bisexual, or other MSM who in the past 6 months have had one of the following:
    - A new diagnosis of at least 1 sexually transmitted disease
      More than 1 sex partner
      Sex at a commercial sex venue
    - Sex in association with a large public event in a geographic area where mpox transmission is occurring
- Persons who are sexual partners of the persons described above
- Persons who anticipate experiencing any of the situations described above
- **Pregnancy:** There is currently no ACIP recommendation for Jynneos use in pregnancy due to lack of safety data in pregnant women. Pregnant women with any risk factor described above may receive Jynneos.
- **Health care personnel:** Vaccination to protect against occupational risk in healthcare settings is not routinely recommended.

For detailed information, see www.cdc.gov/mpox/hcp/vaccine-considerations/vaccination-overview.html.

Pneumococcal vaccination
Routine vaccination

- **Age 50 years or older who have:**
  - **Not previously received a dose of PCV13, PCV15, PCV20, or PCV21 or whose previous vaccination history is unknown:** 1 dose PCV15 or 1 dose PCV20 or 1 dose PCV21
    - If PCV15 is used, administer 1 dose PPSV23 at least 1 year after the PCV15 dose (may use minimum interval of 8 weeks for adults with an immunocompromising condition,* cochlear implant, or cerebrospinal fluid leak).
  - **Previously received only PCV7:** follow the recommendation above.
  - **Previously received only PCV13:** 1 dose PCV20 or 1 dose PCV21 at least 1 year after the last PCV13 dose
  - **Previously received only PPSV23:** 1 dose PCV15 or 1 dose PCV20 or 1 dose PCV21, at least 1 year after the last PPSV23 dose.
    - If PCV15 is used, no additional PPSV23 doses are recommended.
  - **Previously received both PCV13 and PPSV23 but NO PPSV23 was received at age 65 years or older:** 1 dose PCV20 or 1 dose PCV21 at least 5 years after the last pneumococcal vaccine dose.
  - **Previously received both PCV13 and PPSV23, AND PPSV23 was received at age 65 years or older:** Based on shared clinical decision–making, 1 dose of PCV20 or 1 dose of PCV21 at least 5 years after the last pneumococcal vaccine dose.

Special situations

- **Age 19–49 years with certain underlying medical conditions or other risk factors** who have:**
  - **Not previously received a PCV13, PCV15, PCV20, or PCV21 or whose previous vaccination history is unknown:** 1 dose PCV15 or 1 dose PCV20 or 1 dose PCV21
    - If PCV15 is used, administer 1 dose PPSV23 at least 1 year after the PCV15 dose (may use minimum interval of 8 weeks for adults with an immunocompromising condition,* cochlear implant, or cerebrospinal fluid leak).
  - **Previously received only PCV7:** follow the recommendation above.
  - **Previously received only PCV13:** 1 dose PCV20 or 1 dose PCV21 at least 1 year after the last PCV13 dose
  - **Previously received only PPSV23:** 1 dose PCV15 or 1 dose PCV20 or 1 dose PCV21, at least 1 year after the last PPSV23 dose.
- If PCV15 is used, no additional PPSV23 doses are recommended.
  - **Previously received PCV13 and 1 dose of PPSV23:**
    - Cochlear implant, cerebrospinal fluid leak, or an immunocompromising condition*: 1 dose PCV20 or 1 dose PCV21 at least 5 years after the last pneumococcal vaccine dose.
    - Alcoholism, chronic heart/liver/lung disease, cigarette smoking, or diabetes mellitus: no additional PCV or PPSV23 doses recommended at this time. Review pneumococcal recommendations when age 50 years or older.

Adults aged 19 years and older who have received PCV20 or PCV21: no additional pneumococcal vaccine dose recommended.
Pregnancy: no recommendation for PCV or PPSV23 due to limited data. Summary of existing data on pneumococcal vaccination during pregnancy can be found at www.cdc.gov/mmwr/volumes/72/rr/rr7203a1.htm.
PPSV23 not available: adults aged 19 years or older who received PCV15 but have not yet completed PPSV23 series, can complete the series with either 1 dose of PCV20 or 1 dose of PCV21 if they no longer have access to PPSV23.
For guidance on determining which pneumococcal vaccines a patient needs and when, please refer to the mobile app which can be downloaded here: www.cdc.gov/pneumococcal/hcp/vaccine-recommendations/app.html.
***Note:** Immunocompromising conditions include chronic renal failure, nephrotic syndrome, immunodeficiencies, iatrogenic immunosuppression, generalized malignancy, HIV infection, Hodgkin disease, leukemia, lymphoma, multiple myeloma, solid organ transplant, congenital or acquired asplenia, or sickle cell disease or other hemoglobinopathies.
****Note:** Underlying medical conditions or other risk factors include alcoholism, chronic heart/liver/lung disease, chronic renal failure, cigarette smoking, cochlear implant, congenital or acquired asplenia, CSF leak, diabetes mellitus, generalized malignancy, HIV infection, Hodgkin disease, immunodeficiencies, iatrogenic immunosuppression, leukemia, lymphoma, multiple myeloma, nephrotic syndrome, solid organ transplant, or sickle cell disease or other hemoglobinopathies.

Poliovirus vaccination
Routine vaccination
- **Adults known or suspected to be unvaccinated or incompletely vaccinated:** administer remaining doses (1, 2, or 3 IPV doses) to complete a 3-dose primary series.* Unless there are specific reasons to believe they were not vaccinated, most adults who were born and raised in the United States can assume they were vaccinated against polio as children.

Special situations
- **Adults at increased risk for exposure to poliovirus who completed primary series*:** may administer one lifetime IPV booster.

***Note:** Complete primary series consists of at least 3 doses of IPV or trivalent oral poliovirus vaccine (tOPV) in any combination.
For detailed information, see www.cdc.gov/vaccines/vpd/polio/hcp/recommendations.html

Respiratory syncytial virus vaccination
Routine vaccination
- **Pregnant women of any age:**
  - **Pregnant at 32 weeks 0 days through 36 weeks and 6 days gestation from September through January in most of the continental United States*:** 1 dose **Abrysvo**. Administer RSV vaccine regardless of previous RSV infection.
  - Either maternal RSV vaccination with Abrysvo or infant immunization with nirsevimab (RSV monoclonal antibody) is recommended to prevent severe respiratory syncytial virus disease in infants.
  - **All other pregnant women:** RSV vaccine not recommended
  - **Subsequent pregnancies:** additional doses not recommended. No data are available to inform whether additional doses are needed in subsequent pregnancies. Infants born to pregnant women who received RSV vaccine during a previous pregnancy should receive nirsevimab.

***Note:** Providers in jurisdictions with RSV seasonality that differs from most of the continental United States (e.g., Alaska, jurisdictions with tropical climate) should follow guidance from public health authorities on timing of administration. Refer to the 2025 Child and Adolescent Immunization Schedule for considerations regarding nirsevimab administration to infants.
Age 75 years or older
- **Unvaccinated:** 1 dose (Arexvy or Abrysvo or mResvia). Additional doses not recommended
- **Previously vaccinated:** additional doses not recommended. No data are available to inform whether additional doses are needed.

Special situations
- **Age 60–74 years:**
  - **Unvaccinated and at increased risk of severe RSV disease**:** 1 dose (Arexvy or Abrysvo or mResvia). Additional doses not recommended.
  - **Previously vaccinated:** additional doses not recommended. No data are available to inform whether additional doses are needed.

Persons 60 years and older can get RSV vaccine at any time but it is best to administer in late summer and early fall before RSV spreads in communities—ideally August through October in most of continental United States. For further guidance, see www.cdc.gov/mmwr/volumes/73/wr/mm7332e1.htm.
****Note: *People can self–attest to the presence of a risk factor.* The following medical and other conditions increase the risk of severe RSV disease:**
- Chronic cardiovascular disease e.g., heart failure, coronary artery disease, congenital heart disease. Excludes isolated hypertension.
- Chronic lung or respiratory disease e.g., chronic obstructive pulmonary disease, emphysema, asthma, interstitial lung disease, cystic fibrosis
- End stage renal disease or dependence on hemodialysis or other renal replacement therapy
- Diabetes mellitus complicated by chronic kidney disease, neuropathy, retinopathy, or other end–organ damage
- Diabetes mellitus requiring treatment with insulin or sodium–glucose cotransporter 2 (SGLT2) inhibitor
- Neurologic or neuromuscular conditions causing impaired airway clearance or respiratory muscle weakness e.g., post–stroke dysphagia, amyotrophic lateral sclerosis, muscular dystrophy. Excludes history of stroke without impaired airway clearance.
- Chronic liver disease e.g., cirrhosis

(*continued*)

Table 35–7. Recommended adult immunization schedule—United States, 2025. (continued)

- Chronic hematologic conditions e.g., sickle cell disease, thalassemia
- Severe obesity (body mass index ≥ 40 kg/m^2)
- Moderate or severe immune compromise
- Residence in a nursing home
- Other chronic medical conditions or risk factors that a health care provider determines would increase the risk of severe disease due to viral respiratory infection e.g., frailty, concern for presence of undiagnosed chronic medical conditions, residence in a remote or rural community where escalation of medical care is challenging.

Tetanus, diphtheria, and pertussis vaccination
Routine vaccination

- **Completed primary series and received at least 1 dose Tdap at age 10 years or older:** Td or Tdap every 10 years thereafter
- **Completed primary series and did NOT receive Tdap at age 10 years or older:** 1 dose Tdap, then Td or Tdap every 10 years thereafter
- **Unvaccinated or incomplete primary vaccination series for tetanus, diphtheria, or pertussis:** administer remaining doses (1, 2, or 3 doses) to complete 3-dose primary series. 1 dose Tdap followed by 1 dose Td or Tdap at least 4 weeks later, and a third dose of Td or Tdap 6–12 months later (Tdap is preferred as first dose and can be substituted for any Td dose), then Td or Tdap every 10 years thereafter.

Special situations

- **Pregnancy:** 1 dose Tdap during each pregnancy, preferably in early part of gestational weeks 27–36
- **Wound management:** Persons with 3 or more doses of tetanus–toxoid–containing vaccine: For clean and minor wounds, administer Tdap or Td if more than 10 years since last dose of tetanus–toxoid–containing vaccine; for all other wounds, administer Tdap or Td if more than 5 years since last dose of tetanus–toxoid–containing vaccine. Tdap is preferred for persons who have not previously received Tdap or whose Tdap history is unknown. If a tetanus–toxoid–containing vaccine is indicated for a pregnant woman, use Tdap. For detailed information, see www.cdc.gov/mmwr/volumes/69/wr/mm6903a5.htm

Varicella vaccination
Routine vaccination

- **No evidence of immunity to varicella:** 2-dose series 4–8 weeks apart if previously did not receive varicella–containing vaccine (VAR or MMRV [measles–mumps–rubella–varicella vaccine] for children); if previously received 1 dose varicella–containing vaccine, 1 dose at least 4 weeks after first dose.
  - **Evidence of immunity:** U.S.–born before 1980 (except for pregnant women and health care personnel [see below]), documentation of 2 doses varicella–containing vaccine at least 4 weeks apart, diagnosis or verification of history of varicella or herpes zoster by a health care provider, laboratory evidence of immunity or disease.

Special situations

- **Pregnancy with no evidence of immunity to varicella:** VAR contraindicated during pregnancy; after pregnancy (before discharge from health care facility), 1 dose if previously received 1 dose varicella–containing vaccine or dose 1 of 2-dose series (dose 2: 4–8 weeks later) if previously did not receive any varicella–containing vaccine, regardless of whether U.S.–born before 1980.
- **Health care personnel with no evidence of immunity to varicella:** 1 dose if previously received 1 dose varicella–containing vaccine; 2-dose series 4–8 weeks apart if previously did not receive any varicella–containing vaccine, regardless of whether U.S.–born before 1980.
- **HIV infection with CD4 percentages ≥15% and CD4 count ≥200 cells/mm^3 with no evidence of immunity:** Vaccination may be considered (2 doses 3 months apart); VAR contraindicated for HIV infection with CD4 percentage <15% or CD4 count <200 cells/mm^3.
- **Severe immunocompromising conditions:**

VAR contraindicated

Zoster vaccination
Routine vaccination

- **Age 50 years or older*:** 2-dose series recombinant zoster vaccine (RZV, Shingrix) 2–6 months apart (minimum interval: 4 weeks; repeat dose if administered too soon), regardless of previous herpes zoster or history of zoster vaccine live (ZVL, Zostavax) vaccination.

***Note:** Serologic evidence of prior varicella is not necessary for zoster vaccination. However, if serologic evidence of varicella susceptibility becomes available, providers should follow ACIP guidelines for varicella vaccination first. RZV is not indicated for the prevention of varicella, and there are limited data on the use of RZV in persons without a history of varicella or varicella vaccination.

Special situations

- **Pregnancy:** There is currently no ACIP recommendation for RZV use in pregnancy. Consider delaying RZV until after pregnancy.
- **Immunocompromising conditions (including persons with HIV regardless of CD4 count)**:** 2-dose series recombinant zoster vaccine (RZV, Shingrix) 2–6 months apart (minimum interval: 4 weeks; repeat dose if administered too soon). For detailed information, see www.cdc.gov/shingles/hcp/vaccine–considerations/immunocompromised–adults.html

****Note:** If there is no documented history of varicella, varicella vaccination, or herpes zoster, providers should refer to the clinical considerations for use of RZV in immunocompromised adults aged ≥19 years and the ACIP varicella vaccine recommendations for further guidance: www.cdc.gov/mmwr/volumes/71/wr/mm7103a2.htm

Table 35–8. Adverse effects and contraindications to commonly used vaccines in adults (listed in alphabetical order).

Vaccine	Adverse Effects	Contraindications[1]
Haemophilus influenzae type b (Hib)	Minimal. Consist mainly of pain at the injection site.	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.
Hepatitis A	Minimal. Consist mainly of pain at the injection site.	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.
Hepatitis B	Minimal. Consist mainly of pain at the injection site.	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.
HPV	Minimal. Consist mainly of mild to moderate localized pain, erythema, swelling. Systemic reactions, mainly fever, seen in 4% of recipients.	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.
Influenza (intramuscular inactivated and intranasal live attenuated vaccines)	**Intramuscular, inactivated vaccine:** Local reactions (erythema and tenderness) at the site of injection are common, but fevers, chills, and malaise (which last in any case only 2–3 days) are rare. **Either inactivated or live attenuated vaccine:** A potential association between Guillain-Barré syndrome (3000–6000 cases per year in the United States, usually following respiratory infections) and vaccination with intramuscular, inactivated influenza vaccine has been reported (possibly, 1–2 persons per million persons vaccinated), but this rate is lower than the risk of the syndrome developing after influenza itself (given that approximately 750 persons per million adults are hospitalized annually with influenza, and many more cases remain as outpatients). Influenza vaccination may be associated with multiple false-positive serologic tests to HIV, HTLV-1, and hepatitis C, but it is self-limited, lasting 2–5 months.	Contraindication to both inactivated and live attenuated vaccine: History of Guillain-Barré syndrome, especially within 6 weeks of receiving a previous influenza vaccine. Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component, including egg protein.[2] Intranasal, live attenuated vaccine (FluMist) should not be used in: People 50 years of age and over Immunosuppressed individuals and those on immunosuppressive therapy Household members of immunosuppressed individuals Health care workers, or others with close contact with immunosuppressed persons Presence of reactive airway disease (eg, asthma) or chronic underlying metabolic (eg, kidney), pulmonary, or heart diseases (use intramuscular inactivated vaccine) Pregnancy[3] It is recommended that salicylates should be avoided for 6 weeks following vaccination (to prevent Reye syndrome).
Meningococcal, oligosaccharide conjugate (MCV4 or MenACWY [Menveo, MenQuadfi]); meningococcal group B, recombinant (MenB) [Bexsero, Trumenba]; meningococcal serogroup ABCWY [Penbraya]	Minor reactions (fever, redness, swelling, erythema, pain) occur slightly more commonly with MCV4. Major reactions are rare. A potential association between Guillain-Barré syndrome (3000–6000 cases per year in the United States, usually following respiratory infections) and vaccination with MCV4 has been reported, but recommendations favor continued use of MCV4, since the benefits of preventing the serious consequences of meningococcal infection outweigh the theoretical risk of Guillain-Barré syndrome.	Any severe allergic reaction (eg, anaphylaxis) to a previous dose or to a vaccine component (eg, persons with history of adverse reaction to diphtheria toxoid should not receive meningococcal oligosaccharide conjugate and polysaccharide conjugate vaccines since the protein conjugate used in them is diphtheria toxoid).
MMR[4]	Fever will develop in about 5–15% of unimmunized individuals, and a mild rash will develop in about 5% 5–12 days after vaccination. Fever and rash are self-limited, lasting only 2–3 days. Local swelling and induration are common in individuals previously vaccinated with inactivated vaccine.	Pregnancy[5] Known severe immunodeficiency (eg, from hematologic and solid cancers, receipt of chemotherapy, congenital immunodeficiency, long-term immunosuppressive therapy [eg, > 2 weeks of prednisone 20 mg daily or higher]), other disease- or therapy-related immune suppression, or patients with HIV infection who are severely immunocompromised. May be used in asymptomatic individuals with HIV whose CD4 count is > 200/mcL (0.2×10^9/L). Severe allergic reaction (eg, anaphylaxis) to a previous dose or to a vaccine component (eg, neomycin or to related agents such as streptomycin).

(*continued*)

Table 35–8. Adverse effects and contraindications to commonly used vaccines in adults (listed in alphabetical order). (continued)

Vaccine	Adverse Effects	Contraindications[1]
Mpox vaccine (Mpox) [Jynneos]	Mild local reactions (redness, soreness, swelling, and itching) and systemic reactions (fatigue, headache, muscle pain).	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.
Pneumococcal conjugate (PCV13) [Prevnar]; pneumococcal polysaccharide (PPSV23) [Pneumovax]	Mild local reactions (erythema and tenderness) occur in up to 50% of recipients, but systemic reactions are uncommon. Similarly, revaccination at least 5 years after initial vaccination is associated with mild self-limited local but not systemic reactions.	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component (eg, for PCV13 to any vaccine containing diphtheria toxoid).
Respiratory syncytial virus vaccine (RSV) [Arexvy, Abrysvo]	Mild local reactions (pain, redness, swelling) and systemic reactions (fatigue, fever, headache, nausea, diarrhea, muscle or joint pain). Rarely: Guillain-Barré syndrome In pregnancy: preterm birth, high blood pressure, pre-eclampsia.	Any severe allergic reaction (eg, anaphylaxis) to a vaccine component.
Tetanus, diphtheria, and pertussis (DTP, Tdap); tetanus, diphtheria (Td)	Minimal. Consist mainly of pain at the injection site.	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component. For pertussis-containing vaccines: any history of unexplained encephalopathy (eg, coma, decreased level of consciousness, or prolonged seizures) within 7 days of administration of a previous dose of Tdap or diphtheria and tetanus toxoids and pertussis (DTP) or diphtheria and tetanus toxoids and acellular pertussis (Tdap) vaccine.
Varicella	Can occur as late as 4–6 weeks after vaccination. Tenderness and erythema at the injection site are seen in 25%, fever in 10–15%, and a localized maculopapular or vesicular rash in 5%; a diffuse rash, usually with five or fewer vesicular lesions, develops in a smaller percentage. Spread of virus from vaccinees to susceptible individuals is possible, but the risk of such transmission even to immunocompromised patients is small, and disease, when it develops, is mild and treatable with acyclovir.	Known severe immunodeficiency (eg, from hematologic and solid cancers, receipt of chemotherapy, congenital immunodeficiency, long-term immunosuppressive therapy [eg, > 2 weeks of prednisone 20 mg daily or higher; other immunosuppressive medications], other disease- or therapy-related immune suppression, or patients with HIV infection who are severely immunocompromised). Pregnancy. Severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component (eg, neomycin). For theoretical reasons, it is recommended that salicylates should be avoided for 6 weeks following vaccination (to prevent potential for Reye syndrome).
Zoster	Mild and limited to local reactions. Although it is theoretically possible to transmit the virus to susceptible contacts, no such cases have been reported.	Known severe immunodeficiency (eg, from hematologic and solid cancers, receipt of chemotherapy, congenital immunodeficiency, long-term immunosuppressive therapy [eg, > 2 weeks of prednisone 20 mg daily or higher; other immunosuppressive medications], other disease- or therapy-related immune suppression, or patients with HIV infection who are severely immunocompromised. May be used in asymptomatic individuals with HIV whose CD4 count is > 200/mcL [0.2 × 10^9/L]). Pregnancy. Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component (eg, gelatin or neomycin).

General recommendations on immunization: recommendations of the Advisory Committee on Immunization Practices. https://www.cdc.gov/vaccines/hcp/imz-best-practices/contraindications-precautions.html, accessed April 1, 2025; from Hamborsky J et al (editors). Appendix A. Epidemiology and prevention of vaccine preventable diseases. 13th edition. Washington, DC, Public Health Foundation, 2015. Available at https://www.cdc.gov/pinkbook/hcp/table-of-contents/; and from Centers for Disease Control and Prevention. Vaccine Information Statements. Available at: https://www.cdc.gov/vaccines/hcp/current-vis/. Accessed April 1, 2025.

[2] The vaccine has typically been prepared using embryonated chicken eggs. However, a new vaccine using mammalian cell culture is FDA-approved.

[3] The inactivated influenza vaccine can be given during any trimester.

[4] MMR vaccine can be safely given to patients with a history of egg allergy even when severe.

[5] Although vaccination of pregnant women is *not* recommended, with the available RA27/3 vaccine strain, the congenital rubella syndrome does not occur in the offspring of those inadvertently vaccinated during pregnancy or within 3 months before conception.

HIV Infection & AIDS

Monica Gandhi, MD, MPH
Matthew A. Spinelli, MD, MAS

ESSENTIALS OF DIAGNOSIS

ESSENTIALS OF DIAGNOSIS

- Criteria for diagnosis of HIV with or without AIDS.
- Laboratory testing for HIV antibody, antigen, and HIV viral RNA.
- Prominent systemic complaints: sweats, diarrhea, weight loss, and wasting.
- Opportunistic infections due to diminished cellular immunity—often life-threatening.
- Increased risk of some cancers, particularly non-Hodgkin lymphoma.

General Considerations

The CDC AIDS case definition (Table 36–1) includes opportunistic infections and malignancies that rarely occur in the absence of severe immunodeficiency (eg, *Pneumocystis* pneumonia, CNS lymphoma, cytomegalovirus retinitis). It also classifies persons as having AIDS if they have a positive HIV antibody test and certain infections and malignancies that can occur in immunocompetent hosts but that are more common among people with HIV (eg, pulmonary tuberculosis, invasive cervical cancer). Several nonspecific conditions, including dementia and wasting (documented weight loss)—in the presence of a positive HIV test—are also classified as AIDS. The definition includes criteria for both definitive and presumptive diagnoses of certain infections and malignancies. Finally, persons with a positive HIV test whose CD4 lymphocyte count drops below 200 cells/mcL or a CD4 lymphocyte percentage < 14% are considered to have AIDS.

Inclusion of persons with low CD4 counts as AIDS cases reflects the recognition that *immunodeficiency is the defining characteristic of AIDS*. The choice of a cutoff point at 200 cells/mcL is supported by several cohort studies showing that AIDS will develop within 3 years in > 80% of persons with counts below this level in the absence of antiretroviral therapy (ART). Fortunately, the prognosis of people with HIV has dramatically improved due to the development of ART. One consequence is that fewer people with HIV ever develop an infection or malignancy or have a low enough CD4 count to classify them as having AIDS, which means that *the CDC definition has become a less useful measure of the impact of HIV/AIDS in the United States*. Conversely, persons in whom AIDS had been previously diagnosed based on a serious opportunistic infection, malignancy, or immunodeficiency may now be markedly healthier, with high CD4 counts, due to the use of ART. Therefore, the Social Security Administration, as well as most social service agencies, now focus on *functional assessment for determining eligibility for benefits* rather than the simple presence or absence of an AIDS-defining illness, as in the past.

Epidemiology

The modes of transmission of HIV are similar to those of hepatitis B, in particular with respect to sexual, parenteral, and vertical transmission. Although certain sexual behaviors (eg, receptive anal intercourse) confer higher risk than other sexual behaviors (eg, insertive vaginal intercourse), it is difficult to quantify per-contact risks. Nonetheless, the best available estimates indicate that the risk of HIV transmission with receptive anal intercourse is 138 per 10,000 exposures, with insertive anal intercourse being 11 per 10,000 exposures. Receptive vaginal intercourse results in HIV transmission in 8 per 10,000 exposures, with insertive vaginal intercourse being 4 per 10,000 exposures, and a negligible risk with insertive or receptive oral intercourse.

A number of *cofactors* are known to increase the risk of HIV transmission during a given encounter, including the presence of ulcerative or inflammatory sexually transmitted diseases, trauma, active menses, and the absence of male circumcision.

The risk of acquiring HIV infection from a needlestick with blood infected with HIV is estimated to be 23 per 10,000 exposures. Factors known to increase the risk of transmission include depth of penetration, hollow bore needles, visible blood on the needle, and advanced stage of disease in the source. The risk of HIV transmission from a mucosal splash with infected blood is unknown but is assumed to be significantly lower.

Table 36–1. CDC AIDS case definition for surveillance of adults and adolescents.

Definitive AIDS Diagnoses (with or without laboratory evidence of HIV infection)
1. Candidiasis of the esophagus, trachea, bronchi, or lungs.
2. Cryptococcosis, extrapulmonary.
3. Cryptosporidiosis with diarrhea persisting > 1 month.
4. Cytomegalovirus disease of an organ other than liver, spleen, or lymph nodes.
5. Herpes simplex virus infection causing a mucocutaneous ulcer that persists > 1 month; or bronchitis, pneumonitis, or esophagitis of any duration.
6. Kaposi sarcoma in a patient < 60 years of age.
7. Lymphoma of the brain (primary) in a patient < 60 years of age.
8. *Mycobacterium avium* complex or *Mycobacterium kansasii* disease, disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes).
9. *Pneumocystis jirovecii* pneumonia.
10. Progressive multifocal leukoencephalopathy.
11. Toxoplasmosis of the brain.
Definitive AIDS Diagnoses (with laboratory evidence of HIV infection)
1. Coccidioidomycosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes).
2. HIV encephalopathy.
3. Histoplasmosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes).
4. Isosporiasis with diarrhea persisting > 1 month.
5. Kaposi sarcoma at any age.
6. Lymphoma of the brain (primary) at any age.
7. Other non-Hodgkin lymphoma of B cell or unknown immunologic phenotype.
8. Any mycobacterial disease caused by mycobacteria other than *Mycobacterium tuberculosis*, disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes).
9. Disease caused by extrapulmonary *M tuberculosis*.
10. Salmonella (nontyphoid) septicemia, recurrent.
11. HIV wasting syndrome.
12. CD4 lymphocyte count < 200 cells/mcL or a CD4 lymphocyte percentage $< 14\%$.
13. Pulmonary tuberculosis.
14. Recurrent pneumonia.
15. Invasive cervical cancer.
Presumptive AIDS Diagnoses (with laboratory evidence of HIV infection)
1. Candidiasis of esophagus: (a) recent onset of retrosternal pain on swallowing; and (b) oral candidiasis.
2. Cytomegalovirus retinitis. A characteristic appearance on serial ophthalmoscopic examinations.
3. Mycobacteriosis. Specimen from stool or normally sterile body fluids or tissue from a site other than lungs, skin, or cervical or hilar lymph nodes, showing acid-fast bacilli of a species not identified by culture.
4. Kaposi sarcoma. Erythematous or violaceous plaque-like lesion on skin or mucous membrane.
5. *Pneumocystis jirovecii* pneumonia: (a) a history of dyspnea on exertion or nonproductive cough of recent onset (within the past 3 months); and (b) chest film evidence of diffuse bilateral interstitial infiltrates or gallium scan evidence of diffuse bilateral pulmonary disease; and (c) ABG analysis showing an arterial oxygen partial pressure < 70 mm Hg or a low respiratory diffusing capacity $< 80\%$ of predicted values or an increase in the alveolar-arterial oxygen tension gradient; and (d) no evidence of a bacterial pneumonia.
6. Toxoplasmosis of the brain: (a) recent onset of a focal neurologic abnormality consistent with intracranial disease or a reduced level of consciousness; and (b) brain imaging evidence of a lesion having a mass effect or the radiographic appearance of which is enhanced by injection of contrast medium; and (c) serum antibody to toxoplasmosis or successful response to therapy for toxoplasmosis.
7. Recurrent pneumonia: (a) more than one episode in a 1-year period; and (b) acute pneumonia (new symptoms, signs, or radiologic evidence not present earlier) diagnosed on clinical or radiologic grounds by the patient's clinician.
8. Pulmonary tuberculosis: (a) apical or miliary infiltrates and (b) radiographic and clinical response to antituberculous therapy.

The risk of acquiring HIV infection from injection drug use with sharing of needles from a person with HIV is estimated at 63 per 10,000 exposures. Use of clean needles markedly decreases the chance of HIV transmission but does not eliminate it if other drug paraphernalia are shared (eg, cookers).

When blood transfusion from a donor with HIV occurs, the risk of transmission is 93%. Fortunately, since 1985, blood donor screening for HIV has been universally practiced in the United States. HIV antigen and viral load testing has been added to the screening of blood to further lower the chance of HIV transmission. This essentially eliminates donations from persons who have acquired HIV but have not yet developed a positive antigen/antibody test (ie, persons in the "window" period). With these precautions, the chance of HIV transmission with receipt of blood transfusion in the United States is about 1 in 2,000,000.

Between 13% and 40% of children born to a mother with HIV contract HIV infection when the mother has not received treatment or when the child has not received perinatal HIV prophylaxis. The risk is higher with vaginal than with cesarean delivery; higher among mothers with high viral loads; and higher among those who breastfeed their children without being on ART. The combination of prenatal HIV testing and counseling, ART for mothers with HIV during pregnancy and for the infant immediately after birth, scheduled cesarean delivery if the mother has a viral load that is unknown or not virally suppressed at delivery, and avoidance of breastfeeding if the mother is not on ART has reduced the rate of perinatal transmission of HIV to < 1% in the United States and Europe. Importantly, breastfeeding has important nutritional and immunologic benefits for children, so international guidelines *recommend* lactating mothers living with HIV on ART breastfeed their infants. In 2023, US guidelines changed to support breastfeeding for mothers with HIV with undetectable viral loads on ART, with community input advocating for shared decision-making (https://oar.nih.gov/news-and-updates/oar-updates/update-clinical-guidelines-infant-feeding-supports-shared-decision-making).

HIV has not been shown to be transmitted by respiratory droplet spread, by vectors such as mosquitoes, or by casual nonsexual contact. Saliva, sweat, stool, and tears are not considered infectious fluids.

Approximately 1.2 million adults and adolescents in the United States are estimated to be living with HIV. In 2022 31,800 people received an HIV diagnosis in the United States and 6 dependent areas—a 12% decrease from 2018. In 2022, men who have sex with men (MSM) were the population most affected by HIV in the United States and accounted for 67% of all diagnoses. People who acquired HIV through heterosexual contact made up 22% of HIV diagnoses in the United States in 2022, with heterosexual women accounting for 15% of new diagnoses. People who inject recreational drugs (including MSM who use injection drugs) accounted for 7% of new HIV diagnoses in 2022. *Among persons with HIV in the United States, the prevalence of infection in Black, Indigenous and People of Color is disproportionally higher than among White people.* In 2022, people who self-identify as Black represented 12% of the US population but accounted for 37% of new HIV diagnoses, and people who self-identify as Latino/Latina (who represent 19% of the US population) accounted for 33% of new HIV diagnoses.

In general, the progression of HIV-related illness is similar regardless of gender, although women generally have lower viral loads then men early in infection. There are other important differences. Women are at risk for gynecologic complications of HIV, including recurrent candidal vaginitis, pelvic inflammatory disease, and cervical dysplasia and carcinoma. Violence directed against women, pregnancy, and frequent occurrence of drug use and poverty all complicate the treatment of women with HIV.

Worldwide there are an estimated 39.9 million people with HIV, with heterosexual spread being the most common mode of transmission for men and women. There were 1.3 million new HIV infections worldwide in 2023, with 630,000 deaths from HIV/AIDS. Since the beginning of the HIV pandemic, 43.3 million people have died. The reason for the greater risk for transmission with heterosexual intercourse in Africa and Asia than in the United States may relate to cofactors such as general health status, the presence of genital ulcers, relative lack of male circumcision, the number of sexual partners, and different HIV serotypes. Worldwide, 77% of adults have access to lifesaving ART and the overall rate of virologic suppression for people living with HIV is 72%. In the United States, rates of virologic suppression vary by type of care. The Ryan White Care HIV program provides a comprehensive system of primary medical care, ART, and essential support services to people with HIV, including a specific focus on supporting community needs. In 2022 in the United States, for every 100 people diagnosed with HIV, about 87% received some HIV care, 66% were retained in care, and 57% were virally suppressed.

Pathophysiology

Clinically, the syndromes caused by HIV infection are usually explicable by one of three known mechanisms: immunodeficiency, autoimmunity, and allergic and hypersensitivity reactions.

A. Immunodeficiency

Immunodeficiency is a direct result of the effects of HIV upon immune cells as well as the indirect impact of a generalized state of inflammation and immune activation due to chronic viral infection. A spectrum of infections and neoplasms is seen, as in other congenital or acquired immunodeficiency states. Two remarkable features of HIV immunodeficiency are the low incidence of certain infections such as listeriosis and aspergillosis, and the frequent occurrence of certain neoplasms such as lymphoma or Kaposi sarcoma. This latter complication has been seen primarily in MSM, and its incidence steadily declined through the first 15 years of the epidemic. A herpesvirus (HHV-8) is the cause of Kaposi sarcoma.

B. Autoimmunity and Allergic & Hypersensitivity Reactions

Autoimmunity can occur as a result of disordered cellular immune function or B lymphocyte dysfunction. Examples of both lymphocytic infiltration of organs (eg, lymphocytic interstitial pneumonitis) and autoantibody production (eg, immunologic thrombocytopenia) occur. These phenomena may be the only clinically apparent disease or may coexist with obvious immunodeficiency. Moreover, people with HIV appear to have higher rates of allergic reactions to unknown allergens as seen with **eosinophilic pustular folliculitis** ("itchy red bump syndrome") as well as increased rates of hypersensitivity reactions to medications (for example, the fever and sunburn-like rash seen with trimethoprim-sulfamethoxazole reactions).

Clinical Findings

The complications of HIV-related infections and neoplasms affect virtually every organ. The general approach to people with HIV with symptoms is to evaluate the organ systems involved, aiming to diagnose treatable conditions rapidly. As shown in Figure 36–1, *the CD4 lymphocyte count level enables the clinician to focus on the diagnoses most likely to be seen at each stage of immunodeficiency.* Certain infections may occur at any CD4 count, while others rarely occur unless the CD4 lymphocyte count has dropped below a certain level. For example, a patient with a CD4 count of 600 cells/mcL, cough, and fever may have a bacterial pneumonia but would be very unlikely to have ***Pneumocystis jirovecii* pneumonia**.

A. Symptoms and Signs

Many people with HIV remain asymptomatic for years even without ART, with a mean time of approximately 10 years between infection and development of AIDS. When symptoms occur, they may be remarkably protean and nonspecific. Since virtually all the findings may be seen with other diseases, a combination of complaints is more suggestive of HIV infection than any one symptom.

Physical examination may be entirely unremarkable. Abnormal findings range from completely nonspecific to highly specific for HIV infection. Some opportunistic infections specific to HIV infection include oral hairy leukoplakia (due to Epstein-Barr virus) of the tongue, disseminated Kaposi sarcoma, and cutaneous bacillary angiomatosis (due to *Bartonella*). Generalized lymphadenopathy, which is nonspecific, is common early in infection.

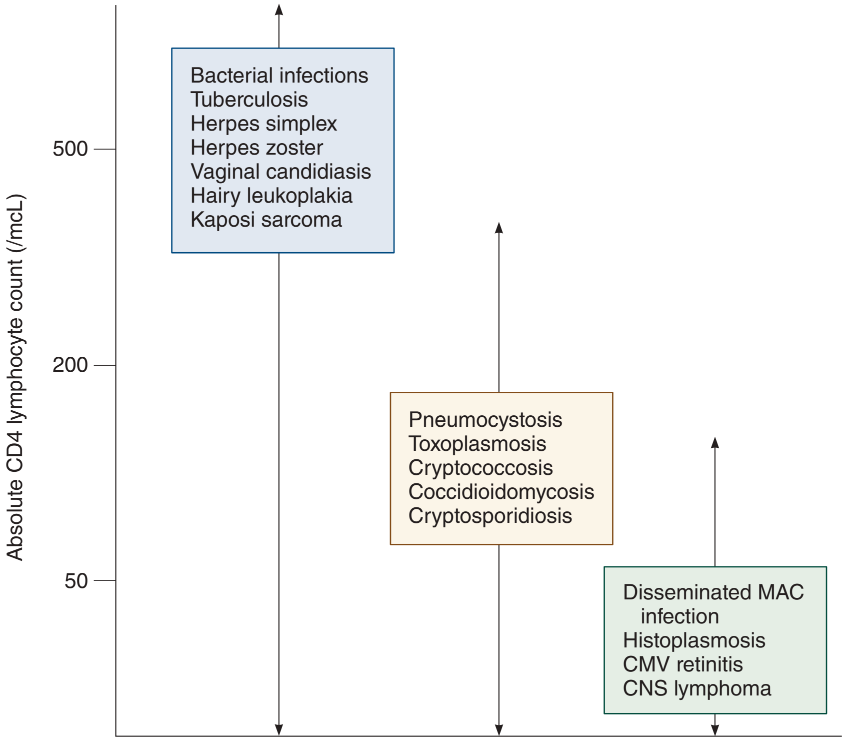

Figure 36–1. Relationship of CD4 count to development of opportunistic infections. MAC, *Mycobacterium avium* complex; CMV, cytomegalovirus.

The specific presentations and management of the various complications of HIV infection are discussed under the Complications section below.

Sonti S et al. HIV-1 persistence in the CNS: mechanisms of latency, pathogenesis and an update on eradication strategies. Virus Res. 2021;303:198523. [PMID: 34314771]

B. Laboratory Findings

Specific tests for HIV include antibody, antigen, and HIV viral load detection (Table 36–2). Initial testing for HIV should use a **fourth-generation HIV antigen/antibody immunoassay**. This test detects both HIV-1 and HIV-2 antibodies and HIV-1 p24 antigen. Reactive specimens are then tested with an **HIV-1/HIV-2 differentiation immunoassay** to confirm infection and to distinguish HIV-1 from HIV-2. For patients who are reactive on both tests, the sensitivity and specificity for chronic HIV approach 100%. Patients who have a reactive HIV antigen/antibody immunoassay but a negative HIV-1/HIV-2 differentiation immunoassay should have an **HIV viral load test (nucleic acid test)**; those with positive viral loads despite a negative differentiation assay are likely to have acute HIV infection. Persons who are reactive on the initial test and then negative on the confirmatory test and have nondetectable viral loads are presumed to have a false-positive test, which may occur with recent influenza vaccination, autoantibodies (eg, with collagen vascular or autoimmune diseases), or alloantibodies from pregnancy. With fourth-generation tests, antibodies will be detectable in 99% of persons within 6 weeks after infection, with the median time to detection of about 2 weeks.

Rapid HIV antibody tests of blood or oral fluid provide results within 10–20 minutes and can be performed in clinician offices, including by personnel without laboratory training and without a Clinical Laboratory Improvement Amendment (CLIA)–approved laboratory. Persons who test positive on a rapid test require confirmation with a standard testing as above. Rapid testing is particularly helpful in settings where a result is needed immediately (eg, a woman in labor who has not recently been tested for HIV; with use of intramuscular cabotegravir as HIV prevention) or when the patient is unlikely to return for a result. Rapid HIV home tests that allow the testers to learn their status privately by simply swabbing along their gum lines are also available (www.oraquick.com).

Nonspecific laboratory findings with HIV infection may include anemia, leukopenia (particularly lymphopenia), and thrombocytopenia in any combination, elevation of the ESR, polyclonal hypergammaglobulinemia, and hypocholesterolemia. Cutaneous anergy is common with immunosuppression.

The **absolute CD4 lymphocyte count** is the most widely used marker to provide prognostic information and to guide decisions for prophylaxis of opportunistic infections (Table 36–2). As counts decrease, the risk of serious opportunistic infection over the subsequent 3–5 years increases. There are many limitations to using the CD4 count, including diurnal variation, depression with intercurrent illness or vaccination for another pathogen, and intra-laboratory and interlaboratory variability. Therefore, *the trend is more important than a single determination* and the CD4 percentage can circumvent some of the limitations of a single absolute CD4 count. The frequency of performance of counts depends on the patient's health

Table 36–2. Commonly ordered tests for HIV infection (listed in alphabetical order).

Test	Significance
Absolute CD4 lymphocyte count	Best test for determining stage of HIV infection. Risk of progression to an AIDS opportunistic infection or malignancy is high with CD4 count < 200 cells/mcL in the absence of treatment.
CD4 lymphocyte percentage	Percentage may be more reliable than the CD4 count. Risk of progression to an AIDS opportunistic infection or malignancy is high with percentage < 14% in the absence of treatment.
HIV-1/HIV-2 antibody differentiation immunoassay	Serves as confirmatory test and differentiates HIV-1 and HIV-2. Tests that are reactive on HIV-1/2 antigen/antibody immunoassay but negative on this confirmatory test should have an HIV-1 viral load test. Sensitivity and specificity of combination of reactive antigen/antibody immunoassay and positive differentiation assay approach 100% for chronic infection.
HIV-1/2 antigen/antibody immunoassay	Detects antibodies for HIV-1 and HIV-2 along with HIV-1 p24 antigen. Positive specimens require testing with HIV-1/HIV-2 antibody differentiation assay.
HIV rapid antibody test	Screening test for HIV. Produces results in 10–20 minutes. Can be performed by personnel with limited training. Sensitivity and specificity for chronic infection are > 99%, although the sensitivity in acute infection is lower. Positive results must be confirmed with standard HIV testing using the HIV-1/2 antigen/antibody immunoassay and the HIV-1/HIV-2 antibody differentiation assay.
HIV-1 viral load tests	This nucleic acid test measures the amount of actively replicating HIV virus. Patients who have a negative result on the HIV-1/2 antigen/antibody immunoassay or the HIV-1/HIV-2 antibody differentiation assay, or both, but have a positive HIV viral load are likely experiencing acute HIV infection; however, caution is warranted when the test result shows low-level viremia (ie, < 1000 copies/mL) as this may represent a false-positive result. Besides its use in diagnosing acute HIV infection, HIV viral load is the most accurate indicator of viral activity and response to treatment.

status and whether or not they are receiving ART. **All patients regardless of CD4 count should be offered ART and the CD4 count monitored regularly until virologic suppression achieved**; regular CD4 monitoring after the achievement of a CD4 count > 350 cells/mcL and virologic suppression is not necessary. Initiation of *Pneumocystis jirovecii* prophylactic therapy is recommended when the CD4 count drops below 200 cells/mcL, with prophylaxis of *Toxoplasma gondii* recommended in those who are IgG-positive for the pathogen with CD4 count < 100 cells/mcL. Initiation of *Mycobacterium avium complex* prophylaxis is now only recommended in the rare cases of individuals with CD4 counts < 50 cells/mcL who do not initiate ART (eg, per patient preference). The **percentage of CD4 lymphocytes** can be a more reliable indicator of prognosis than the absolute counts (with a percentage < 14% roughly predictive of a CD4 count < 200 cells/mcL), particularly in the setting of acute illness. While the CD4 count measures immune dysfunction, it does not provide a measure of how actively HIV is replicating in the body. HIV viral load tests assess the level of viral replication and provide useful prognostic information that is independent of the information provided by CD4 counts. *The goal of ART in the United States is virologic suppression below or at the limits of detection of the assay.*

Differential Diagnosis

HIV infection may mimic a variety of other medical illnesses. Specific differential diagnosis depends on the mode of presentation. In patients presenting with constitutional symptoms such as weight loss and fevers, differential considerations include cancer, chronic infections such as tuberculosis and endocarditis, autoimmune conditions, and endocrinologic diseases such as hyperthyroidism. When pulmonary processes dominate the presentation, acute and chronic lung infections must be considered as well as other causes of diffuse interstitial pulmonary infiltrates, including SARS-CoV-2 infection (COVID-19). When neurologic disease is the mode of presentation, conditions that cause mental status changes or neuropathy—eg, alcohol use disorder (alcoholism), liver disease, kidney dysfunction, thyroid disease, and vitamin deficiency—should be considered. If a patient presents with headache and a CSF pleocytosis, other causes of chronic meningitis enter the differential. When diarrhea is a prominent complaint, infectious enterocolitis, antibiotic-associated colitis, IBD, and malabsorptive syndromes must be considered.

Complications

A. Systemic Complaints

Fever, night sweats, and weight loss are common symptoms in people with HIV and may occur without a complicating opportunistic infection. Patients with persistent fever and no localizing symptoms should nonetheless be carefully examined and evaluated with a CXR (*Pneumocystis* pneumonia can present with subtle respiratory symptoms), bacterial blood cultures if the fever is > 38.0°C, as well as serum cryptococcal antigen and mycobacterial cultures of the blood in those with low CD4 cell counts. Abdominal CT scans can be considered to evaluate occult intrabdominal infections or cancers.

Pahwa S et al. NIH Workshop on HIV-associated comorbidities, coinfections, and complications: summary and recommendation for future research. J Acquir Immune Defic Syndr. 2021;86:11. [PMID: 33306561]

1. Weight changes—Weight loss is a particularly distressing complication of long-standing HIV infection. Patients typically have *disproportionate loss of muscle mass*, with maintenance or less substantial loss of fat stores. The mechanism of HIV-related weight loss is not completely understood but appears to be multifactorial, with some of the older thymidine analog medications implicated. In the setting of the newer medications, weight gain has been seen with some ART regimens, with integrase strand transfer inhibitors associated with greater weight gain than protease inhibitors or nonnucleoside reverse transcriptase inhibitors. Among nucleoside/tide reverse transcriptase inhibitors, tenofovir alafenamide is associated with greater weight gain than tenofovir disoproxil fumarate or abacavir.

A. Presentation—Patients with AIDS frequently experience anorexia, nausea, and vomiting, all of which contribute to weight loss by decreasing caloric intake. In some cases, these symptoms are secondary to a specific infection, such as viral hepatitis. In other cases, however, evaluation of the symptoms yields no specific pathogen, and it is assumed to be due to a primary effect of HIV. Malabsorption also plays a role in decreased caloric intake. Patients may suffer diarrhea from infections with bacterial, viral, or parasitic agents.

Exacerbating the decrease in caloric intake, many patients with uncontrolled HIV have an increased metabolic rate. This increased rate has been shown to exist even among asymptomatic people with HIV, but it accelerates with disease progression and secondary infection. People with HIV with secondary infections also have decreased protein synthesis, which makes maintaining muscle mass difficult.

B. Management—Several strategies have been developed to slow **AIDS wasting**. In the long term, nothing is as effective as ART, since it treats the underlying HIV infection. In the short term, effective fever control decreases the metabolic rate and may slow the pace of weight loss, as does treating any underlying opportunistic infection. Food supplementation with high-calorie drinks and appetite stimulants may enable patients with low appetite to maintain their intake.

Two pharmacologic approaches for increasing appetite and weight gain are the progestational agent megestrol acetate liquid suspension (400–800 mg orally daily in divided doses) and the antiemetic agent dronabinol (2.5–5 mg orally three times a day), but *neither of these agents increases lean body mass*. Side effects from megestrol acetate are rare, but thromboembolic phenomena, edema, nausea, vomiting, and rash have been reported. In 3–10% of patients using dronabinol, euphoria, dizziness, paranoia, and somnolence and even nausea and vomiting have been reported. Dronabinol contains only one of the active ingredients in marijuana, and some patients experience better relief of nausea and improvement of appetite with medical cannabis (THC is thought to be more effective than CBD; administered via smoking, vaporization, essential oils, or cooked in food). In the United States, 38 states and the District of Columbia and 3 US territories have legalized medical marijuana, and 23 states and the District of Columbia and Guam have legalized recreational (nonmedical) use. However, the use and sale of marijuana are still illegal under federal law.

Saeteaw M et al. Efficacy and safety of pharmacological cachexia interventions: systematic review and network meta-analysis. BMJ Support Palliat Care. 2021;11:75. [PMID: 33246937]

2. Nausea—Nausea leading to weight loss is sometimes due to esophageal candidiasis. Patients with oral candidiasis and nausea should be empirically treated with an oral antifungal agent. Patients with weight loss due to nausea of unclear origin may benefit from use of antiemetics or promotility agents prior to meals (ondansetron, 8 mg three times daily; prochlorperazine, 10 mg three times daily; or metoclopramide, 10 mg three times daily). Dronabinol (5 mg three times daily) or medical cannabis can also be used to treat nausea, although in some individuals it can worsen nausea and vomiting. Depression and adrenal insufficiency are two potentially treatable causes of weight loss.

B. Pulmonary Disease

1. *Pneumocystis* pneumonia—(See also Chapter 41.) *P jirovecii* pneumonia is the most common opportunistic infection associated with AIDS. *Pneumocystis* pneumonia may be difficult to diagnose because the symptoms—fever, cough, and shortness of breath—are nonspecific and typically subacute. Furthermore, the severity of symptoms ranges from fever and no respiratory symptoms through mild cough or dyspnea to frank respiratory distress.

Hypoxemia may be severe, with a $PO_2 < 60$ mm Hg. *The cornerstone of diagnosis is the CXR or CT scan* (Figure 36–2). Diffuse or perihilar infiltrates are most characteristic, but only two-thirds of patients with *Pneumocystis* pneumonia have this finding. Normal CXRs are seen in 5–10% of patients with *Pneumocystis* pneumonia, although sensitivity is increased with CT scanning, while the remainder have diffuse ground glass opacities. Severe cases can lead to pneumothoraces. Large pleural effusions are uncommon with *Pneumocystis* pneumonia; their presence suggests bacterial pneumonia, other infections such as tuberculosis, or pleural Kaposi sarcoma.

Definitive diagnosis can be obtained in 70–90% of cases by *Wright-Giemsa stain* or *direct fluorescence antibody (DFA) test* of induced sputum. PCR testing is also available and has high sensitivity and specificity. Sputum induction is performed by having patients inhale an aerosolized solution of 3% saline produced by an ultrasonic nebulizer. Patients should not eat for at least 8 hours and should not use toothpaste or mouthwash prior to the procedure since they can interfere with test interpretation. The next step for patients with negative sputum examinations in whom *Pneumocystis* pneumonia is still suspected should be *bronchoalveolar lavage.* This technique establishes the diagnosis in > 95% of cases.

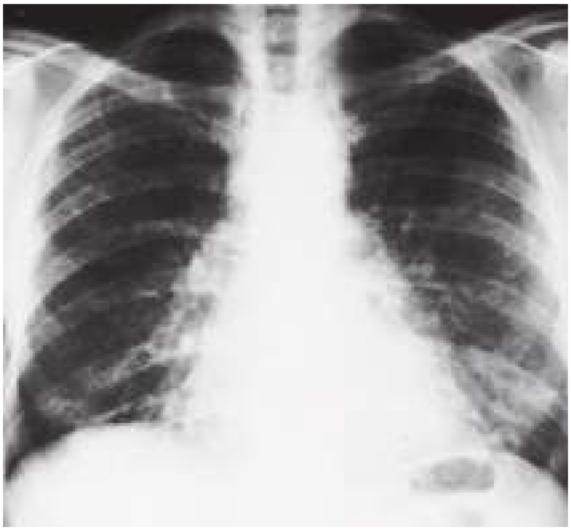

Figure 36–2. *Pneumocystis* pneumonia in a Haitian woman (she/her) in whom underlying HIV/AIDS is suspected. Typical CXR showing bilateral diffuse interstitial infiltrates extending out from the hilar areas. (Reproduced, with permission, from Grippi MA, Elias JA, Fishman JA et al (editors). *Fishman's Pulmonary Diseases and Disorders*, 5th ed. McGraw-Hill, 2015.)

In patients with symptoms suggestive of *Pneumocystis* pneumonia but with negative or atypical CXRs and negative sputum examinations, other diagnostic tests may provide additional information in deciding whether to proceed to bronchoalveolar lavage. Elevation of *serum LD* occurs in 95% of cases of *Pneumocystis* pneumonia, but the specificity of this finding is at best 75%. A normal *serum β-glucan test* makes *Pneumocystis* pneumonia unlikely, although a variety of factors can cause a false-positive serum β-glucan test. Either a normal *diffusing capacity of carbon monoxide* (*DL_{CO}*) or a *high-resolution CT scan* of the chest that demonstrates no interstitial lung disease makes the diagnosis of *Pneumocystis* pneumonia very unlikely. In addition, a CD4 count > 250 cells/mcL within 2 months prior to evaluation of respiratory symptoms makes a diagnosis of *Pneumocystis* pneumonia unlikely; only 1–5% of cases occur above this CD4 count level (see Figure 36–1). This is true even if the patient previously had a CD4 count lower than 200 cells/mcL but has had an increase with ART. Pneumothoraces can be seen in people with HIV with a history of *Pneumocystis* pneumonia.

Trimethoprim-sulfamethoxazole is the preferred treatment of *Pneumocystis* pneumonia (Table 36–3). In addition to specific anti-*Pneumocystis* treatment, corticosteroid therapy has been shown to improve the course of patients with moderate to severe *P jirovecii* pneumonia ($PaO_2 < 70$ mm Hg

Table 36–3. Treatment of AIDS-related opportunistic infections and malignancies[1] (listed in alphabetical order).

Infection or Malignancy	Treatment	Complications[2]
Cryptococcal meningitis	Preferred regimen: Induction: Liposomal amphotericin B, 3–4 mg/kg/day intravenously, with flucytosine, 25 mg/kg/dose orally four times daily for minimum of 2 weeks (adjust flucytosine dose for kidney function), then fluconazole, 400 mg orally daily for a minimum of 8 weeks (consolidation), then 200 mg orally daily to complete a minimum of 1 year of therapy (maintenance)	Liposomal amphotericin: fever, chills, hypokalemia, kidney disease Flucytosine: bone marrow suppression, kidney disease, hepatitis Fluconazole: hepatitis
	Induction: Amphotericin B, 0.7–1.0 mg/kg/day intravenously, with flucytosine, 25 mg/kg/dose orally four times daily for a minimum of 2 weeks (adjust flucytosine dose for kidney function), then fluconazole, 400 mg orally daily for a minimum of 8 weeks (consolidation), then 200 mg orally daily to complete a minimum of 1 year of therapy (maintenance)	Amphotericin: fever, chills, hypokalemia, kidney disease Flucytosine: bone marrow suppression, kidney disease, hepatitis Fluconazole: hepatitis
	Fluconazole, used alone, is inferior to amphotericin B as induction therapy; it is recommended only for patients who cannot tolerate or do not respond to the preferred regimen above. If used for primary induction therapy, give fluconazole, 1200 mg orally daily, with flucytosine, 25 mg/kg/dose orally four times daily for a minimum of 2 weeks (adjust flucytosine dose for kidney function), then 400 mg orally daily for a minimum of 8 weeks (consolidation), then 200 mg orally daily to complete a minimum of 1 year of therapy.	Hepatitis
Cytomegalovirus retinitis (immediate sight-threatening)	Preferred regimen: First-line therapy is oral valganciclovir, 900 mg orally twice a day with food for 21 days followed by 900 mg daily (maintenance). For sight-threatening infections involving the macula or optic nerve, add intravitreal ganciclovir (2 mg/injection) or foscarnet (2.4 mg/injection) for 1–4 doses/day for 7–10 days	For valganciclovir: neutropenia, anemia, thrombocytopenia (avoid in patients with hemoglobin < 8 g/dL, neutrophil count < 500 cells/mcL [0.5×10^9/L] or platelet count < 25,000/mcL [25×10^9/L]). Potentially embryotoxic.
	Ganciclovir, 10 mg/kg/day intravenously in two divided doses for 14–21 days, followed by 5 mg/kg daily (maintenance)	Neutropenia, anemia, thrombocytopenia Adjust ganciclovir dose for kidney function. Potentially embryotoxic.
	Foscarnet, 90 mg/kg intravenously every 12 hours for 14 days, followed by 90–120 mg/kg once daily	Nausea, hypokalemia, hypocalcemia, hyperphosphatemia, azotemia Adjust foscarnet dose for kidney function.
	Cidofovir, 5 mg/kg/week intravenously for 2 weeks, then 5 mg/kg every other week with probenecid, 2 g orally 3 hours before dose, 1 g orally 2 hours after dose, and 1 g orally 8 hours after dose	Nephrotoxicity (to reduce likelihood, pre- and post-saline hydration, along with probenecid), ocular hypotony, anterior uveitis, neutropenia Avoid in patients with sulfa allergy because of cross hypersensitivity with probenecid.
Esophageal candidiasis or recurrent vaginal candidiasis	Fluconazole, 100–200 mg orally daily for 14–21 days for esophageal disease and > 7 days for recurrent vaginal disease	Hepatitis, development of azole resistance. Fluconazole should *not* be given to women who are or may be pregnant because of risk of spontaneous abortion.
Herpes simplex infection	Acyclovir, 400 mg orally three times daily for 5–10 days; or acyclovir, 5 mg/kg intravenously every 8 hours for severe cases	Resistant herpes simplex with long-term therapy
	Valacyclovir, 1 g orally twice daily for 5–10 days	Nausea
	Famciclovir, 500 mg orally twice daily for 5–10 days	Nausea
	Foscarnet, 40 mg/kg intravenously every 8 hours, for acyclovir-resistant cases	Nausea, hypokalemia, hypocalcemia, hyperphosphatemia, azotemia Adjust foscarnet dose for kidney function.
Herpes zoster	Preferred regimen: Valacyclovir, 1000 mg orally three times daily for 7–10 days	Nausea
	Preferred regimen: Famciclovir, 500 mg orally three times daily for 7–10 days	Nausea
	Acyclovir, 800 mg orally five times daily for 7–10 days. Intravenous therapy at 10 mg/kg every 8 hours for extensive cutaneous or visceral disease until clinical improvement, then switch to oral therapy to complete a 10- to 14-day course. For ocular involvement, consult an ophthalmologist immediately.	Nausea

(*continued*)

Table 36–3. Treatment of AIDS-related opportunistic infections and malignancies[1] (listed in alphabetical order). (continued)

Infection or Malignancy	Treatment	Complications[2]
Kaposi sarcoma		
Mild to moderate	Initiation or optimization of antiretroviral treatment	Side effects of antiretroviral treatment
Advanced disease	Chemotherapy (eg, liposomal doxorubicin or daunorubicin)	Bone marrow suppression, cardiac toxicity
	Pomalidomide, 5 mg/day orally on days 1–21 of every 28-day cycle; alternative to chemotherapy	Fatigue, asthenia, dyspnea, anemia, neutropenia; contraindicated in pregnancy
Mycobacterium avium complex infection	Clarithromycin, 500 mg orally twice daily, or azithromycin, 600 mg once daily with ethambutol, 15 mg/kg/day orally (maximum, 1 g). May also add:	Clarithromycin: hepatitis, nausea, diarrhea Ethambutol: hepatitis, optic neuritis
	Rifabutin, 300 mg orally daily	Rash, hepatitis, uveitis
Non-Hodgkin lymphoma	Combination chemotherapy (eg, R-CHOP and G-CSF). CNS disease: Radiation treatment with dexamethasone for edema	Nausea, vomiting, anemia, neutropenia, thrombocytopenia, cardiac toxicity (with doxorubicin)
Pneumocystis jirovecii infection[3]	Preferred regimen: Trimethoprim-sulfamethoxazole, 15 mg/kg/day (based on trimethoprim component) intravenously or one double-strength tablet orally three times a day for 21 days. Add prednisone when PaO_2 < 70 mm Hg on room air or alveolar-arterial O_2 gradient > 35 mm Hg: 40 mg orally twice a day on days 1–5, 40 mg orally daily on days 6–10, 20 mg orally daily on days 11–21	Nausea, neutropenia, anemia, hepatitis, rash, Stevens-Johnson syndrome
	Pentamidine, 3–4 mg/kg/day intravenously for 21 days plus prednisone when indicated as above	Hypotension, hypoglycemia, anemia, neutropenia, pancreatitis, hepatitis
	Primaquine, 30 mg/day orally, and clindamycin, 600 mg every 8 hours orally, for 21 days plus prednisone when indicated as above	Primaquine: hemolytic anemia in patients with G6PD deficiency,[3] methemoglobinemia, neutropenia, colitis Clindamycin: rash, nausea, abdominal pain, colitis
	Not recommended for severe disease: Trimethoprim, 15 mg/kg/day orally in three divided doses, with dapsone, 100 mg/day orally, for 21 days,[3] plus prednisone when indicated as above	Nausea, rash, hemolytic anemia in patients with G6PD deficiency[3]; methemoglobinemia (weekly levels should be < 10% of total hemoglobin)
	Not recommended for severe disease: Atovaquone, 750 mg orally twice daily with food for 21 days, plus prednisone when indicated as above	Rash, elevated aminotransferases, anemia, neutropenia
Toxoplasmosis	Preferred regimen: Pyrimethamine, 200 mg orally as loading dose, followed by 50 mg daily (weight ≤ 60 kg) or 75 mg daily (weight > 60 kg), combined with sulfadiazine, 1000 mg orally four times daily (weight ≤ 60 kg) or 1500 mg orally four times daily (weight > 60 kg), and leucovorin, 10–25 mg orally daily, for at least 6 weeks. Longer courses are necessary for extensive disease or incomplete clinical or radiographic resolution. Maintenance therapy with pyrimethamine, 25–50 mg orally, plus sulfadiazine, 2000–4000 mg in two to four divided doses, plus leucovorin, 10–25 mg orally daily. Long-term treatment should be maintained until immune reconstitution with antiretroviral treatment occurs.	Pyrimethamine: leukopenia, anorexia, vomiting Sulfadiazine: nausea, vomiting, Stevens-Johnson syndrome
	For patients who are intolerant of sulfa who cannot be desensitized: Substitute clindamycin, 600 mg intravenously or orally every 6 hours, for the sulfadiazine in the above regimen	Clindamycin: rash, nausea, abdominal pain, colitis
	If pyrimethamine not available: Trimethoprim-sulfamethoxazole, 10 mg/kg/day (based on trimethoprim component)	Nausea, neutropenia, anemia, hepatitis, rash, Stevens-Johnson syndrome

[1] Recommendations drawn from Centers for Disease Control and Prevention. Guidelines for the prevention and treatment of opportunistic infections in HIV-infected adults and adolescents. February 11, 2020. Downloaded from https://aidsinfo.nih.gov/guidelines on February 14, 2020.

[2] List of complications is not exhaustive.

[3] Prior to use of primaquine or dapsone, check glucose-6-phosphate dehydrogenase (G6PD) level in Black patients and those of Mediterranean origin.

G-CSF, granulocyte colony-stimulating factor (filgrastim); R-CHOP, rituximab, cyclophosphamide, doxorubicin, vincristine, prednisolone.

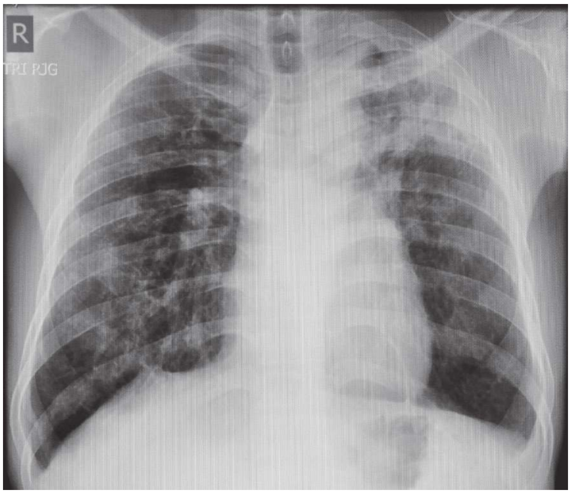
on room air or alveolar-arterial O_2 gradient greater or equal to 35 mm Hg) when administered within 72 hours of the start of anti-*Pneumocystis* treatment. Steroids should be started as early as possible after initiation of treatment, using prednisone 40 mg orally twice daily for days 1–5, 40 mg daily for days 6–10, and 20 mg daily for days 11–21 (for patients who cannot take oral medication, intravenous methylprednisolone can be substituted at 75% of the oral dose). The mechanism of action for the steroids to improve outcomes is presumed to be a decrease in alveolar inflammation.

US Department of Health and Human Services. Guidelines for the prevention and treatment of opportunistic infections in adults and adolescents with HIV. Accessed March 25, 2025. https://clinicalinfo.hiv.gov/en/guidelines/adult-and-adolescent-opportunistic-infection/whats-new-guidelines

2. Other infectious pulmonary diseases—Other infectious causes of pulmonary disease in patients with AIDS include bacterial, mycobacterial, and viral etiologies.

A. Bacterial—*Community-acquired pneumonia is the most common cause of pulmonary disease in people with HIV*. The incidence of pneumococcal pneumonia with septicemia and *Haemophilus influenzae* pneumonia is higher among people with HIV. *Pseudomonas aeruginosa* is an important respiratory pathogen in advanced disease and, more rarely, pneumonia from *Nocardia* species or *Rhodococcus equi* infection can occur sometimes along with concomitant brain abscesses in advanced AIDS. Since B-cell dysfunction is more common early on in HIV infection, recurrent bacterial infections can be one clue of a new diagnosis.

B. Mycobacterial—Tuberculosis occurs in an estimated 4.2% of persons in the United States who have HIV. Patients with active tuberculosis and CD4 counts above 350 cells/mcL are likely to present with upper lobe and hilar infiltrates and paratracheal adenopathy, findings similar to persons without HIV (Figure 36–3). With advanced immunodeficiency, lower lobe, middle lobe, interstitial, and miliary infiltrates are more common, along with mediastinal adenopathy and extrapulmonary involvement. Although a *purified protein derivative (PPD)* test or an *interferon γ release assay* (IGRA)—including the QuantiFERON and T-SPOT tests—should be performed on all people with HIV in whom a diagnosis of tuberculosis is being considered, the lower the CD4 cell count, the greater the likelihood of falsely negative PPD or IGRA test results or of indeterminate IGRA test results. It is recommended to repeat PPD or IGRA testing following improvement in the CD4 count for those with CD4 count < 200 cells/mcL.



▲ **Figure 36–3.** A 36-year-old man (he/him) with **pulmonary tuberculosis.** There is an opacification of a portion of the left upper lung in association with a cavity, findings consistent with pulmonary tuberculosis. Also, there is an infiltrate in the right lung. The extent of his disease raises the specter that he has underlying HIV/AIDS. (Reproduced with permission from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 3rd ed. McGraw-Hill, 2019.)

In cases of active tuberculosis, treatment of people with HIV is similar to that of people without HIV. However, *rifampin should* not *be given to patients receiving a boosted protease inhibitor (PI) regimen*. In these cases, rifabutin may be substituted, but it may require dosing modifications depending on the antiretroviral regimen. Tenofovir alafenamide should not be used with rifampin and should be substituted for tenofovir disoproxil fumarate (TDF). Dolutegravir may be given with rifampin but should be dose adjusted to twice daily. **Multidrug-resistant (MDR) tuberculosis** has been a major problem in several metropolitan areas of the developed world, and cases of **extremely resistant tuberculosis** in patients with HIV are an important global concern. Nonadherence with prescribed antituberculous medications is a major risk factor. Several of the reported outbreaks appear to implicate nosocomial spread. *The emergence of medication resistance makes it essential that antibiotic sensitivities be performed on all positive cultures*. Medication therapy should be individualized. Patients with MDR *M tuberculosis* infection should receive at least three medications to which their organism is sensitive. The rise of MDR TB and extensively resistant TB in Eastern Europe and Russia has prompted increasing use of bedaquiline/pretomanid/linezolid–based regimens.

Atypical mycobacteria can cause pulmonary disease in patients with AIDS with or without preexisting lung disease and responds variably to treatment. Distinguishing between *M tuberculosis* and atypical mycobacteria is typically accomplished using *M tuberculosis* nucleic acid amplification (NAA) if available, which can also identify rifampin resistance rapidly, or via culture. DNA probes allow for presumptive identification usually within days of a positive culture. Definitive species identification for nontuberculous mycobacteria typically requires culture of sputum specimens. While awaiting definitive diagnosis, if clinical suspicion is high, clinicians should err on the side of treating patients as if they have *M tuberculosis* infection. Clinicians may wait for definitive diagnosis if the person is smear-negative for acid-fast bacilli, *M tuberculosis* NAA negative, clinically stable, and not living in a communal setting. It is important to note that isolated *M avium complex* pneumonia is relatively uncommon in AIDS, so diagnostic work-up for unexplained pneumonia should continue if preexisting structural lung disease is not present.

c. Viral (SARS-CoV-2 and other)—COVID-19, the illness caused by SARS-CoV-2, causes a very wide spectrum of illness, ranging from no symptoms to a mild upper respiratory tract illness with fever and cough, to a clinical triad of fever, cough, and dyspnea, to pneumonia, to acute respiratory distress syndrome (ARDS), and even to fulminant multisystem organ failure and death. CXRs and CT scans may be normal early in the disease course, then may show nonspecific diffuse ground glass opacities, multilobar infiltrates, and consolidations, some progressing to full-blown ARDS (see Chapter 37).

People with HIV prior to COVID-19 vaccines have a greater propensity for severe COVID-19 disease, in part related to higher rates of medical comorbidities (eg, CVD, lung disease, long-term smoking), although low CD4 counts and virologic nonsuppression also portend higher risk. *People with HIV should be considered a priority group for preventive strategies*, including boosting the initial vaccination series, and early treatment approaches with antivirals.

People with HIV should not alter their ART regimens or add medications for the purpose of possibly preventing or treating SARS-CoV-2 infection. With ongoing vaccination and natural infection, population immunity has risen in all groups, including people living with HIV. When COVID-19 is diagnosed in a person with HIV, ART should be continued, even if nirmatrelvir/ritonavir is initiated, since the course of the latter is only 5 days, despite the potential for drug-drug interactions.

Isolation of cytomegalovirus (CMV) from bronchoalveolar lavage fluid occurs commonly in patients with AIDS but does not establish a definitive diagnosis, with CMV pneumonitis remaining a very rare opportunistic infection among people with AIDS. Diagnosis of CMV pneumonitis typically requires biopsy; response to treatment is poor. Histoplasmosis, coccidioidomycosis, and cryptococcal disease as well as more common respiratory viral infections should also be considered in the differential diagnosis of unexplained pulmonary infiltrates.

US Department of Health and Human Services. Guidance for COVID-19 and persons with HIV. Updated 2022 Feb 22. Accessed August 31, 2024. https://clinicalinfo.hiv.gov/en/guidelines/guidance-covid-19-and-people-hiv/guidance-covid-19-and-people-hiv

3. Noninfectious pulmonary diseases—

a. Presentation—Noninfectious causes of lung disease in HIV infection include Kaposi sarcoma, non-Hodgkin lymphoma, interstitial pneumonitis, primary effusion lymphoma, and increasingly, in the current ART era, lung cancer. Some of these cancers (eg, lymphoma, Kaposi sarcoma) have an underlying viral etiology. In patients with known Kaposi sarcoma, pulmonary involvement complicates the course in approximately one-third of cases. However, pulmonary involvement is rarely the presenting manifestation of Kaposi sarcoma. Non-Hodgkin lymphoma may involve the lung as the sole site of disease, but more commonly involves other organs as well, especially the brain, liver, and GI tract. Both of these processes may show nodular or diffuse parenchymal involvement, pleural effusions, and mediastinal adenopathy on CXRs.

Nonspecific interstitial pneumonitis may mimic *Pneumocystis* pneumonia. Lymphocytic interstitial pneumonitis seen in lung biopsies has a variable clinical course. Typically, these patients present with several months of mild cough and dyspnea; CXRs show interstitial infiltrates. Performed rarely, transbronchial biopsies demonstrate interstitial inflammation ranging from an intense lymphocytic infiltration (consistent with lymphoid interstitial pneumonitis) to a mild mononuclear inflammation.

4. Sinusitis—Chronic sinusitis can be a frustrating problem for people with HIV. Symptoms include sinus congestion and discharge, headache, and fever. Some patients may have radiographic evidence of sinus disease on sinus CT scan in the absence of significant symptoms.

C. Central Nervous System Disease

CNS disease in people with HIV can be divided into intracerebral space-occupying lesions, encephalopathy, meningitis, and spinal cord processes. Many of these complications have declined markedly in prevalence in the era of effective ART. Cognitive declines, however, may be more common in persons with HIV, especially as they age (older than 50 years), even among those who remain virologically suppressed.

Stephens RJ et al. Central nervous system infections in the immunocompromised adult presenting to the emergency department. Emerg Med Clin North Am. 2021;39:101. [PMID: 33218652]

1. Toxoplasmosis—Toxoplasmosis used to be one of the most common CNS space-occupying lesion in people with HIV. Headache, focal neurologic deficits, seizures, or altered mental status may be presenting symptoms. The diagnosis is usually made presumptively based on the characteristic appearance of cerebral imaging studies in an individual known to be seropositive for *Toxoplasma.* Typically, *toxoplasmosis appears as multiple contrast-enhancing lesions on CT scan that do not reduce on diffusion on MRI scan.* Lesions tend to be peripheral, with a predilection for the basal ganglia.

Single lesions are atypical of toxoplasmosis. When a single lesion has been detected by CT scanning, MRI scanning may reveal multiple lesions because of its greater sensitivity. *If a patient has a single lesion on MRI and is neurologically stable, clinicians may pursue a 2-week empiric trial of toxoplasmosis therapy.* A repeat scan should be performed at 2 weeks. If the lesion has not diminished in size, biopsy of the lesion should be performed. A positive *Toxoplasma* serologic test does *not* confirm the diagnosis because many people with HIV have detectable titers without having active disease. Conversely, < 3% of patients with toxoplasmosis have negative titers. Therefore, negative *Toxoplasma* titers in a patient with HIV infection and a space-occupying lesion should be a cause for aggressively pursuing an alternative diagnosis. The preferred treatment of toxoplasmosis is with pyrimethamine and sulfadiazine (Table 36–3). If pyrimethamine is not available, patients can be treated with oral trimethoprim-sulfamethoxazole.

2. CNS lymphoma—Primary non-Hodgkin lymphoma is the second most common CNS space-occupying lesion in people with HIV. Symptoms are similar to those with toxoplasmosis. While imaging techniques cannot distinguish these two diseases with certainty, lymphoma more often is solitary. Other less common lesions should be suspected if there is preceding bacteremia, tuberculosis risk factors, fungemia, or injection drug use. These include bacterial abscesses, cryptococcomas, tuberculomas, and *Nocardia* lesions.

Stereotactic brain biopsy should be strongly considered if lesions are solitary or do not respond to toxoplasmosis treatment, especially if they are easily accessible. Diagnosis of lymphoma is important because many patients benefit from treatment (radiation therapy). A positive PCR assay of CSF for Epstein-Barr virus (EBV) DNA is consistent with a diagnosis of lymphoma; a *PCR for EBV DNA in CSF is 100% sensitive and 98.5% specific for AIDS-associated primary CNS lymphoma*, making it useful as a diagnostic tumor marker.

3. HIV-associated dementia and neurocognitive disorders—Patients with HIV-associated neurocognitive disorders, including dementia typically have difficulty with cognitive tasks (eg, memory, attention), exhibit diminished motor function, and have emotional or behavioral problems. Patients may first notice a deterioration in their handwriting. The manifestations of cognitive impairment or dementia may wax and wane, with persons exhibiting periods of lucidity and confusion over the course of a day. The diagnosis of HIV-associated dementia most commonly occurs in untreated patients with advanced HIV infection, and is one of exclusion based on a brain imaging study and on spinal fluid analysis that excludes other pathogens. Neuropsychiatric testing is helpful in distinguishing patients with dementia from those with depression. Many patients improve with ART. However, slowly progressive neurocognitive deficits may still develop in patients taking ART as they age.

Metabolic abnormalities may also cause changes in mental status: hypoglycemia, hyponatremia, hypoxia, and drug overdose are important considerations in this population. Other less common infectious causes of encephalopathy include progressive multifocal leukoencephalopathy (discussed below), CMV, syphilis, and herpes simplex encephalitis.

4. Cryptococcal meningitis—Cryptococcal meningitis typically presents with fever and headache. Less than 20% of patients have meningismus. Diagnosis is based on a positive latex agglutination test of serum or CSF that detects cryptococcal antigen (or "CrAg") or positive culture of spinal fluid for *Cryptococcus*. *Approximately 99% of patients with cryptococcal meningitis have a positive serum CrAg.* Thus, a negative serum CrAg test makes a diagnosis of cryptococcal meningitis unlikely and can be useful in the initial evaluation of a patient with headache, fever, and normal mental status. Treatment has three phases: induction, consolidation, and maintenance. Induction treatment is given for a minimum of 2 weeks plus evidence of clinical improvement and a negative CSF culture on repeat lumbar puncture. The preferred induction treatment is liposomal amphotericin with flucytosine (Table 36–3), followed by an oral fluconazole treatment, and then secondary prophylaxis. Prophylaxis can be stopped if the patient is asymptomatic, has a CD4 cell count of > 100/mcL for at least 3 months, and has suppressed viral load on ART. Of note, a 2022 study showed that an alternative induction regimen of just a single dose of liposomal amphotericin B with 14 days of flucytosine and concomitant fluconazole was noninferior to the longer course of amphotericin B; this can be considered an alternative approach in resource-limited settings or if liposomal amphotericin B is not tolerated.

5. Meningococcal meningitis—People with HIV infection are at increased risk for bacterial meningococcal disease. Treatment is the same as in people without infection. The Advisory Committee on Immunization Practices recommends the *meningococcal conjugate vaccine* routinely (serogroups A, C, W, and Y) for all persons aged 2 months or older with HIV infection. In settings of meningococcal outbreaks, the meningococcal B vaccine may be administered to adolescents and young adults with HIV, not necessarily all patients with HIV, for short-term protection against most strains of serogroup B meningococcal disease. Routine administration of meningococcal B vaccine to patients with HIV, however, is *not* indicated.

National Institutes of Health (NIH). HIVinfo. Guidelines for the Prevention and Treatment of Opportunistic Infections in Adults and Adolescents with HIV. 2023 Sept 7. Accessed August 31, 2024. https://clinicalinfo.hiv.gov/en/guidelines/hiv-clinical-guidelines-adult-and-adolescent-opportunistic-infections/immunizations

6. HIV meningitis and HIV myelopathy—HIV meningitis, characterized by lymphocytic pleocytosis of the spinal fluid with negative culture, is common early in HIV infection. Spinal cord function may also be impaired in individuals with HIV infection. HIV myelopathy presents with leg weakness and incontinence. Spastic paraparesis and sensory ataxia are seen on neurologic examination. Myelopathy is usually a late manifestation of HIV disease, and most patients will have concomitant HIV encephalopathy. Pathologic evaluation of the spinal cord reveals vacuolation of white matter. Because HIV myelopathy is a diagnosis of exclusion, symptoms suggestive of myelopathy should be evaluated by lumbar puncture to rule out CMV polyradiculopathy (described below) and an MRI or CT scan to exclude epidural lymphoma.

Leffert J et al. HIV-vacuolar myelopathy: an unusual early presentation in HIV. Int J STD AIDS. 2021;32:205. [PMID: 33323068]

7. Progressive multifocal leukoencephalopathy (PML)— PML is a viral infection (with the JC polyomavirus) of the white matter of the brain seen in patients with very advanced HIV infection. It typically results in focal neurologic deficits such as aphasia, hemiparesis, and cortical blindness. Imaging studies are strongly suggestive of the diagnosis if they show non-enhancing white matter lesions without mass effect; the diagnosis is verified by JC virus positivity via PCR in the CSF. Patients can stabilize or improve after ART initiation; there is no other treatment. In the setting of wide-scale ART and because PML occurs at very low CD4 counts, the prevalence of this condition is rare.

Cortese I et al. Progressive multifocal leukoencephalopathy and the spectrum of JC virus-related disease. Nat Rev Neurol. 2021;17:37. [PMID: 33219338]

D. Peripheral Nervous System

A. PRESENTATION—Peripheral nervous system syndromes include inflammatory polyneuropathies, sensory neuropathies, and mononeuropathies.

An **inflammatory demyelinating polyneuropathy** similar to Guillain-Barré syndrome can occur in people with HIV, usually prior to frank immunodeficiency. The syndrome in many cases improves with plasmapheresis, supporting an autoimmune basis of the disease. CMV can cause an ascending polyradiculopathy characterized by lower extremity weakness and a neutrophilic pleocytosis on spinal fluid analysis with a negative bacterial culture. Transverse myelitis can be seen with herpes zoster or CMV.

Peripheral neuropathy is common among people with HIV. Patients typically complain of numbness, tingling, and pain in the lower extremities. Symptoms are disproportionate to findings on gross sensory and motor evaluation. Beyond HIV infection itself, the most common cause is prior ART with a thymidine analog, such as stavudine or didanosine (although both are no longer available in the United States). Unfortunately, medication-induced neuropathy was not always reversed when the offending agent was discontinued. Patients with advanced disease may also develop peripheral neuropathy; in some cases, it occurs among those with suppressed viral loads. In many patients, the neuropathy improves after persistent virologic suppression is achieved. Evaluation should rule out other causes of sensory neuropathy such as alcohol use disorder, thyroid disease, diabetes, vitamin B_{12} deficiency, and syphilis.

B. MANAGEMENT—Treatment of peripheral neuropathy is aimed at symptomatic relief; those not taking ART consistently should be encouraged to improve their ART adherence and achieve virologic suppression. Those with comorbid diabetes should be encouraged to improve diabetes control. Patients may be treated initially with gabapentin (start at 300 mg at bedtime and increase to 300–900 mg orally three times a day) or other co-analgesics for neuropathic pain (see Chapter 5). Opioid analgesics should be avoided because the condition tends to be chronic and patients are likely to become dependent on these agents without significant improvement in their functional status.

Julian T et al. Human immunodeficiency virus-related peripheral neuropathy: a systematic review and meta-analysis. Eur J Neurol. 2021;28:1420. [PMID: 33226721]

E. Rheumatologic and Bone Manifestations

Arthritis, involving single or multiple joints, with or without effusion, has been commonly noted in people with HIV. Involvement of large joints is most common. Although the cause of HIV-related arthritis is unknown, most patients will respond to NSAIDs. Patients with a sizable effusion, especially if the joint is warm or erythematous, should have the joint aspirated, followed by culture of the fluid to rule out suppurative arthritis as well as fungal and mycobacterial disease.

Several rheumatologic syndromes, including reactive arthritis, psoriatic arthritis, sicca syndrome, and SLE, are reported in people with HIV (see Chapter 23). However, it is unclear if the prevalence is greater than in the general population. Cases of avascular necrosis of the femoral heads have been reported sporadically, generally in the setting of advanced disease with long-standing infection and in patients receiving long-term ART. The etiology is not clear but is probably multifactorial in nature.

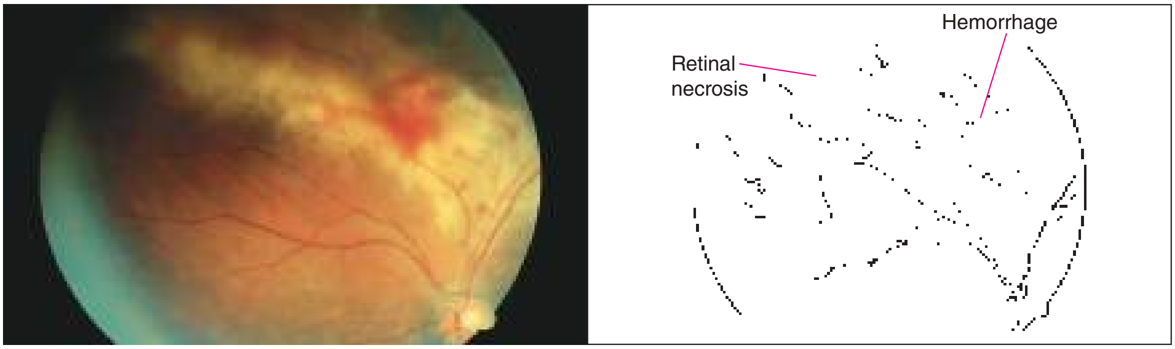
Osteoporosis and osteopenia appear to be more common in people with HIV with chronic infection and is associated with long-term use of TDF and PI-based ART. Vitamin D deficiency appears to be quite common among people with HIV and monitoring vitamin D levels and instituting replacement therapy for detected deficiency are recommended. Bone mineral density scans for postmenopausal women with HIV and men 50 years old or older are also recommended.

F. Myopathy

Myopathies are infrequent in the era of effective ART but can be related to either HIV infection or ART, particularly with use of the older agent zidovudine (azidothymidine [AZT]). Proximal muscle weakness is typical, and patients may have varying degrees of muscle tenderness. Given its long-term toxicities, zidovudine is no longer recommended when alternative treatments are available. Integrase strand transferase inhibitors rarely have been associated with creatine phosphokinase elevations and myopathy.

G. Retinitis

In people with HIV, complaints of visual changes must be evaluated immediately by an ophthalmologist familiar with



▲ **Figure 36–4. CMV retinitis.** Retina has classic "pizza pie" or "cheese and ketchup" appearance, with hemorrhages and dirty white, granular appearing retinal necrosis adjacent to major vessels (see diagrammatic map). (Reproduced with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ. *The Atlas of Emergency Medicine*, 5th ed. McGraw Hill, 2021.)

the manifestations of HIV disease. CMV retinitis, characterized by perivascular hemorrhages and white fluffy exudates, is the most common retinal infection in patients with AIDS, usually with CD4 counts ≤ 50 cells/mcL, and can be rapidly progressive (Figure 36–4). In contrast, cotton wool spots, which also are common in people with HIV, are benign, remit spontaneously, and appear as small indistinct white spots without exudation or hemorrhage. Ocular syphilis also should be considered, with the incidence of syphilis rising over time among people with HIV. Other rare retinal processes include other herpesvirus infections or toxoplasmosis. Choice of treatment for CMV retinitis (Table 36–3) depends on severity and location of lesions, as well as the patient's overall condition and circumstances.

Ballard B et al. CMV retinitis. EyeWiki. 2020 Oct 22. Accessed August 31, 2024. https://eyewiki.org/CMV_Retinitis#General_treatment

H. Oral Lesions

A. Presentation—Oral candidiasis can be bothersome to patients, many of whom experience an unpleasant taste or mouth dryness. The two most common forms of oral candidiasis seen are *pseudomembranous* (removable white plaques) and *erythematous* (red friable plaques). Angular cheilitis—fissures at the sides of the mouth—is usually due to *Candida* as well.

Oral hairy leukoplakia is caused by the Epstein-Barr virus. The lesion is not usually troubling to patients and sometimes regresses spontaneously. Hairy leukoplakia is commonly seen as a white lesion on the lateral aspect of the tongue. It may be flat or slightly raised, is usually corrugated, and has vertical parallel lines with fine or thick ("hairy") projections (see Figure 8–6). Unlike oral candidiasis, this lesion cannot be scraped off, a distinguishing feature in the physical examination.

The presence of oral candidiasis or hairy leukoplakia is significant for several reasons. First, these lesions are highly suggestive of HIV infection in patients who have no other obvious cause of immunodeficiency. Second, several studies have indicated that patients with candidiasis have a high rate of progression to AIDS even with statistical adjustment for CD4 count.

Gingival disease is common in people with HIV and is thought to be due to an overgrowth of microorganisms. Aphthous ulcers are painful and may interfere with eating.

Other lesions seen in the mouths of people with HIV include Kaposi sarcoma (usually on the hard palate) and oral warts.

B. Management—Treatment of mild oral candidiasis is with topical agents such as clotrimazole 10-mg troches (one troche four or five times a day). Patients with moderate to severe disease or with candidiasis that does not respond to topical antifungals can be treated with fluconazole (100–200 mg orally once a day for 7–14 days). Angular cheilitis can be treated topically with ketoconazole cream (2%) twice a day.

Gingival disease usually responds to professional dental cleaning and chlorhexidine rinses. A particularly aggressive gingivitis or periodontitis will develop in some people with HIV; these patients should be given antibiotics that cover anaerobic oral flora (eg, metronidazole, 250 mg four times a day for 4 or 5 days) and referred to oral surgeons with experience with these entities.

Aphthous ulcers can be treated with fluocinonide (0.05% ointment mixed 1:1 with a plain oral paste containing benzocaine (eg, Orabase) and applied six times a day to the ulcer). For lesions that are difficult to reach, patients should use dexamethasone swishes (0.5 mg in 5 mL elixir three times a day). The pain of the ulcers can be relieved with an anesthetic spray (10% lidocaine).

I. Gastrointestinal Manifestations

1. Candidal and other esophagitis—(See also Chapter 17.) Esophageal candidiasis is a common AIDS complication. In a patient with characteristic symptoms, empiric antifungal treatment is begun with fluconazole (200–400 mg orally daily for 14–21 days). Improvement in symptoms should be apparent within 1–2 days of antifungal treatment.

If there is no improvement, fungal culture to exclude fluconazole resistance, and further evaluation to identify other causes of esophagitis (herpes simplex, CMV) is recommended.

2. Hepatic disease—

A. Presentation—Autopsy studies have demonstrated that the liver is a frequent site of infections and neoplasms in people with HIV. However, many of these infections are not clinically symptomatic. Mild elevations of alkaline phosphatase and aminotransferases are often noted on routine chemistry panels. Mycobacterial disease, CMV, hepatitis B virus, hepatitis C virus, and lymphoma cause liver disease and can present with varying degrees of nausea, vomiting, right upper quadrant abdominal pain, and jaundice. Sulfonamides, imidazole medications, antituberculous medications, pentamidine, and clarithromycin have also been associated with hepatitis. *The thymidine analog medications in the nucleoside reverse transcriptase inhibitor (NRTI) class (ie, zidovudine) can cause lactic acidosis and hepatic steatosis, which can be fatal.* However, these medications, especially didanosine and stavudine, are rarely used in ART regimens any longer and are not available in the United States. Finally, people with HIV with chronic hepatitis may have more rapid progression of liver disease because of the concomitant immunodeficiency or hepatotoxicity of ART. Percutaneous liver biopsy may be helpful in diagnosing liver disease, but some common causes of liver disease (eg, *M avium* complex, lymphoma) can be determined by less invasive measures (eg, blood culture, biopsy of a more accessible site).

B. Management—With patients living longer as a result of advances in ART, advanced liver disease and hepatic failure due to chronic active hepatitis B or hepatitis C, or both, are increasing causes of morbidity and mortality. *People with HIV who also have hepatitis B infection should be treated with antiretroviral regimens that include two medications with activity against both viruses (TDF or tenofovir alafenamide [TAF], and lamivudine or emtricitabine).* It is important to be extremely cautious about discontinuing these medications in coinfected patients as sudden discontinuation could lead to a fatal flare of hepatitis B infection. Hepatitis D co-infection is underdiagnosed in patients with hepatitis B but may require greater screening in the future since a new antiviral (bulevirtide) has been approved for its treatment in Europe. Nonalcoholic fatty liver disease is a growing concern among people with HIV, particularly given concerns for weight gain and insulin resistance with integrase inhibitors and tenofovir alafenamide. Treatment involves lifestyle modification, avoidance of alcohol, and optimization of diabetes control. If nonalcoholic steatohepatitis (NASH) with fibrosis is identified on biopsy, vitamin E therapy can be considered.

Hepatitis C is more virulent in patients with HIV and should be treated using HCV direct-acting antivirals (DAAs) (see Table 18–6). Prior to treatment, the patient's HCV viral load and HCV genotype should be determined. Pan-genotypic regimens such as glecaprevir/pibrentasvir are increasingly used. Because new DAAs are available and because HCV treatment is a rapidly changing field, clinicians should check the guidelines of the American Association for the Study of Liver Disease (ASLD)/Infectious Diseases Society of America (IDSA) (https://www.hcvguidelines.org/) to see the latest recommended regimens (see also Tables 18–6 and 18–7).

Although the recommended regimens are the same for people with HIV, potential drug interactions with ART may complicate treatment. Clinicians should check the guidelines of the AASLD/IDSA and US Department of Health and Human Services or the guidelines of the University of Liverpool to determine interactions between proposed hepatitis C regimen and HIV regimen. Ritonavir-containing protease inhibitor regimens for HIV are the most likely to cause drug–drug interactions.

Liver transplants have been performed successfully in people with HIV. This strategy is most likely to be successful in persons who have CD4 counts > 100 cells/mcL and nondetectable viral loads.

University of Liverpool. HEP drug interactions. Accessed August 31, 2024. https://www.hep-druginteractions.org

3. Biliary disease—Cholecystitis presents with manifestations similar to those seen in immunocompetent hosts but is more likely to be acalculous. Sclerosing cholangitis and papillary stenosis have also been reported in people with HIV. Typically, the syndrome presents with severe nausea, vomiting, and right upper quadrant pain. Liver enzymes generally show alkaline phosphatase elevations disproportionate to elevation of the aminotransferases. Although dilated ducts can be seen on ultrasound, the diagnosis is made by endoscopic retrograde cholangiopancreatography, which reveals intraluminal irregularities of the proximal intrahepatic ducts with "pruning" of the terminal ductal branches. Stenosis of the distal common bile duct at the papilla is commonly seen. CMV, *Cryptosporidium*, and microsporidia are thought to play inciting roles in this syndrome, but these conditions are rarely seen unless the patient is experiencing very advanced HIV-related immunodeficiency.

4. Enterocolitis—

A. Presentation—Enterocolitis is a common problem in people with HIV. Organisms known to cause enterocolitis include bacteria (*Campylobacter*, *Salmonella*, *Shigella*), viruses (CMV, adenovirus, SARS-CoV-2), and protozoans (*Cryptosporidium*, *Entamoeba histolytica*, *Giardia*, *Isospora*, microsporidia, *Cyclospora*). HIV itself may cause enterocolitis. Several of the organisms causing enterocolitis in people with HIV also cause diarrhea in immunocompetent persons. However, people with HIV tend to have more severe and more chronic symptoms, including high fevers and severe abdominal pain that can mimic acute abdominal catastrophes. Bacteremia and concomitant biliary involvement are also more common with enterocolitis in people with HIV. Relapses of enterocolitis following adequate therapy have been reported with both *Salmonella* and *Shigella* infections.

Because of the wide range of agents known to cause enterocolitis, a stool culture and multiple stool examinations for ova and parasites (including modified acid-fast staining for *Cryptosporidium* and *Giardia* antigen testing) should be performed. Patients who have *Cryptosporidium* in one stool with improvement in symptoms in < 1 month should *not* be considered to have AIDS, as *Cryptosporidium* is a cause of self-limited diarrhea in HIV-negative persons. More commonly, people with HIV with subsequent immunodeficiency with *Cryptosporidium* infection have persistent enterocolitis with profuse watery diarrhea.

B. MANAGEMENT—For individuals who do not improve with ART initiation, nitazoxanide (500–1000 mg twice daily) has been FDA-approved for the treatment of cryptosporidiosis, and paromomycin has been used occasionally in refractory cases based on data from small randomized studies. The diarrhea can be treated symptomatically with loperamide or diphenoxylate with atropine (one or two tablets orally three or four times a day). Durable remission usually requires immune reconstitution with ART.

Patients with a negative stool examination and persistent symptoms should be evaluated with colonoscopy and biopsy. Patients whose symptoms last longer than 1 month with no identified cause of diarrhea are considered to have a presumptive diagnosis of HIV enteropathy. Patients may respond to ART initiation, antimotility agents, or crofelemer (an antidiarrheal agent).

5. Other disorders—Two other important GI abnormalities in people with advanced AIDS are gastropathy and malabsorption. It has been documented that some people with HIV do not produce normal levels of stomach acid and therefore are unable to absorb medications that require an acid medium. This decreased acid production may explain, in part, the susceptibility of people with HIV to *Campylobacter*, *Salmonella*, and *Shigella*, all of which are sensitive to acid concentration. There is no evidence that *Helicobacter pylori* is more common in people with HIV.

A malabsorption syndrome occurs commonly in patients with AIDS. It can be due to infection of the small bowel with *M avium* complex, *Cryptosporidium*, or microsporidia.

J. Endocrinologic Manifestations

Hypogonadism is probably the most common endocrinologic abnormality in men with HIV. The adrenal gland is also a commonly afflicted endocrine gland in patients with AIDS, either from HIV, TB, CMV, histoplasmosis, or other mycobacterial organisms. Abnormalities demonstrated on autopsy include infection, especially with CMV and *M avium* complex (ie, those with severe immunocompromise), infiltration with Kaposi sarcoma, and injury from hemorrhage and presumed autoimmunity. The prevalence of clinically significant adrenal insufficiency is low. Patients with suggestive symptoms should undergo a cosyntropin stimulation test.

Although frank deficiency of cortisol is rare, an isolated defect in mineralocorticoid metabolism may lead to salt-wasting and hyperkalemia. Such patients should be treated with fludrocortisone (0.1–0.2 mg orally daily). Trimethoprim-sulfamethoxazole also may cause hyperkalemia through its effects on the distal nephron, so it should be used with caution.

Patients with AIDS appear to have abnormalities of thyroid function tests different from those of patients with other chronic diseases. Patients with AIDS have been shown to have high levels of triiodothyronine (T_3), thyroxine (T_4), and thyroid-binding globulin and low levels of reverse triiodothyronine (rT_3). The causes and clinical significance of these abnormalities are unknown and generally improve with ART initiation.

Pezzaioli LC et al. The importance of SHBG and calculated free testosterone for the diagnosis of symptomatic hypogonadism in HIV-infected men: a single-centre real-life experience. Infection. 2021;49:295. [PMID: 33289905]

Santi D et al. The prevalence of hypogonadism and the effectiveness of androgen administration on body composition in HIV-infected men: a meta-analysis. Cells. 2021;10:2067. [PMID: 34440836]

K. Skin Manifestations

The skin manifestations that commonly develop in people with HIV can be grouped into viral, bacterial, fungal, neoplastic, and nonspecific dermatitides.

1. Viral dermatitides—

A. HERPES SIMPLEX INFECTIONS—These infections (Figure 36–5) occur more frequently, tend to be more severe, and are more likely to disseminate in patients with AIDS than in immunocompetent persons. Because of the

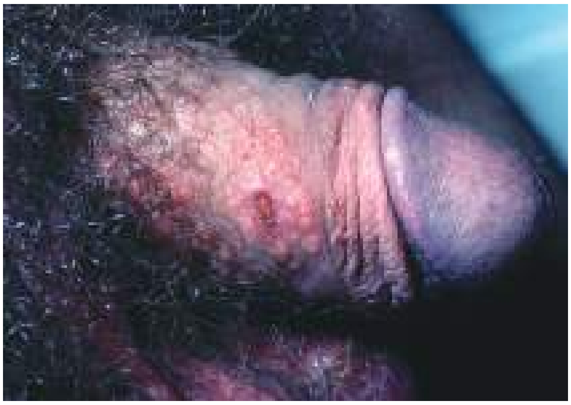

Figure 36–5. Herpes simplex viral skin infection, frequently found in men (he/him) with HIV. Shown are grouped vesicles typical of herpes simplex on the penis, with both intact vesicles of initial eruption and visible crusts of resolving lesions. (Reproduced, with permission, from Eric Kraus, MD, in: Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas and Synopsis of Family Medicine*, 3rd ed. McGraw-Hill, 2019.)

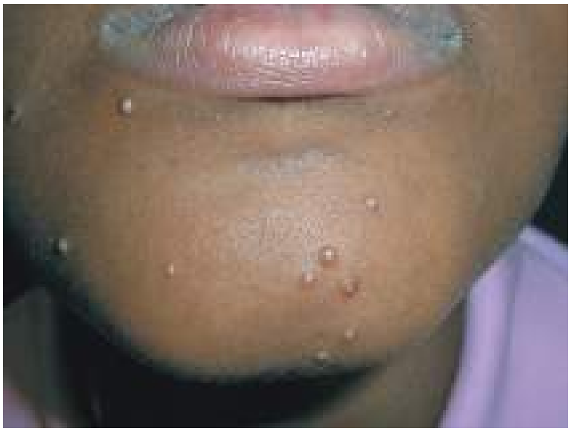
risk of progressive local disease, *all herpes simplex attacks should be treated for 5–10 days with valacyclovir (1000 mg orally twice daily), acyclovir (400 mg orally three times a day), or famciclovir (250 mg orally three times a day)* (Table 36–3). To avoid the complications of attacks, many clinicians recommend suppressive therapy for people with HIV with a history of recurrent herpes. Options for suppressive therapy include valacyclovir (1000 mg orally daily), acyclovir (400 mg orally twice daily), or famciclovir (250 mg orally twice daily). Long-term suppressive herpes prophylaxis with acyclovir does not reduce HIV transmission between heterosexual men and women from low- and middle-income countries.

B. Varicella zoster—This is a common manifestation of HIV infection. Patients with varicella zoster infections should be treated for 7–10 days with valacyclovir (1000 mg three times a day) or famciclovir (500 mg orally three times a day). Acyclovir can also be used, but it requires more frequent dosing (800 mg orally five times per day for 7 days). Vesicular lesions should be cultured if there is any question about their origin, since herpes simplex requires much lower doses of acyclovir than does varicella zoster. Disseminated zoster and cases with ocular involvement should be treated with intravenous acyclovir (10 mg/kg every 8 hours for 7–10 days). *The recombinant zoster vaccine (Shingrix, two doses administered 2–6 months apart) should be given to people with HIV*, and there is no longer an age requirement in these patients. Because it is not a live virus like the previous zoster vaccine (Zostavax), it is not contraindicated in patients with immune deficiency—but, based on other vaccines, people with HIV are likely to develop more robust immune response to the vaccine when their CD4 count is > 200/mcL.

Harbecke R et al. Herpes zoster vaccines. J Infect Dis. 2021;224:S429. [PMID: 34590136]

C. Molluscum contagiosum—This infection is caused by a pox virus and is seen in people with HIV, as in other immunocompromised patients. The characteristic umbilicated fleshy papular lesions have a propensity for spreading widely over the patient's face and neck (Figure 36–6) and should be treated with topical liquid nitrogen.



▲ **Figure 36–6. Molluscum contagiosum.** Extensive molluscum contagiosum lesions on the face of a young person, suggestive of HIV. (Reproduced with permission from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 3rd ed. McGraw-Hill, 2019.)

D. Mpox (monkeypox)—Mpox (formerly called "monkeypox") is an orthopoxvirus in the same genus as the variola and vaccinia viruses (virus that causes smallpox and virus that is used in the smallpox vaccine, respectively). Cowpox is the fourth orthopoxvirus in the family, and Borealpox virus has recently been added as the fifth member. Although originally isolated in a colony of laboratory monkeys, mpox can be isolated in a variety of rodents, with humans as incidental hosts. Prior to a global outbreak of clade 2 mpox in 2022, the majority of transmissions were thought to be from rodents to humans in mpox-endemic regions in Western and Central Africa. However, in May 2022, cases of mpox from non-endemic countries were reported, prompting the WHO to declare a global health emergency of international concern in July 2022. The vast majority of the cases (98–99%) were in men and mostly among MSM. With viable virus isolated from anal and urethral swabs and its particular distribution, mpox was reclassified by some organizations as an STI. As of 2024, > 100,000 mpox cases had been reported from 115 countries, although incidence started dropping worldwide in the early fall of 2022 due to a combination of natural infection in the population and mpox vaccination of affected populations. The first global health emergency was declared over by the WHO as of May 11, 2023. Unfortunately, despite access to widespread mpox vaccination in high-income countries during the first global outbreak, vaccines were not provided to areas in Africa with endemic circulating virus. As of August 14, 2024, the WHO had to declare a new public health emergency of international concern due to a large mpox clade 1b outbreak starting in the Democratic Republic of the Congo, with cases identified throughout Central and Easter Africa. Sporadic travel-related cases have been identified worldwide, with the first clade 1 case identified in the United States in California in November 2024.

In the clade 2 outbreak which began in 2022, a higher rate of mpox cases occurred among people with HIV (~40% of all cases), although it is unclear if this due to greater susceptibility to the virus, the disproportionate outbreak among MSM, proclivity toward orthopoxviruses with HIV infection, or other factors. Risk factors for greater severity of mpox disease in HIV include having a CD4+ T-cell count < 200 cells/mcL, although some studies suggest greater rash burden among people with HIV regardless of T-cell count. Patients may first develop fevers, chills, and myalgias, which are then followed by the characteristic rash, which begins as small macules that then evolve into papules, vesicles, and pseudo-pustules filled with cell debris rather than pus. The lesions eventually crust over and fall off approximately 7–14 days after the beginning of the rash. The rash is often painful and, in the most recent outbreak, frequently occurs in the anogenital or perioral areas. Proctitis occurring with the disease may or may not be associated with anorectal lesions. Ocular lesions may occur, and coalescence of lesions may lead to bacterial superinfection. Cases of encephalitis, sepsis, myocarditis, and bowel obstruction have been described but are rare. Diagnosis is made by orthopoxvirus DNA PCR performed on swab of the lesions. Most patients will recover with supportive care, although tecovirimat therapy was previously used for individuals with or at risk for severe disease, including uncontrolled HIV, as well as those with lesions in the eyes, confluent lesions, severe oral lesions limiting oral intake, or systemic life-threatening disease. In the PALM007 trial, tecovirimat was safe but not effective in reducing the duration of mpox lesions in children and adults in the clade 1 outbreak in the Democratic Republic of the Congo. The NIH-sponsored international STOMP trial also showed no efficacy of tecovirimat in mitigating severe disease with clade 2 mpox, so this medication should not longer be used. A modified vaccinia vaccine (called Modified Vaccinia Ankara [MVA] or Jynneos vaccine) was the mainstay of prevention during the mpox global outbreak and is safe for people with HIV. Anyone with risk factors for mpox or who have had a recent exposure should be vaccinated. See also Chapter 37.

2. Bacterial dermatitides—

A. STAPHYLOCOCCAL INFECTION—*Staphylococcus* is the most common bacterial cause of skin disease in people with HIV; it usually presents as folliculitis, superficial abscesses (furuncles), or bullous impetigo. These lesions should be treated aggressively since sepsis can occur. Folliculitis is initially treated with topical mupirocin or clindamycin, and patients may benefit from regular washing with benzoyl peroxide. Intranasal mupirocin, bleach baths, and cleaning intact skin with chlorhexidine soap have been used successfully for staphylococcal decolonization in other settings. In people with HIV with recurrent staphylococcal infections, weekly intranasal mupirocin should be considered in addition to topical care and systemic antibiotics. Abscesses often require incision and drainage. Patients may need antistaphylococcal antibiotics as well. Due to high frequency of methicillin-resistant *Staphylococcus aureus* (MRSA) skin infections in people with HIV, *coverage of MRSA in empiric regimens is necessary*. Recommendations for empiric treatment of serious infections are either (1) trimethoprim-sulfamethoxazole (one double-strength tablet orally twice daily); (2) doxycycline (100 mg orally twice daily); or (3) linezolid (600 mg orally twice daily) with close follow-up.

Hatlen TJ et al. Staphylococcal skin and soft tissue infections. Infect Dis Clin North Am. 2021;35:81. [PMID: 33303329]

B. BACILLARY ANGIOMATOSIS—It is caused by two closely related organisms: *Bartonella henselae* and *Bartonella quintana*. The epidemiology of these infections suggests zoonotic transmission from fleas of infected domestic cats (*henselae)* or contact with human body louse feces (*quintana*). The most common manifestation is raised, reddish, highly vascular skin lesions that can mimic lesions of Kaposi sarcoma. Fever is a common manifestation of this infection; involvement of bone, lymph nodes, liver (peliosis hepatis due to *B henselae*) and endocarditis have also been reported. The infection is treated with doxycycline, 100 mg orally twice daily and rifampin, 300 mg orally twice daily for a prolonged period depending on the seriousness of the infection. Patients who are seriously ill with visceral involvement or endocarditis may require at least 6 months of therapy.

Ding F et al. Clinical and echocardiographic characteristics of Bartonella infective endocarditis: an 8-year single-centre experience in the United States. Heart Lung Circ. 2022;31:350. [PMID: 34456130]

3. Fungal rashes—

A. RASHES DUE TO DERMATOPHYTES AND *CANDIDA*—Most fungal rashes afflicting patients with AIDS are due to dermatophytes and *Candida*. While particularly common in the inguinal region, they may occur anywhere on the body. Fungal rashes generally respond well to topical clotrimazole (1% cream twice a day) or ketoconazole (2% cream twice a day).

B. EOSINOPHILIC FOLLICULITIS—Eosinophilic folliculitis is a pruritic skin eruption with eosinophilic infiltration of hair follicles leading to papules or pustules, predominantly located on the scalp, face, neck, and torso. Eosinophilic folliculitis in advanced HIV is thought to be noninfectious although the pathophysiology is unknown. The mainstay of treatment is topical corticosteroids with ART and isotretinoin therapy in severe cases.

C. SEBORRHEIC DERMATITIS—This is more common in people with HIV. Scrapings of seborrhea have revealed *Malassezia furfur* (*Pityrosporum ovale*), implying that the seborrhea is caused by this fungus. A consistent finding is that seborrhea responds well to topical clotrimazole (1% cream) as well as hydrocortisone (1% cream).

4. Neoplastic dermatitides—See Chapter 6 and the Kaposi sarcoma section below.

5. Nonspecific dermatitides—

A. Xerosis—This condition presents in people with HIV with severe pruritus. The patient may have no rash, or nonspecific excoriations from scratching. Treatment is with emollients (eg, absorption base cream) and antipruritic lotions (eg, camphor 9.5% and menthol 0.5%).

B. Psoriasis—Psoriasis can be very severe in people with HIV. Phototherapy, topical retinoids, and etretinate (0.25–9.75 mg/kg/day orally in divided doses) may be used for recalcitrant cases in consultation with a dermatologist.

L. HIV-Related Malignancies

Four cancers are included in the CDC classification of AIDS: Kaposi sarcoma, non-Hodgkin lymphoma, primary lymphoma of the brain, and invasive cervical carcinoma. Epidemiologic studies have shown that between 1973 and 1987, among single men in San Francisco, the risk of Kaposi sarcoma increased > 5000-fold and the risk of non-Hodgkin lymphoma > 10-fold. In the current treatment era, cancers not classified as AIDS-related, such as lung cancer, are being increasingly diagnosed in aging people with HIV despite optimal ART. *Cohort studies suggest that adults with HIV are at increased risk for a variety of cancers compared with age-matched adults who do not have HIV.* Mortality secondary to malignancies represents an increasing cause of death in people with HIV.

Chiao EY et al. The effect of non-AIDS-defining cancers on people living with HIV. Lancet Oncol. 2021;22:e240. [PMID: 34087151]
Pumpalova YS et al. The impact of HIV on non-AIDS defining gastrointestinal malignancies: a review. Semin Oncol. 2021;48:226. [PMID: 34593219]

1. Kaposi sarcoma—

A. Presentation—Kaposi sarcoma is caused by human herpesvirus-8 (HHV-8) and can occur at any CD4 count although the risk increases at lower CD4 cell counts. Lesions may appear anywhere; careful examination of the eyelids, conjunctiva, pinnae, palate, and toe webs is mandatory to locate potentially occult lesions. In light-skinned individuals, Kaposi lesions usually appear as purplish, nonblanching lesions that can be papular or nodular. In dark-skinned individuals, the lesions may appear browner. In the mouth, lesions are most often palatal papules, though exophytic lesions of the tongue and gingivae may also be seen. Kaposi lesions may be confused with other vascular lesions such as angiomas and pyogenic granulomas. Pulmonary Kaposi sarcoma can present with chronic cough, hemoptysis, or both and is associated with peribronchovascular nodules on CT scan. It can be diagnosed via bronchoscopy following visualization of the typical lesions. Gastrointestinal Kaposi sarcoma most often manifests as GI bleeding. Kaposi sarcoma lesions can occur shortly after initiating ART, especially in patients starting ART who have advanced immunodeficiency. In this situation, Kaposi sarcoma is likely to be an immune reconstitution reaction (see Inflammatory Reactions, below).

B. Management—Patients with mild to moderate forms of Kaposi sarcoma do not require specific treatment as the lesions usually resolve with effective ART. However, it should be noted that the lesions may flare when ART is first initiated—probably as a result of an immune reconstitution process. Advanced disease is treated with chemotherapy (Table 36–3).

2. Non-Hodgkin lymphoma—

A. Presentation—Non-Hodgkin lymphomas in HIV-infected persons tend to be very aggressive. These malignancies are usually of B-cell origin and characterized as diffuse large-cell tumors. Over 70% of the malignancies are extranodal.

B. Management—The prognosis of patients with systemic non-Hodgkin lymphoma depends primarily on the degree of immunodeficiency at the time of diagnosis. Patients with high CD4 counts do markedly better than those diagnosed with lower CD4 counts. Patients with primary CNS lymphoma typically are treated by oncology with high-dose methotrexate-based chemotherapy with or without rituximab.

3. Hodgkin disease—Although Hodgkin disease is not included as part of the CDC definition of AIDS, studies have found that HIV infection is associated with a fivefold increase in the incidence of Hodgkin disease. HIV-infected persons with Hodgkin disease are more likely to have mixed cellularity and lymphocyte depletion subtypes of Hodgkin disease and to seek medical attention at an advanced stage of disease.

4. Anal dysplasia and squamous cell carcinoma—These lesions are generally a result of HPV infection and noted in people of all genders with HIV. Although many report a history of anal warts or have visible warts, a significant percentage have silent papillomavirus infection. Cytologic (using Papanicolaou smears) and papillomavirus DNA studies can be performed on specimens obtained by anal swab. Because of the risk of progression from dysplasia to cancer in patients with HIV, *regular anal cytologic examinations or high-resolution anoscopy should be performed.* An **anal Papanicolaou smear** is performed by rotating a moistened Dacron swab about 2 cm into the anal canal. The swab is immediately inserted into a cytology bottle.

Some experts also recommend high-risk HPV PCR testing be included. In the large ANCHOR study, which involved nearly 4500 individuals with anal high-grade squamous intraepithelial lesions (HGSIL), nine patients who were assigned to aggressive therapy (mostly office-based electrocautery) developed anal cancer compared with 21 of those in an active monitoring group (no treatment), representing a 57% decrease in relative risk of anal cancer over the median 25.8-month follow-up period. *This pivotal study has changed care toward more aggressive screening for HGSIL and treatment to prevent progression to anal cancer among people with HIV*.

HPV also plays a causative role in cervical dysplasia and carcinoma in women with HIV (discussed below).

Palefsky JM et al; ANCHOR Investigators Group. Treatment of anal high-grade squamous intraepithelial lesions to prevent anal cancer. N Engl J Med. 2022;386:2273. [PMID: 35704479]

M. Gynecologic Manifestations

Vaginal candidiasis, cervical dysplasia and neoplasia, and pelvic inflammatory disease are more common in women with HIV than in women without HIV. These manifestations also tend to be more severe when they occur in association with HIV infection. Therefore, *women with HIV need frequent gynecologic care*. Vaginal candidiasis may be treated with topical agents or a single dose of oral fluconazole (150 mg) (see Chapter 41). Recurrent vaginal candidiasis should be treated with fluconazole (100–200 mg) for at least 7 days. A single dose of fluconazole 150 mg to treat vaginal candidiasis is considered category C, although other uses are considered category D given the risk of rare birth defects.

Women with HIV have a six-fold increased risk of cervical cancer compared with women without HIV. Because of this finding, *recommended screening for women with HIV is more extensive than for women without HIV* (see Chapter 21). For women younger than age 30 years, a Papanicolaou smear should be performed within a year of the onset of sexual activity, but no later than age 21 years. If normal, Papanicolaou smears should be performed yearly. After three negative examinations, screening should be done every 3 years. HPV DNA testing of the cervical specimen is *not* recommended for women younger than age 30 years.

For women aged 30 years or older, screening should continue beyond age 65 years (unlike the general population). There are two accepted screening protocols: cytology alone and cytology with HPV DNA co-testing. A Papanicolaou smear is done when HIV is diagnosed and every 12 months thereafter, and after three negative smears, ongoing screening can be performed every 3 years. Alternatively, a Papanicolaou smear with co-testing for HPV DNA can be performed when HIV is diagnosed or starting when patients are 30 years old. If Papanicolaou smear is normal and HPV test is negative, then the next screening can be in 3 years.

The American Society of Colposcopy and Cervical Pathology recommends colposcopy for all results of HPV-positive ASC-US or higher, or LSIL or higher regardless of HPV status, among women with HIV. If HPV testing is not performed and the result is ASC-US, then cytology should be repeated in 6–12 months, with referral for colposcopy pursued if the repeat result is ASC-US or higher or if HPV positive. Treatment should follow the consensus guidelines in the references below.

While pelvic inflammatory disease appears to be more common in women with HIV, the bacteriology of this condition appears to be the same as among women without HIV. Women with HIV who have pelvic inflammatory disease should be treated with the same regimens as women without HIV (see Chapter 21).

Strickler HD et al. Primary HPV and molecular cervical cancer screening in US women living with HIV. Clin Infect Dis. 2021;72:1529. [PMID: 32881999]

N. Coronary Artery Disease

People with HIV are at higher risk for CAD than age- and sex-matched controls. Part of this increase in CAD may be due to residual inflammation that can occur despite ART. Results from the practice-changing 2023 REPRIEVE study indicate that *statin treatment can benefit patients with HIV at lower ASCVD risk scores (2.5–5%)*. Some data suggest abacavir may be associated with MI, possibly related to increased platelet aggregation, although this association has not been found in all studies. Some of the risk appears to be due to HIV infection, independent of its therapy. It is important that clinicians pay close attention to this issue because MIs tend to present at a younger age in individuals with HIV than in individuals without HIV. People with HIV with symptoms of CAD such as chest pain or dyspnea should be rapidly evaluated. Clinicians should aggressively treat conditions that result in increased risk of heart disease, especially smoking, hypertension, hyperlipidemia, obesity, diabetes mellitus, and sedentary lifestyle.

Grinspoon SK et al; REPRIEVE Investigators. Pitavastatin to prevent cardiovascular disease in HIV infection. N Engl J Med. 2023;389:687. [PMID: 37486775]

Patel AA et al. Coronary artery disease in patients with HIV infection: an update. Am J Cardiovasc Drugs. 2021;21:411. [PMID: 33184766]

O. Inflammatory Reactions (Immune Reconstitution Inflammatory Syndromes)

With initiation of ART, some patients experience inflammatory reactions that appear to be associated with immune reconstitution as indicated by a rapid increase in CD4 count. These inflammatory reactions may present with generalized signs of fevers, sweats, and malaise with or without more localized manifestations that usually represent unusual presentations of opportunistic infections. For example, vitreitis has developed in patients with CMV retinitis after they have been treated with ART.

M avium can present as focal even suppurative lymphadenitis or granulomatous masses in patients receiving ART.

Tuberculosis may paradoxically worsen with new or evolving pulmonary infiltrates and lymphadenopathy. PML and cryptococcal meningitis may also behave atypically. Clinicians should be alert to these syndromes, which are most often seen in patients who have initiated ART in the setting of advanced disease and who show rapid decreases in HIV viral load and increases in CD4 counts with treatment. The diagnosis of immune reconstitution inflammatory syndrome (IRIS) is one of exclusion and can be made only after recurrence or new opportunistic infection has been ruled out as the cause of the clinical deterioration. Management of IRIS is conservative and supportive with use of corticosteroids only for severe reactions, with ART continued.

Prevention

A. Primary Prevention

Prevention of HIV infection depends on HIV testing and counseling, including initiation of ART among people with HIV as a prevention tool for transmission to others, pre-exposure and postexposure use of antiretrovirals, precautions regarding sexual practices and injection drug use, perinatal management including antiretroviral treatment of the mother, screening of blood products, and infection control practices in the health care setting.

1. HIV testing and counseling—Primary care clinicians should routinely obtain a sexual history and provide risk factor assessment of their patients. *The USPSTF recommends that clinicians screen for HIV infection in adolescents and adults ages 15 to 65 years at least once in a lifetime.* Younger adolescents and older adults who are at increased risk should also be screened, with repeat screening as often as indicated for anyone at ongoing risk. Clinicians should review the risk factors for HIV infection with the patient and discuss HIV prevention strategies and safer needle use as well as the meaning of a positive test. Although the CDC recommends “opt-out” testing in medical settings, some states require specific written consent. For people whose test results are positive, it is critically important that they be connected to medical care. *Public health guidelines and HIV specialists advocate for initiating care and treatment the same day that someone tests positive, including patients in safety-net settings* (see Antiretroviral Therapy, below). Referrals for partner-notification services, social services, mental health services, and HIV prevention services should also be provided.

For patients whose test results are negative, clinicians should review HIV prevention strategies, needle use practices, or both. Pre-exposure prophylaxis (PrEP) and post-exposure prophylaxis are highly effective HIV prevention strategies and are reviewed below. To prevent sexual transmission of HIV, only *latex or polyurethane condoms* should be used, along with a water-soluble lubricant. Although nonoxynol-9, a spermicide, kills HIV, it is *contraindicated* because in some patients it may cause genital ulcers that could facilitate HIV transmission. Patients should be counseled that condoms are not 100% effective, and may be ineffective among MSM if not used reliably with all partners. They should be made familiar with the use of condoms, including, specifically, the advice that condoms must be used every time, that space should be left at the tip of the condom as a receptacle for semen, that intercourse with a condom should not be attempted if the penis is only partially erect, that men should hold on to the base of the condom when withdrawing the penis to prevent slippage, and that condoms should not be reused. Several randomized trials in Africa demonstrated that *male circumcision* significantly reduced HIV incidence in men and, eventually, in female partners. This has led to circumcision roll-out programs across the African continent.

Persons using injection drugs should be cautioned not to share needles or other drug paraphernalia. When sterile needles are not available, bleach does appear to inactivate HIV and can be used to clean needles. PrEP is an effective prevention option if clean needles are not readily available (see below).

2. ART for decreasing transmission of HIV to others (treatment as prevention)—Besides preventing progression of HIV disease, effective ART decreases the risk of HIV transmission between sexual partners. Among serodiscordant couples (MSM or heterosexual), stably suppressing HIV with ART completely eliminated the risk of HIV transmission to the uninfected partner in three large cohort studies. Although HIV-negative persons in stable long-term partnerships with persons with HIV represent only one group of at-risk persons, increasing the use of ART among the population of people with HIV appears to decrease community-wide transmission of HIV. *Despite major improvements in effectiveness and tolerability of ART, only about two-thirds of people with HIV in the United States are virally suppressed. Persons in whom the HIV virus remains consistently suppressed (< 200 copies/mL) do not transmit HIV sexually (thus,* ***“undetectable” means “untransmittable”****).* The efficacy of treatment as prevention for transmission via injection drug use is less clear; people with HIV or at risk of HIV should be encouraged to avoid sharing injection equipment to prevent forward transmission.

3. Pre-exposure ART prophylaxis—Several large randomized double-blind placebo-controlled trials demonstrated that administering tenofovir disoproxil fumarate/emtricitabine (TDF/FTC) can reduce the risk of sexual transmission of HIV among uninfected individuals at high risk for infection. Pre-exposure tenofovir has also been shown to reduce HIV infection among people from Thailand who inject recreational drugs. In addition, real-world studies and demonstration projects of MSM and cisgender women, where adherence with emtricitabine/TDF has been adequate (average of at least four doses/week), have found **PrEP** to be highly effective in preventing HIV infection. Subsequent trials and open-label studies have also shown high efficacy with the use of *event-based dosing* (two tablets 2 to 24 hours prior to sex, and then one tablet 24 hours later, and a final tablet 24 hours after that) for TDF/FTC among MSM. And, finally, tenofovir alafenamide (TAF)/FTC was also shown to be noninferior to TDF/FTC among MSM and transgender women so is approved for non-vaginal sex. TAF/FTC is associated with lower bone and renal toxicity than TDF/FTC but increased weight gain and dyslipidemia. TAF/FTC and event-based PrEP dosing (ie, 2-1-1 dosing) are both not yet approved for cisgender women. Cabotegravir, a long-acting medication for PrEP, was approved by the FDA in 2022 for use as PrEP as an injectable medication, every 8 weeks. This medication has been shown to be superior to oral TDF/FTC in preventing HIV infection among MSM, transgender women who have sex with men, and cisgender women. The most common adverse reaction to cabotegravir are injection site reactions, although these improve with subsequent injections and most patients do not discontinue therapy as a result of injection site reactions. Given the potential for delayed seroconversion to occur in individuals who develop an HIV breakthrough infection on injectable cabotegravir, HIV RNA testing is recommended at initiation. As of 2025, the use of HIV RNA testing at follow-up visits is being debated, due to the potential for false positives (the positive predictive value of a positive HIV RNA is only 18.5%) and the challenges that frequent RNA testing poses for implementation of injectable cabotegravir in many settings. An isolated positive HIV RNA at cabotegravir PrEP follow-up, particularly if it is at the limit of detection (ie, < 20 but detected), should be repeated and the patient should be counseled that there is a higher probability of false positives than a true positive. Approval of a new long-acting PrEP agent, biyearly subdermal lenacapavir (LEN), is pending as of January 2024 given the positive results reported from (1) the PURPOSE-1 trial, which found 100% efficacy of lenacapavir among cisgender women (0 HIV infections with LEN vs background HIV incidence of 2.4 per 100 person-years; 39 infections with F/TAF), and (2) the PURPOSE-2 trial, finding 96% efficacy among cisgender gay, bisexual, and other men, transgender women, transgender men, and gender-nonbinary individuals compared with background HIV incidence.

CDC guidelines recommend that all sexually active adults and adolescents be informed about PrEP for prevention of HIV acquisition. Risk for HIV is a combination of the likelihood of having a partner who is living with HIV and the likelihood that the behavior (eg, type of intercourse, shared needles) puts them at risk of HIV transmission. MSM and transgender women are the groups with the highest HIV seroprevalence in the United States, and they are likely to have partners who may be living with HIV or of unknown HIV status. Those who have receptive anal intercourse have the highest risk of HIV because the behavior is more efficient at transmitting HIV than other sexual practices. People who use drugs are also at high risk for HIV infection if they do not consistently use clean needles or if they trade drugs for sex. It can be difficult to assess the risk of heterosexual people who are not at risk from drug use because it requires assessing the likelihood that their partners have HIV risks. However, it is important to assess risk as accurately as possible among cisgender women in order to offer PrEP when indicated. Factors known to increase the risk of HIV transmission and potential exposure to HIV are shown in Table 36–4. CDC guidelines also acknowledge that sexual histories taken by medical providers may be inaccurate, or patients may not feel comfortable reporting their sexual practices; hence, *any patient who requests PrEP should be offered PrEP*.

Finally, for PrEP to be effective, patients need to have adequate adherence, particularly around the time of exposure. MSM and transgender women study participants who took at least four daily doses in a week were protected as well as those who took the drug every day, indicating that occasional missed doses do not render the treatment ineffective. PrEP demonstration projects conducted in cisgender women show similar findings. For patients preparing to stop PrEP, dosing should be continued for at least 2 days beyond the last exposure for MSM based on the 2-1-1 protocol. It is not clear how long other groups should continue PrEP following the last exposure, with some clinicians recommending 28 days based on postexposure prophylaxis studies, although this is likely conservative.

Recommendations on initial and follow-up assessments are shown in Table 36–4. TDF/FTC is contraindicated for persons with kidney disease (creatinine clearance < 60 mL/min) because of the small risk of kidney toxicity with TDF. Decreases in bone mineral density have been documented in persons taking TDF/FTC for PrEP at 24 weeks; whether this decrease will have clinical significance is unknown, and declines appear to reverse after stopping PrEP. For MSM who have creatinine clearance < 60 mL/min but > 30 mL/min, or osteoporosis/osteopenia (or at risk for these conditions), clinicians may opt to use TAF/FTC, injectable cabotegravir PrEP, or injectable LEN when it becomes available for this indication. Oral lead-in dosing of cabotegravir prior to injection should be considered optional, as breakthrough seroconversions occurred during the oral lead-in period in one of the cabotegravir studies, and injectable cabotegravir is well tolerated. While some guidelines recommend coverage of the first week of cabotegravir PrEP with daily TDF/FTC or TAF/FTC based on pharmacokinetic data, most large PrEP clinics are not implementing this without breakthrough HIV infections noted. When using injectable cabotegravir, the most sensitive HIV testing available should be used (ideally HIV RNA testing), given the potential for delayed seroconversion to occur with this therapy. The *cabotegravir tail* (detectable drug levels persistent after last medicine administration) should be covered after discontinuation while at ongoing risk of HIV with TDF/FTC or TAF/FTC, with quarterly HIV RNA testing performed for a year.

High rates of STIs have also been seen in persons taking PrEP, indicating the importance of regular follow-up in patients using PrEP. Regular asymptomatic STI screening and subsequent treatment among PrEP users (including rectal and pharyngeal testing for people exposed at those sites) can make substantial impact on the worsening non-HIV STI epidemic. Some patients are reluctant to use insurance to cover the cost of the medication for fear of revealing that they are at risk for HIV; without insurance, the cost is high. Programs are available from the medication manufacturer to cover the cost of treatment for low-income uninsured persons and to cover insurance copays

Table 36–4. Recommendations for preexposure prophylaxis (PrEP) of HIV infection.

Patients for whom PrEP should definitely be considered as a good option for HIV prevention
Sexually active MSM, transgender persons who have sex with men, and heterosexuals and bisexual women who are likely to have partners with HIV risks
Injection drug users
Factors that increase the likelihood that PrEP is a good option
Patient has receptive anal intercourse
Patient has a partner with a known HIV infection without durable virologic suppression, or a partner of unknown HIV status
Patient has a history of STIs
Patient has a high number of sex partners
Patient is a commercial sex worker
Patient with inconsistent or no condom use
Patient who has been incarcerated or who has partners that have been incarcerated
Patient is from or whose partners are from an area where HIV incidence is high
Patient who is sharing needles or related paraphernalia (“works”)
Initial assessment before prescribing PrEP
HIV antibody test to confirm HIV-negative (HIV RNA if using injectable cabotegravir)
Symptom review to exclude primary HIV infection (eg, no history of acute illness with fever and rash in prior month)
STI tests: syphilis; gonorrhea (at risk site-specific); and chlamydia (at risk site-specific)
Serum creatinine and eGFR[1]
Confirm immunity to HBV or vaccinate if nonimmune[2]
Pregnancy test
Discuss that PrEP does not protect against other STIs and review common side effects
Counsel patients that they can use latex or polyurethane condoms to prevent STIs and clean needles to prevent bacterial infections and hepatitis C, in addition to PrEP
Assess illicit substance use and offer treatment, if needed
Discuss importance of adherence to daily medication, every 8-week injections, or 2-1-1 PrEP around the time of exposures
PrEP prescription
Emtricitabine/TDF (Truvada) 1 tablet orally daily, 90-day prescription supply recommended. (Double dose is recommended on day 1 for MSM but would shorten the time to therapeutic drug levels in any patient)
Emtricitabine/TAF (Descovy) 1 tablet orally daily, 90-day prescription supply recommended (MSM and transgender women only)
Cabotegravir (Apretude) 600 mg injection given 1 month apart (loading) then every 2 months. Medication may be prescribed with oral cabotegravir 30 mg daily for 4 weeks as a lead-in or without (optional)
Follow-up assessment
HIV test every 3 months (every 8 weeks HIV RNA if using injectable cabotegravir)
Serum creatinine every 6–12 months (optional with cabotegravir)
Pregnancy test every 3 months
STI tests: syphilis, gonorrhea (at risk site-specific); and chlamydia (at risk site-specific)
Assess and support medication adherence
Reinforce benefits of using latex or polyurethane condoms and clean needles with PrEP
Assess substance use and offer treatment, if needed

[1] Emtricitabine/TDF is contraindicated if creatinine clearance < 60 mL/min.

[2] Persons with HBV infection may experience HBV reactivation and liver damage if emtricitabine/TDF is stopped.

HBV, hepatitis B virus; MSM, men who have sex with men; TAF, tenofovir alafenamide fumarate; TDF, tenofovir disoproxil fumarate.

PrEP checklists for providers and patients are available at https://www.cdc.gov/hiv/risk/prep/index.html (Last reviewed August 31, 2024).

for insured patients. Studies demonstrating the efficacy of doxycycline postexposure prophylaxis among MSM and transgender women with and without HIV (single 200 mg dose after sex up to 72 hours) have shown it effective in preventing chlamydia and syphilis, and in one study, gonorrhea. The study among HIV-negative cisgender women did not show efficacy, although adherence was low in this study. However, one study presented at the 2024 AIDS conference did demonstrate a large reduction in chlamydia and syphilis infections after initiating doxycycline *pre*-exposure prophylaxis with daily doxycycline 100 mg in a pre/post study among 40 female sex workers in Japan. Finally, latex or polyurethane condoms will prevent other STIs and pregnancy.

4. Postexposure prophylaxis for sexual and drug use exposures to HIV—The goal of *postexposure prophylaxis* is to reduce or prevent local viral replication prior to dissemination such that the infection can be aborted. Although there is no prior clinical trial showing that administration of antiretroviral medications following a sexual or parenteral drug use exposure reduces the likelihood of infection, there is suggestive data from animal models, perinatal experience, and a case-control study of health care workers who experienced a needle stick.

Treatment of persons who have been exposed to HIV should be within 72 hours, but sooner is better. All exposed persons should first receive HIV testing to exclude the possibility that they already have infection. If rapid tests are not available, treatment should begin pending the results of a standard HIV test.

The choice of antiretroviral agents and the duration of treatment are the same as those for exposures that occur through the occupational route; the preferred regimen is tenofovir 300 mg with emtricitabine 200 mg daily with dolutegravir 50 mg once daily or raltegravir 400 mg twice a day. In contrast to those with occupational exposures, some individuals may present very late after exposure. Because the likelihood of success declines with length of time from HIV exposure, *treatment is not recommended after > 72 hours after exposure.* In addition, because the psychosocial issues involved with postexposure prophylaxis for sexual and drug use exposures are complex, it should be offered with prevention counseling. Counseling should focus on how to prevent future exposures. Individuals with ongoing risk for HIV infection should be considered candidates for PrEP, sometimes called PEP-to-PrEP. Clinicians needing more information on postexposure prophylaxis for occupational or nonoccupational exposures should contact the *National Clinicians' Post-Exposure Prophylaxis Hotline* (1-888-448-4911; http://nccc.ucsf.edu/clinician-consultation/pep-post-exposure-prophylaxis/).

O'Connell KA et al. HIV post-exposure prophylaxis in the emergency department: an updated assessment and opportunities for HIV prevention identified. Am J Emerg Med. 2021;46:323. [PMID: 33069548]

5. Prevention of perinatal transmission of HIV—Prevention of perinatal transmission of HIV begins by offering HIV counseling and testing to all women who are pregnant or considering pregnancy. Women with HIV who are pregnant should start ART with at least three medications as quickly as possible. The recommended regimens include a dual-NRTI combination and dolutegravir. Cesarean delivery should be planned if HIV viral load is unsuppressed or unknown near the time of delivery and one or more antiretroviral medications administered to the newborn for 6 weeks to reduce the risk of perinatal acquisition. The infant feeding guidelines in the United States changed in 2023 to allow for shared decision-making with the mother on the decision to breastfeed.

6. Prevention of HIV transmission in health care settings—In health care settings, *universal body fluid precautions* should be used, including use of gloves when handling body fluids and the addition of gown, mask, and goggles for procedures that may result in splash or droplet spread, and use of specially designed needles with sheath devices to decrease the risk of needle sticks.

Epidemiologic studies show that needle sticks occur commonly among health care professionals, especially among surgeons performing invasive procedures, inexperienced hospital house staff, and medical students. Efforts to reduce needle sticks should focus on avoiding recapping needles and use of safety needles whenever doing invasive procedures under controlled circumstances. The risk of HIV transmission from a needle stick with blood from a patient with HIV infection is approximately 1:300, although determinants of risk include deep punctures, large inoculum, and source patients with high viral loads. The risk from mucous membrane contact and contact to non-intact skin is 1:1000 or less.

Health care professionals who sustain needle sticks should be counseled and offered HIV testing as soon as possible. HIV testing is done to establish a negative baseline in case there is a subsequent conversion. Follow-up testing is usually performed at 6 weeks and 3 months. With the patient's permission, their blood can be tested for HIV, with postexposure prophylaxis and further follow-up discontinued for the healthcare worker if the source patient tests negative.

A case-control study by the CDC indicates that administration of zidovudine following a needle stick decreased the rate of HIV seroconversion by 79%. Therefore, *clinicians should be offered ART as soon as possible after exposure and continued for 4 weeks.* Modern antiretrovirals have not been studied, but the efficacy is expected to be higher with more potent and better-tolerated integrase inhibitor–based three-drug regimens. The preferred regimen is TDF 300 mg with emtricitabine 200 mg (Truvada) daily with dolutegravir 50 mg once daily or raltegravir 400 mg twice a day. Clinicians who have exposures to persons who are likely to have antiretroviral medication resistance (eg, persons receiving therapy who have detectable viral loads) should have their therapy individualized, using at least two medications to which the source is unlikely to be resistant.

Centers for Disease Control and Prevention (CDC). Human immunodeficiency virus (HIV) and occupational exposure. 2019 Sep 5. Accessed August 31, 2024. https://www.cdc.gov/hiv/workplace/healthcareworkers.html

7. Prevention of transmission of HIV through blood or blood products—Current efforts in the United States to screen blood and blood products have lowered the risk of HIV transmission with transfusion of a unit of blood to 1:2,000,000. Use of blood and blood products should be judicious and only when clinically indicated.

8. HIV vaccine—Primate model data have suggested that development of a protective vaccine may be possible, but clinical trials in humans have been disappointing. Only one vaccine trial has shown any degree of efficacy. In this randomized, double-blind, placebo-controlled trial, a recombinant canarypox vector vaccine plus two booster injections of a recombinant gp120 vaccine reduced the risk of HIV among a primarily heterosexual population in Thailand, but efficacy was too low (31%) for widespread use. A mosaic HIV vaccine resulted in a strong immune response among adult humans and protection against infection with an HIV-like virus in rhesus monkeys. Unfortunately, initial results from a phase 2b trial in cisgender women using this mosaic vaccine (Imbokodo study) did not show efficacy. In January 2023, a phase 3 study (Mosaico) using a different formulation of the mosaic vaccine among 3900 MSM and transgender women conducted in Latin America, North America, and Europe had to be discontinued for lack of efficacy in preventing HIV infection. The latest trial of two vaccine candidates in combination, called the PrEPVacc trial, being tested in 1500 participants in Uganda, Tanzania, and South Africa, also closed early in December 2023 due to lack of efficacy. Although the results from these HIV vaccine trials were disheartening, prior vaccine candidates for HIV have not managed to elicit broadly neutralizing antibodies and T cells against the virus. However, preliminary work with a novel mRNA vaccine developed for HIV shows the development of both. Moreover, protection against simian HIV infection was demonstrated in a small group of macaques using the adapted mRNA HIV vaccine. Therefore, the first clinical trials of mRNA vaccines against HIV/AIDS launched in 2022 and are ongoing as of 2025.

B. Secondary Prevention

In the era prior to the development of effective ART, cohort studies of individuals with documented dates of seroconversion demonstrate that AIDS developed within 10 years in approximately 50% of untreated seropositive persons. With currently available treatment, progression of disease has been markedly decreased. In addition to ART, prophylactic regimens can prevent opportunistic infections and improve survival. Prophylaxis and early intervention prevent several infectious diseases, including tuberculosis and syphilis, which are transmissible to others. Recommendations for screening tests, vaccinations, and prophylaxis are listed in Table 36–5.

1. Tuberculosis—Because of the increased occurrence of tuberculosis among people with HIV, these patients should undergo an intradermal PPD test or an IGRA blood test at baseline and yearly thereafter if they remain at risk of exposure (eg, incarcerated, living in congregate settings). Those with a positive PPD (defined for people with HIV as > 5 mm of induration) or a positive IGRA assay (results that are reported as positive and not negative or indeterminate) should be clinically evaluated for active tuberculosis, including by a CXR. Patients with an opacity in any location, especially if accompanied by mediastinal adenopathy, should have sputum sent for acid-fast staining and nucleic acid amplification testing. Patients with active tuberculosis should be treated as outlined in Chapter 9. Patients with a positive PPD or IGRA assay, and a normal CXR or negative sputum evaluation for active tuberculosis are classified as having latent tuberculosis infection. Patients with latent tuberculosis infection who have not been previously treated for (active or latent) tuberculosis should receive once-weekly isoniazid (900 mg orally weekly for patients > 50 kg) and rifapentine (900 mg orally weekly for patients > 50 kg) for 12 weeks. Other preferred regimens are rifampin daily (10 mg/kg; maximum and usual adult dose is 600 mg orally daily) for 4 months, although all people with HIV should be evaluated for drug interactions, including with ART and 3 months of once daily rifampin and isoniazid once daily (300 mg orally daily). The WHO also recommends 1 month of daily isoniazid and daily rifapentine (300 mg daily for a weight of < 35 kg, 450 mg daily for a weight of 35 to 45 kg, and 600 mg for a weight of > 45 kg) as a short-course regimen, although this regimen is not recommend in conjunction with integrase inhibitors due to concern for induction of metabolism by daily rifapentine. An alternative, less preferred regimen given low completion rates, is 9 months of daily isoniazid. In patients with advanced immunodeficiency, both the PPD and IGRA assay are more likely to be falsely negative or (for IGRA assay) indeterminant. Therefore, it may be worth obtaining a CXR, tuberculosis sputum evaluation, or both in people at high risk for tuberculosis, and retesting patients with initially low CD4 counts once they have received ART and have immune reconstitution (CD4 count ≥ 200 cells/mcL).

2. Syphilis—Because of the increased number of cases of syphilis among MSM, including those living with HIV, *all*

Table 36–5. Health care maintenance and monitoring of people with HIV.

For all people with HIV:
CD4 counts every 3–6 months (can decrease to every 12 months if viral load suppressed on ART for 2 years and CD4 count > 300 cells/mcL, optional if consistently above 500 cells/mcL)
Viral load tests every 3–6 months and 2–4 weeks following a change in therapy
Genotypic resistance testing at baseline and if viral load not fully suppressed and patient taking ART
CBC, chemistry profile, transaminases and total bilirubin, at baseline and every 3–6 months
UA at baseline and annually during ART (every 6 months if ART regimen includes TDF)
Glucose or hemoglobin A_{1c} at baseline and annually during ART
Lipid panel at baseline, 4–8 weeks after starting or changing an ART regimen that affects lipids, and annually for everyone > 40 years of age
PPD or IGRA at baseline and annually if at high risk for exposure to persons with active TB
Latent TB infection treatment for those with positive PPD or IGRA, normal CXR, and no history of treatment for active or latent TB
RPR or VDRL at entry and periodically based on sexual activity
Toxoplasma IgG serology at baseline
Hepatitis serologies: hepatitis A antibody, hepatitis B surface antigen, hepatitis B surface antibody, hepatitis B core antibody, hepatitis C antibody
Pneumococcal vaccine
Meningococcal vaccine
Herpes zoster vaccine[1]
Inactivated influenza vaccine annually in season
Hepatitis A vaccine for those without immunity to hepatitis A
Hepatitis B vaccine for those who are hepatitis B surface antigen and antibody negative (use 40 mcg formulation at 0, 1, and 6 months; repeat if no immunity 1 month after three-vaccine series)
Combined tetanus, diphtheria, pertussis vaccine
COVID-19 vaccination
HPV vaccine for women aged 26 years or younger with HIV
Haemophilus influenzae type b vaccination
Bone mineral density monitoring for postmenopausal women and men aged 50 years or older
Papanicolaou smears annually; if three smears are negative, can switch to longer intervals (see Complications, Section M. Gynecologic Manifestations)
Consider anal swabs for cytologic evaluation
For people with HIV with CD4 < 200 cells/mcL:
Pneumocystis jirovecii prophylaxis (see Treatment, Section A. Prophylaxis for Complications of HIV Infection and Table 36–6)
For people with HIV with CD4 < 100 cells/mcL and Toxoplasma IgG-positive:
Ensure current prophylaxis covers toxoplasma, and if not, add toxoplasma prophylaxis (see Treatment, Section A. Prophylaxis for Complications of HIV Infection and Table 36–6)

[1] Consider in patients age > 50 years, should not give live vaccine (Zostavax) to individuals with CD4 T-cells < 200 cells/mcL.

ART, antiretroviral therapy; CMV, cytomegalovirus; IgG, immunoglobulin G; IGRA, interferon γ release assay; INH, isoniazid; PPD, purified protein derivative; RPR, rapid plasma reagin; TB, tuberculosis; TDF, tenofovir disoproxil fumarate; VDRL, Venereal Disease Research Laboratories.

such men should be screened for syphilis by a syphilis enzyme immunoassay, rapid plasma reagin (RPR), or Venereal Disease Research Laboratories (VDRL) test every 3–6 months. Increases of syphilis cases among people with HIV are of particular concern because these individuals are at increased risk for neurosyphilis and other complications of syphilis. People with HIV may lose fluorescent treponemal antibody absorption (FTA-ABS) reactivity after treatment for syphilis, particularly if they have low CD4 counts. Thus, *in this population, a nonreactive treponemal test does not rule out a past history of syphilis*. People with HIV should be evaluated carefully for otic, ophthalmic, or any other neurologic symptoms after a diagnosis of syphilis, with lumbar puncture pursued if there are neurologic symptoms, assuming empiric treatment is not pursued due to the presence of unexplained ophthalmic or otic symptoms. CSF cell count and CSF-VDRL should be examined in these cases. Those without neurologic symptoms or a normal CSF evaluation are treated as having *early latent syphilis* (prior syphilis evaluation within 1 year or symptoms of early syphilis) with one dose of benzathine penicillin G, 2.4 million units intramuscularly. Those with unknown or > 1 year since a prior syphilis evaluation are treated as *late latent syphilis* (benzathine penicillin G, 2.4 million units intramuscularly weekly for 3 weeks). Those with a pleocytosis or a positive CSF-VDRL test are treated as having *neurosyphilis* (aqueous penicillin G, 2–4 million units intravenously every 4 hours for 10–14 days). Given higher rates of clinical failure, people with HIV should be evaluated for treatment response, with nonresponse defined as lack of fourfold decrease in titers in 1 year after early latent syphilis treatment or 2 years after late latent syphilis treatment. These individuals should be evaluated for neurosyphilis, particularly if there is no clinical evidence of reinfection. For a more detailed discussion of this topic, see Chapter 39.

3. Immunizations—Patients with HIV should receive immunizations as outlined in Table 36–5. Patients without evidence of hepatitis B surface antigen or surface antibody should receive hepatitis B vaccination, using the 40-mcg formulation (the higher dose is to increase the chance of developing protective immunity) or using the new two-dose CpG-adjuvanted hepatitis B vaccine (Heplisav-B). Although the CpG-adjuvanted vaccine was not initially studied among people with HIV, data presented at IDWeek 2022 demonstrated that a three-dose regimen led to excellent serologic responses. It is not clear if a three-dose regimen or two-dose regimen should be used among people with HIV. If the patient does not have immunity 1 month after series completion, then the series should be repeated. People with HIV should also receive the standard inactivated vaccines such as tetanus, diphtheria, and pertussis boosters that would be given to uninfected persons. *Most live vaccines, such as yellow fever vaccine, should be avoided in people with CD4+ T-cell counts < 200 cells/mcL*. However, the mpox vaccine (which is a live attenuated vaccine) was found to be safe when administered to people with HIV with a range of CD4 cell counts in the 2022 mpox outbreak. Measles vaccination, while a live virus vaccine, appears relatively safe when administered to patients with HIV and should be given if the patient has never had measles (with the vaccine developed in 1963) or been adequately vaccinated. The recombinant adjuvanted herpes zoster vaccine (Shingrix), two doses 2–6 months apart, is recommended for people all adults with HIV. COVID-19 vaccines are safe and effective for people with HIV. Although most people with HIV will produce a serologic response to vaccination, there is evidence of reduced serologic response among some people with HIV, particularly those with low CD4+ T-cell counts or unsuppressed viral loads. Booster vaccination is therefore recommended for this population.

Spinelli MA et al. Differences in post-mRNA vaccination severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) immunoglobulin G (IgG) concentrations and surrogate virus neutralization test response by human immunodeficiency virus (HIV) status and type of vaccine: a matched case-control observational study. Clin Infect Dis. 2022;75:e916. [PMID: 34864962]

4. Other measures—STI screening should continue as there are high rates of syphilis, gonorrhea, and chlamydia infection among people with HIV. Postexposure prophylaxis (PEP) with doxycycline has been shown to reduce the incidence of STIs among MSM and transgender women and is recommended for those groups if sexual risk is ongoing. Substance use treatment should be recommended for persons with substance use disorders, as this can improve adherence and treatment engagement. They should be warned to avoid consuming raw meat, eggs, or shellfish to avoid infections with *Toxoplasma, Campylobacter*, and *Salmonella*. Those with CD4+ counts < 200 cells/mcL should wash their hands thoroughly after cleaning cat litter or should forgo this household chore to avoid possible exposure to toxoplasmosis. To reduce the likelihood of infection with *Bartonella* species, patients with low CD4 counts should avoid activities that might result in cat scratches or bites.

Treatment

Treatment for HIV infection can be broadly divided into the following categories: (1) prophylaxis for opportunistic infections, malignancies, and other complications of HIV infection; (2) treatment of opportunistic infections, malignancies, and other complications of HIV infection; and (3) treatment of the HIV infection itself with ART.

A. Prophylaxis for Complications of HIV Infection

In general, decisions about prophylaxis of opportunistic infections are based on the CD4 count, recent HIV viral load, and a history of having had the infection in the past. Studies have shown that *in patients with robust improvements in immune function—as measured by increases in CD4 counts above the levels that are used to initiate treatment—or prolonged virologic suppression in the setting of poor immunologic response, prophylactic regimens can safely be discontinued.*

Because people with advanced HIV infection are susceptible to a number of opportunistic pathogens, the use of agents with activity against more than one pathogen is preferable.

1. Prophylaxis against *Pneumocystis* pneumonia—Patients with CD4 counts < 200 cells/mcL, a CD4 lymphocyte percentage < 14%, or oral candidiasis should be offered primary prophylaxis for *Pneumocystis* pneumonia. Patients with a history of *Pneumocystis* pneumonia should receive secondary prophylaxis until their viral load is undetectable and they have maintained a CD4 count of 200 cells/mcL or more while receiving ART for longer than 3 months. Regimens for *Pneumocystis* prophylaxis are given in Table 36–6.

2. Prophylaxis against *M avium* complex infection—Prophylaxis against *M avium* complex is *no longer recommended* in most individuals who are initiating ART, including in those with CD4+ counts < 50 cells/mcL. The incidence of *M avium* complex infection is very low among those on ART. In rare cases where individuals delay ART (eg, per patient preference) whose CD4 counts fall to < 50 cells/mcL, prophylaxis against *M avium* complex infection should be offered. Clarithromycin (500 mg orally twice daily) and azithromycin (1200 mg orally weekly) are the recommended regimens. The azithromycin regimen is generally preferred based on high adherence and low cost. Prophylaxis against *M avium* complex infection may be discontinued in patients who initiate ART.

3. Prophylaxis against toxoplasmosis—Toxoplasmosis prophylaxis is desirable in patients with a positive IgG toxoplasma serology and CD4 counts < 100 cells/mcL. Trimethoprim-sulfamethoxazole (one double-strength tablet daily) offers good protection against toxoplasmosis, as does a combination of pyrimethamine, 25 mg orally once a week, plus dapsone, 50 mg orally daily, plus leucovorin, 25 mg orally once a week. A glucose-6-phosphate dehydrogenase (G6PD) level should be checked prior to

Table 36–6. *Pneumocystis jirovecii* prophylaxis (listed in order of preference).

Medication	Dose	Side Effects	Limitations
Trimethoprim-sulfamethoxazole	One double-strength tablet three times a week to one tablet daily	Rash, neutropenia, hepatitis, Stevens-Johnson syndrome	Hypersensitivity reaction is common but, if mild, it may be possible to treat through.
Dapsone	50–100 mg orally daily or 100 mg two or three times per week	Anemia, nausea, methemoglobinemia, hemolytic anemia	Less effective than above. Glucose-6-phosphate dehydrogenase (G6PD) level should be checked prior to therapy. Check methemoglobin level after 1 month of treatment.
Atovaquone	1500 mg orally daily with a meal	Rash, diarrhea, nausea	Less effective than suspension trimethoprim-sulfamethoxazole; equal efficacy to dapsone, but more expensive.
Aerosolized pentamidine	300 mg monthly	Bronchospasm (pretreat with bronchodilators); rare reports of pancreatitis	Apical *P jirovecii* pneumonia, extrapulmonary *P jirovecii* infections, pneumothorax.

dapsone therapy, and a methemoglobin level should be checked at 1 month. Prophylaxis can be discontinued when the CD4 cells have increased to > 200 cells/mcL for > 3 months.

B. Treatment of Complications of HIV Infection

Treatment of common AIDS-related complications is detailed above and in Table 36–3. In the era prior to the use of ART, patients required lifelong treatment for many infections, including CMV retinitis, toxoplasmosis, and cryptococcal meningitis. However, *among patients who have a good response to ART, maintenance therapy for opportunistic infections can be terminated*. For example, in consultation with an ophthalmologist, maintenance treatment for CMV infection can be discontinued when persons receiving ART have had a sustained increase in CD4 count to > 100 cells/mcL for at least 3–6 months. Similar results have been observed in patients with *M avium* complex bacteremia, who have completed a year or more of therapy for *M avium* complex and have an increase in their CD4 count to 100 cells/mcL for > 6 months while receiving ART. Cessation of secondary prophylaxis for *Pneumocystis* pneumonia is described above.

Treating patients with repeated episodes of the same opportunistic infection can pose difficult therapeutic challenges. For example, patients with second or third episodes of *Pneumocystis* pneumonia may have developed allergic reactions to standard treatments with a prior episode. Fortunately, there are several alternatives available for the treatment of *Pneumocystis* infection. Trimethoprim with dapsone and primaquine with clindamycin are two combinations that often are tolerated in patients with a prior allergic reaction to trimethoprim-sulfamethoxazole and intravenous pentamidine.

C. Antiretroviral Therapy

The availability of agents that in combination suppress HIV replication (Table 36–7) has had a profound impact on the natural history of HIV infection. Indeed, *with the advent of effective ART, the life expectancy of people with HIV approaches that of people without infection when treatment is initiated early in the course of the disease and maintained.*

The recognition that HIV damages the immune system from the beginning of infection, even when the damage is not easily measured by conventional tests, combined with the greater potency, the improved side-effect profile, and the decreased pill burden of modern HIV regimens, have led to the recommendation to **start treatment as soon as possible for all people with HIV, including patients having acute HIV infection, regardless of CD4 count**.

Rapid initiation programs have been created, where treatment can be started on the same day that patients test positive for HIV, so patients can start receiving treatment promptly and avoid being lost to follow-up. The clinician should provide sufficient resources to help patients cope with these major events in a short time, receive sufficient insurance and benefits coverage, and connect to other social services resources (ie, food assistance, housing, etc). If treatment is started before the results of resistance testing are available, a nonnucleoside reverse transcriptase inhibitor (NNRTI) should not be used given the possibility of transmitted drug resistance. Recommended regimens for initiating treatment before resistance testing results are available include (1) dolutegravir plus TAF/emtricitabine or TDF/emtricitabine (or lamivudine), (2) bictegravir/TAF/emtricitabine, or (3) boosted darunavir plus TAF/emtricitabine or TDF/emtricitabine (or lamivudine). The latter regimen is recommended (until resistance testing is known) if a patient developed an HIV seroconversion while on cabotegravir-based PrEP due to the possibility of the development of integrase inhibitor resistance. Also, patients requiring abacavir as part of their regimen should not start treatment prior to the results of HLA-B*5701 allele testing or hepatitis B testing.

The primary goal of therapy should be complete suppression of viral replication as measured by the serum viral load. Partially suppressive combinations should be avoided. Similarly, if toxicity develops, it is preferable to change the

Table 36–7. Antiretroviral therapy agents by class (listed in alphabetical order within classes).

Medication	Dose	Common Side Effects	Special Monitoring[1]
Nucleoside Reverse Transcriptase Inhibitors (NRTIs)			
Abacavir (Ziagen)	600 mg orally once daily	Rash, fever—if occur, rechallenge may be fatal	No special monitoring
Emtricitabine (Emtriva)	200 mg orally once daily	Skin discoloration palms/soles (mild)	No special monitoring
Lamivudine (Epivir)	150 mg orally twice daily or 300 mg daily	Rash, peripheral neuropathy	No special monitoring
Zidovudine (AZT) (Retrovir)	600 mg orally daily in two divided doses	Anemia, neutropenia, nausea, malaise, headache, insomnia, myopathy	CBC with differential 4–8 weeks after starting AZT
Nucleotide Reverse Transcriptase Inhibitors (NRTIs)			
Tenofovir alafenamide (TAF)/emtricitabine (Descovy)	25 mg of TAF with 200 mg of emtricitabine once daily	Weight gain; dyslipidemia; lower but still present risk of nephrotoxicity and bone resorption	Creatinine at baseline, at 2–8 weeks, then every 3–6 months; UA and urine glucose and protein at baseline and repeated as clinically indicated; HBsAg, liver enzymes at baseline, at 2–8 weeks, then every 3–6 months, continue for months after discontinuation; consider bone densitometry
Tenofovir (TDF) (Viread)	300 mg orally once daily	Kidney dysfunction, bone resorption, GI distress	Creatinine at baseline, at 2–8 weeks, then every 3–6 months; UA and urine glucose and protein at baseline and repeated as clinically indicated; consider bone densitometry
Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)			
Doravirine (Pifeltro)	100 mg daily	Headache, fatigue, abdominal pain	No special monitoring
Efavirenz (Sustiva)	600 mg orally daily	Neurologic disturbances, rash, hepatitis	No special monitoring
Etravirine (Intelence)	200 mg orally twice daily	Rash, peripheral neuropathy	No special monitoring
Nevirapine (Viramune)	200 mg orally daily for 2 weeks, then 200 mg orally twice daily	Rash	No special monitoring
Rilpivirine (Edurant)	25 mg daily	Depression, rash	No special monitoring
Protease Inhibitors (PIs)			
Atazanavir (Reyataz)	400 mg orally once daily or 300 mg atazanavir with 100 mg ritonavir daily	Hyperbilirubinemia	Bilirubin level every 3–4 months
Atazanavir/cobicistat (Evotaz)	300 mg of atazanavir with 150 mg of cobicistat orally once daily	Hyperbilirubinemia	Bilirubin level every 3–4 months
Darunavir/cobicistat (Prezcobix)	800 mg of darunavir and 150 mg of cobicistat orally once daily	Rash	No special monitoring
Darunavir/ritonavir (Prezista/Norvir)	**PI-experienced patients:** 600 mg of darunavir and 100 mg of ritonavir orally twice daily **For PI-naïve patients:** 800 mg of darunavir and 100 mg of ritonavir orally daily	Rash	No special monitoring
Lopinavir/ritonavir (Kaletra)	400 mg/100 mg orally twice daily	Diarrhea	No special monitoring

(*continued*)

Table 36–7. Antiretroviral therapy agents by class (listed in alphabetical order within classes). (continued)

Medication	Dose	Common Side Effects	Special Monitoring[1]
Ritonavir (Norvir)	600 mg orally twice daily or in lower doses (eg, 100 mg orally once or twice daily) for boosting other PIs	GI distress, peripheral paresthesias	No special monitoring
Entry Inhibitors			
Enfuvirtide (Fuzeon)	90 mg subcutaneously twice daily	Injection site pain and allergic reaction	No special monitoring
Integrase Inhibitors			
Bictegravir	50 mg orally daily. No longer marketed as a single agent; used in antiretroviral combination (Table 36–8)	Diarrhea, nausea, headache	No special monitoring
Cabotegravir	Oral regimen of 30 mg daily with rilpivirine 25 mg daily for 1 month (optional); then intramuscular loading dose of 600 mg with rilpivirine 900 mg intramuscularly in separate buttock injections; followed by (1) this dosage every 8 weeks or (2) monthly intramuscular injections of 400 mg with 600 mg rilpivirine thereafter	Injection site reactions with intramuscular dose	No special monitoring
Dolutegravir (Tivicay)	Treatment-naïve or integrase-naïve patients: 50 mg daily When administered with efavirenz or rifampin: 50 mg twice daily When administered to integrase-experienced patients with suspected integrase resistance: 50 mg twice daily	Hypersensitivity, insomnia, fatigue, headache, rash	No special monitoring
Elvitegravir	No longer marketed as a single agent; used in antiretroviral combinations (Table 36–8)	Diarrhea, headache	No special monitoring
Raltegravir (Isentress)	400 mg orally twice daily	Diarrhea, nausea, headache	No special monitoring
Entry and Fusion Inhibitors			
Enfuvirtide (Fuzeon)	90 mg subcutaneously twice daily	Injection site pain and allergic reaction	No special monitoring
Ibalizumab (Trogarzo)	Loading dose of 2000 mg intravenously over 30 minutes; maintenance dose of 800 mg intravenously every 2 weeks thereafter	Diarrhea, dizziness, nausea, rash, elevated creatinine, lymphopenia	Monthly CBC, creatinine, bilirubin, glucose, lipase
Maraviroc (Selzentry)	150 mg orally twice daily or 300 mg orally twice daily	Cough, fever, rash	No special monitoring
Capsid Inhibitor			
Lenacapavir	At first, 927 mg (2 vials) injected under the skin and 600 mg (2 tablets) once a day on day 1. Followed by 600 mg (2 tablets) once a day on day 2. For maintenance, 927 mg (2 vials) injected under the skin once a day every 6 months.	Subcutaneous nodules and injection site pain	No special monitoring
Attachment Inhibitor			
Fostemsavir	600 mg orally twice a day	Nausea	No special monitoring

[1] Standard monitoring is CBC and differential, basic chemistries, serum aminotransferases, and total bilirubin every 3–6 months, UA at baseline and annually during antiretroviral treatment, fasting glucose or hemoglobin A_{1c} at baseline and annually during antiretroviral treatment, and fasting lipid profile at baseline, 4–8 weeks after starting an antiretroviral treatment regimen that affects lipids, and annually for everyone > 40 years of age.

offending medication given availability of multiple effective and well-tolerated medications.

Although the HIV treatment protocol has traditionally included three medications from at least two different classes, *several two-drug regimens using medications from at least two different classes have been shown to be effective.* A combination of dolutegravir plus lamivudine (Table 36–8) has been shown to be noninferior to dolutegravir plus TDF and emtricitabine as initial therapy in patients with HIV viral load of < 500,000 copies/mL. A second exception is the coformulation of dolutegravir and rilpivirine (Table 36–8); this combination is FDA-approved as an alternative treatment for patients who have been successfully virally suppressed for at least 6 months, have no history of treatment failure, and are not resistant to either of the two component agents. A third approved two-drug regimen is cabotegravir with rilpivirine provided as intramuscular injections given every 4 or 8 weeks in patients who have first achieved virologic suppression on oral ART.

The presence of an acute opportunistic infection in most cases does not preclude the initiation of ART. Randomized trials compared early initiation of ART (within 2 weeks of starting treatment for an opportunistic infection or tuberculosis) with ART that was deferred until after treatment of the opportunistic infection was completed (6 weeks after its start); results demonstrated that early initiation reduced death or AIDS progression by 50%. The reduced progression rates were related to more rapid improvements in CD4 counts in patients with advanced immunodeficiency. Furthermore, IRIS and other adverse events were no more frequent in the early ART arm.

Several randomized studies have also demonstrated improved clinical outcomes in HIV/tuberculosis coinfected patients who initiate ART early in the setting of active treatment for tuberculosis and whose CD4 counts are < 50 cells/mcL. *The exception to early ART in the setting of active infections may be in patients with a CNS-associated infection, such as cryptococcal or tuberculosis meningitis.* Several studies from low-income countries have shown high mortality rates with early ART initiation in this setting.

An initial antiretroviral regimen should be chosen to minimize side effects. For hospitalized patients, initiating treatment in patients with opportunistic infections requires close coordination between inpatient and outpatient clinicians to ensure that treatment is continued once patients are discharged.

D. Choosing an Antiretroviral Treatment Regimen

HIV antiretroviral medications can be grouped into six major categories: nucleoside and nucleotide reverse transcriptase inhibitors (NRTIs); NNRTIs; PIs; integrase inhibitors; entry and fusion inhibitors; and attachment inhibitors. A capsid inhibitor administered as a subcutaneous injection (lenacapavir) every 26 weeks is FDA-approved for multidrug-resistant HIV in combination with oral antiretroviral agents with residual activity.

1. Nucleoside and nucleotide reverse transcriptase inhibitors—There are currently six NRTI agents available (counting TDF and TAF as separate agents) for use. The choice of which agent to use depends primarily on the patient's prior treatment experience, results of resistance testing, medication side effects, other underlying conditions, and convenience of formulation. However, most clinicians use fixed-dose combinations (see Table 36–8) of including either emtricitabine/TDF, emtricitabine/TAF, or abacavir/lamivudine (ABC/lamivudine), all of which can be given once a day. Abacavir should be given only to HLA-B*5701-negative persons due to a risk of hypersensitivity in those who are HLA-B*5701-positive. In patients with viral loads > 100,000 copies/mL, ABC/lamivudine was less effective than emtricitabine/TDF when combined with efavirenz or ritonavir-boosted atazanavir. However, ABC/lamivudine appears to be equally efficacious as emtricitabine/TDF in patients with viral loads > 100,000 copies/mL when combined with dolutegravir. In some studies, abacavir increased risks of MI, and therefore should be avoided in patients at high risk for CVD. Zidovudine is now rarely used due to toxicity (eg anemia or neutropenia). Of the available agents, zidovudine is the most likely to cause anemia or neutropenia. Emtricitabine, TDF, TAF, and lamivudine have activity against hepatitis B. TDF, TAF, emtricitabine, abacavir, and lamivudine can be administered once daily. Information specific to each medication is given below and in Table 36–7.

A. Lamivudine—Lamivudine is a safe and well-tolerated agent. The dosage is 300 mg orally once a day. The dose should be reduced in patients with CKD, although toxicity is not anticipated. There are no significant side effects with lamivudine; it has activity against hepatitis B, though HBV resistance to it is an increasing problem, and it is always given with tenofovir in the setting of HIV/hepatitis B coinfection.

B. Emtricitabine—Emtricitabine is dosed at 200 mg orally once daily. Emtricitabine also has activity against hepatitis B but should not be used as monotherapy. Its dosage should be reduced in patients with CKD.

C. Abacavir—Abacavir is dosed at 600 mg once daily. Prior to initiation of abacavir, patients should undergo testing for HLA typing. *Those with the B*5701 allele should not be treated with abacavir because the likelihood of a hypersensitivity reaction developing is high*; the reaction is characterized by a flu-like syndrome with rash and fever that worsens with successive doses. Unfortunately, the absence of this allele does not guarantee that the patient will avoid the hypersensitivity reaction. Individuals in whom the hypersensitivity reaction develops should *not* be rechallenged with this agent because subsequent hypersensitivity reactions can be fatal. Abacavir, specifically recent use, has also been associated with an increased risk of MI in some cohort studies, generally in patients who have underlying risks for CVD. Abacavir is usually prescribed as a fixed-dose combination pill with lamivudine for use as a once-daily pill (Epzicom; Table 36–8).

D. Tenofovir—Tenofovir is the only licensed nucleotide analog. It comes in two forms: TDF and tenofovir alafenamide (TAF). TDF is available for use both in the form of a

Table 36–8. Fixed-dose antiretroviral combinations (listed in alphabetical order by brand name).

Brand Name	Components	Dosing and Special Considerations
Atripla	TDF 300 mg Emtricitabine 200 mg Efavirenz 600 mg	One pill daily constitutes a complete ART regimen.
Biktarvy	Emtricitabine 200 mg TAF 25 mg Bictegravir 50 mg	One pill daily constitutes a complete ART regimen. One of the recommended initial treatment regimens.
Complera	TDF 300 mg Emtricitabine 200 mg Rilpivirine 25 mg	One pill daily constitutes a complete ART regimen. Only for patients with HIV viral load < 100,000/mL.
Delstrigo	TDF 300 mg Lamivudine 300 mg Doravirine 100 mg	One pill daily constitutes a complete ART regimen.
Descovy	TAF 25 mg Emtricitabine 200 mg	One pill daily along with an NNRTI, PI, integrase inhibitor, or maraviroc (entry inhibitor). The difference between Descovy and Truvada is that Descovy has a different form of tenofovir (TAF) that has less effect on kidney function and bone mineral density than the form of tenofovir (TDF) in Truvada. Descovy is approved for use as a single agent for PrEP in men (not studied in women).
Dovato	Dolutegravir 50 mg Lamivudine 300 mg	One pill daily constitutes a complete ART regimen in adults with no prior antiviral treatment and no known substitutions associated with resistance to either component.
Epzicom	Abacavir 600 mg Lamivudine 300 mg	One pill daily along with an NNRTI, PI, integrase inhibitor, or maraviroc (entry inhibitor).
Genvoya	TAF 10 mg Emtricitabine 200 mg Elvitegravir 150 mg Cobicistat 150 mg	One pill daily constitutes a complete ART regimen. Although it contains four medications, one component (cobicistat) is a medication booster only. The only difference between Stribild and Genvoya is that Genvoya has a different form of tenofovir (TAF) that appears to be safer than tenofovir TDF with less effect on kidney function and bone mineral density.
Juluca	Dolutegravir 50 mg Rilpivirine 25 mg	One pill daily with a meal for patients who have been virologically suppressed (viral load < 50 copies/mL) on a stable ART regimen for ≥ 6 months and no history of treatment failure or resistance to dolutegravir or rilpivirine.
Odefsey	TAF 25 mg Emtricitabine 200 mg Rilpivirine 25 mg	One pill daily constitutes a complete ART regimen. Only for patients with no history of HIV viral load ≥ 100,000 copies/mL. Or for replacement of stable antiretroviral regimen in patients fully suppressed for > 6 months, with no history of treatment failure, and with no known resistance to components of the drug combination.
Stribild	TDF 300 mg Emtricitabine 200 mg Elvitegravir 150 mg Cobicistat 150 mg	One pill daily constitutes a complete ART regimen. Although it contains four medications, one component (cobicistat) is a medication booster only.
Symtuza	TAF 10 mg Emtricitabine 200 mg Darunavir 800 mg Cobicistat 150 mg	One pill daily constitutes a complete ART regimen. Although it contains four medications, one component (cobicistat) is a medication booster only. One of the recommended initial treatment regimens.
Triumeq	Abacavir 600 mg Lamivudine 300 mg Dolutegravir 50 mg	One pill constitutes a complete ART regimen. One of the recommended initial treatment regimens.
Trizivir	Abacavir 300 mg Lamivudine 150 mg Zidovudine 300 mg	One tablet twice daily with an NNRTI, PI, integrase inhibitor, or maraviroc (entry inhibitor). Although it contains three medications it *does not* constitute a complete ART regimen.
Truvada	TDF 300 mg Emtricitabine 200 mg	One pill daily with an NNRTI, PI, integrase inhibitor, or maraviroc (entry inhibitor). Tenofovir is the most commonly used NRTI backbone. Associated with less weight gain and lipid abnormalities than TAF. Truvada is approved for use as a single agent for PrEP.

ART, antiretroviral therapy; NNRTI, nonnucleoside reverse transcriptase inhibitor (eg, delavirdine, efavirenz, etravirine, nevirapine, rilpivirine); NRTI, nucleoside/nucleotide reverse transcriptase inhibitor (eg, abacavir, didanosine, emtricitabine, lamivudine, stavudine, tenofovir, zidovudine); PI, protease inhibitor; PrEP, pre-exposure prophylaxis; TAF, tenofovir alafenamide; TDF, tenofovir disoproxil fumarate.

single pill at an oral dose of 300 mg once daily and as an oral fixed-dose combination pill with emtricitabine 200 mg (Truvada; Table 36–8) once daily. Several other single-tablet once-a-day complete regimens include TDF (Atripla, Complera, Stribild) (Table 36–8). Tenofovir is active against hepatitis B, including isolates that have resistance to lamivudine. TDF is associated with a clinically modest loss of kidney function, a small increased risk of AKI, and increased rate of bone resorption. In patients taking boosted therapy (eg, therapy including cobicistat or ritonavir), TAF appears to cause fewer problems with kidney dysfunction and bone loss and is the preferred choice.

TAF attains higher levels in cells with a much lower plasma level. For this reason, it appears to cause less harm to kidneys and less bone resorption. TAF should not be used with rifamycins. TDF appears to be associated with lower lipid levels, and TAF seems to be associated with greater weight gain when combined with integrase inhibitors.

2. Nonnucleoside reverse transcriptase inhibitors— NNRTIs inhibit reverse transcriptase at a site different from that of the nucleoside and nucleotide agents described above. The major advantage of NNRTIs is that four of them (efavirenz, rilpivirine, doravirine, and nevirapine) have potencies comparable to that of PIs (next section), at least for patients with viral loads under 100,000 copies/mL—with lower pill burden and fewer side effects. However, they have lower barrier to resistance when compared to PIs and integrase inhibitors. Unlike PIs, they do *not* cause lipodystrophy and do not seem to cause weight gain; patients with cholesterol and triglyceride elevations who are switched from a PI to an NNRTI may have improvement in their lipids. The resistance patterns of NNRTIs are distinct from those of the PIs. Because these agents may cause alterations in the clearance of PIs, dose modifications may be necessary when these two classes of medications are administered concomitantly. There is a high degree of cross-resistance among the "first-generation" NNRTIs, such that resistance to one medication in this class uniformly predicts resistance to other medications. However, the "second-generation" NNRTIs etravirine, rilpivirine, and doravirine can have consistent antiviral activity in patients with prior exposure and resistance to nevirapine or efavirenz, although genotypic analysis is needed first in these contexts. In particular, the *K103N* pathologic variant does not have an impact on etravirine, doravirine, or rilpivirine. There is no therapeutic reason for using more than one NNRTI at the same time.

A. Efavirenz—Efavirenz can be given once daily in a single dose (600 mg orally) and is available in a once-daily fixed-dose combination with TDF and emtricitabine in a single pill (Atripla; Table 36–8). The major side effects are rash and psychiatric/neurologic complaints, with patients reporting symptoms ranging from lack of concentration and strange dreams to delusions and mania. These side effects tend to wane over time, usually within a month or so; however, there are some patients who cannot tolerate these effects, especially if they persist longer than a month. Participant level data from four randomized trials of efavirenz regimens versus non-efavirenz-containing regimens found *increased suicidality* (hazard ratio of 2.6) among those taking efavirenz. As a result of these neuropsychiatric side effects, efavirenz is no longer a preferred regimen. Administration of efavirenz with food, especially fatty food, may increase its serum levels and consequent neurotoxicity. Therefore, it should be taken on an empty stomach; taking before bedtime may also reduce patients' experience of neuropsychiatric symptoms.

B. Doravirine—Dosed at 100 mg orally daily, this medication can be taken with or without food. Two 48-week phase 3 studies showed that, in previously untreated individuals, doravirine, when used with two NRTIs resulted in similar levels of viral suppression as efavirenz plus two NRTIs or darunavir/ritonavir plus two NRTIs. It is also available as a single-pill combination with TDF and lamivudine (Delstrigo; Table 36–8). It is well tolerated. In cases of virologic failure, NNRTI cross-resistance may develop.

C. Rilpivirine—This medication, dosed at 25 mg once daily, is equal in efficacy to efavirenz in patients with HIV viral loads < 100,000 copies/mL. Oral rilpivirine should *not* be used in patients with baseline viral loads of 100,000 copies/mL or greater or those with CD4 counts < 200 cells/mcL because of greater risk of viral failure. As is true of efavirenz, rilpivirine is available in a once-daily fixed-dose combination with TDF and emtricitabine (Complera; Table 36–8) and with TAF and emtricitabine (Odefsey; Table 36–8) to be taken with a meal. It is also available in a two-drug regimen with dolutegravir (Juluca; Table 36–8). PPIs should not be given with rilpivirine. Rilpivirine has fewer neurologic side effects than efavirenz. The FDA has approved a long-acting formulation of rilpivirine for monthly or every 8-week intramuscular injections to be given with the integrase inhibitor cabotegravir (see below).

D. Nevirapine—The dose of nevirapine is 400 mg orally daily (extended release), but it is initiated at a dose of 200 mg once a day to decrease the incidence of rash, which is as high as 40% when full doses are begun immediately. If rash develops while the patient is taking 200 mg daily, liver enzymes should be checked and the dose should not be increased until the rash resolves. Patients with mild rash and no evidence of hepatotoxicity can continue to be treated with nevirapine. Nevirapine should not be used in treatment-naïve women with CD4 counts > 250 cells/mcL or in males with CD4 counts > 400 cells/mcL because they have greater risk of hepatotoxicity. In general, because of the risk of fatal hepatotoxicity, *nevirapine should be used only when there is not a better alternative.*

E. Etravirine—Etravirine is an NNRTI approved for the treatment of patients with prior NNRTI intolerance or resistance. Etravirine has been shown to be effective in treatment-experienced patients even when some degree of NNRTI resistance is present, making it a true "second-generation" medication in this class. Etravirine dosage is one 200 mg tablet twice daily or 400 mg once daily. The most common side effects are nausea and rash; rarely, the rash can be severe (toxic epidermal necrolysis). *Patients with signs of severe rash or hypersensitivity reactions should* *immediately discontinue the medication.* Prior rash due to treatment with one of the other NNRTIs does not make rash more likely with etravirine. Etravirine should not be taken by people with severe liver disease or administered with atazanavir/ritonavir, full-dose ritonavir, or PIs without low-dose ritonavir.

3. Protease inhibitors—Four PIs—ritonavir, lopinavir (in combination with ritonavir), atazanavir, and darunavir—are still available (with others used rarely). Darunavir boosted with ritonavir or cobicistat is the most commonly used PI in the United States. PIs are potent suppressors of HIV replication and are administered as part of a combination regimen.

All of the PIs—to differing degrees—are metabolized by the cytochrome P450 system, and each can inhibit and induce various P450 isoenzymes. Therefore, medication interactions are common and difficult to predict. Clinicians should consult the product inserts before prescribing PIs with other medications. Medications that are known to induce the P450 system, such as rifampin, should be avoided.

The fact that the PIs are dependent on metabolism through the cytochrome P450 system has led to the use of ritonavir to *boost* the medication levels of other PIs, allowing use of lower doses and simpler dosing schedules of these PIs. A second boosting agent, cobicistat, is coformulated with the PI atazanavir (Evotaz) and darunavir (Prezcobix and Symtuza). Similar to ritonavir, cobicistat also inhibits liver enzymes that metabolize other HIV medications.

All PIs have been linked to varying degrees of metabolic side effects, including elevated cholesterol levels, elevated triglyceride levels, insulin resistance, diabetes mellitus, and changes in body fat composition (eg, abdominal obesity). The lipid abnormalities and body habitus changes are referred to as *lipodystrophy*. Although lipodystrophy is commonly associated with PIs, it has been seen also in people with HIV who have never been treated with these agents. In particular, the lipoatrophy effects seen in patients receiving ART appear to be more related to the nucleoside toxicity and in particular to the thymidine analogs (ie, zidovudine).

Of the different manifestations of lipodystrophy, the dyslipidemias that occur are of particular concern because of the likelihood that increased levels of cholesterol and triglycerides will result in increased prevalence of heart disease. *All patients taking PIs should have fasting serum cholesterol, LDL cholesterol, and triglyceride levels assessed.* Clinicians should assess for CHD (see Chapter 33) and consider initiating dietary changes or medication therapy (or both). PIs inhibit statin metabolism. Lovastatin and simvastatin should be avoided. In general, the least interaction is with pravastatin (20 mg daily orally). Atorvastatin (10 mg daily orally) or rosuvastatin (5 mg/day orally initially; maximum 10 mg/day) may also be used cautiously. Patients with persistently elevated fasting serum triglyceride levels of 500 mg/dL or more who do not respond to dietary intervention should be treated with one of the statin medications, followed by gemfibrozil (600 mg twice daily prior to the morning and evening meals). PIs are associated with abnormalities in cardiac conduction, especially prolongation of the PR interval.

A. Ritonavir—Use of this potent PI at full dose (600 mg orally twice daily) has been limited by its inhibition of the cytochrome P450 pathway causing a large number of drug-drug interactions and by its frequent side effects of fatigue, nausea, and paresthesias. However, it is widely used in lower dose (eg, 100 mg daily to 100 mg twice daily) as a booster or pharmacokinetic enhancer of other PIs.

B. Lopinavir/r—Lopinavir/r is lopinavir (200 mg) coformulated with a low dose of ritonavir (50 mg) to maximize the bioavailability of lopinavir. The usual dose is lopinavir 400 mg with ritonavir 100 mg (two tablets) orally twice daily with food. When given along with efavirenz or nevirapine, a higher dose (600 mg/150 mg—three tablets) is usually prescribed. The most common side effect is diarrhea, and lipid abnormalities are frequent. Because of these side effects, lopinavir/r has fallen off the list of medications recommended as part of first-line treatment regimens.

C. Atazanavir—Atazanavir is available alone and coformulated with cobicistat (Evotaz). Atazanavir can be dosed as 400 mg (two 200-mg capsules) daily with food or it can be dosed as 300 mg in combination with 100 mg of ritonavir once daily with food. When coformulated with cobicistat, it is dosed at 300-mg atazanavir and 150-mg cobicistat. The most common side effect is mild hyperbilirubinemia that resolves with discontinuation of the medication. Nephrolithiasis and cholelithiasis have also been reported with this PI. Both tenofovir and efavirenz lower the serum concentration of atazanavir. Therefore, when either of these two medications is used with atazanavir, it should be boosted by administering ritonavir or given coformulated with cobicistat. PPIs are contraindicated in patients taking atazanavir because atazanavir requires an acidic pH to remain in solution.

D. Darunavir—Darunavir has impressive antiviral activity in the setting of significant PI resistance and in treatment-naïve patients. It is formulated by itself and coformulated with cobicistat (Prezcobix). When formulated without cobicistat it requires boosting with ritonavir. For initial treatment of HIV or for treatment-experienced patients without darunavir-related resistance pathologic variants, daily dosing is 800 mg of darunavir with 100 mg of ritonavir or with 150 mg of cobicistat. Darunavir 800 mg is also available in a coformulated tablet with emtricitabine, TAF, and cobicistat (Symtuza, Table 36–8). For patients with PI resistance (with 1–3 pathologic variants known to impact darunavir), darunavir should be dosed at 600 mg orally twice daily, with ritonavir, 100 mg orally twice daily. Darunavir has a safety profile similar to other PIs, such as ritonavir-boosted lopinavir, but is generally better tolerated. Darunavir is a sulfa-containing medication, and its use should be closely monitored in patients with sulfa allergy.

4. Integrase inhibitors—Integrase inhibitors slow HIV replication by blocking the HIV integrase enzyme needed for the virus to multiply. *They are now the preferred regimens for initiating therapy because of the combination of* *efficacy, ease of administration, and low incidence of side effects.* Five integrase inhibitors are currently available: raltegravir; elvitegravir; dolutegravir; bictegravir; and cabotegravir, which is given via injections along with injections of rilpivirine every 4 or 8 weeks. Clinical trials of available integrase inhibitors reveal a consistent pattern of more rapid decline in viral load compared with more standard PI/r or NNRTI-based regimens. Integrase inhibitors are effective (when combined with other active medications) in the treatment of people with HIV with documented resistance to each of the three main classes of antiretroviral medications (nucleoside analogs, PIs, NNRTIs). Avoid administering oral integrase inhibitors with antacids or other medications with divalent cations (Ca^{2+}, Mg^{2+}, Al^{2+}, Fe^{2+}) because chelation of the integrase inhibitor by the cation reduces absorption. When these medications must be taken with integrase inhibitors, they should either be taken together with food or the integrase inhibitor taken 2 hours before divalent cations. Integrase inhibitors have been associated with weight gain, with or without tenofovir alafenamide.

a. Raltegravir—The dose of raltegravir is 400 mg orally twice daily or 1200 mg orally once daily (two pills of 600 mg). It has been found to be superior to efavirenz and ritonavir-boosted darunavir and ritonavir-boosted atazanavir. Common side effects are diarrhea, nausea, and headache, but overall, it is well tolerated and has the additional advantage over PI-based regimens and efavirenz-based regimens in that it appears to have little impact on lipid profiles or glucose metabolism. Given the higher barrier to resistance with good tolerability of once-daily dosing, second-generation integrase inhibitors (dolutegravir, bictegravir), raltegravir is now rarely used.

b. Elvitegravir—Elvitegravir is not manufactured as a single agent. It can be prescribed in a once-a-day combination pill (Stribild) that contains 125 mg of elvitegravir and 150 mg of cobicistat, a boosting agent, along with standard doses of TDF and emtricitabine (Table 36–8). Stribild has been shown to be noninferior to two preferred first-line regimens: Atripla and boosted atazanavir with emtricitabine/TDF. The main side effect of Stribild is an increase in serum creatinine levels that has been shown to be related to the cobicistat inhibition of tubular secretion of creatinine by the kidney and is thought to be nonpathologic and reversible. However, because of this effect, *Stribild is recommended in patients with estimated creatinine clearance > 70 mL/min.* A UA should be done at baseline and at initial follow-up to look for proteinuria and glycosuria, which are signs of tubulopathy. Diarrhea and rash may also occur, although overall the medication is well tolerated. Elvitegravir is also coformulated with emtricitabine and TAF along with cobicistat boosting in a single once-a-day pill (Genvoya, Table 36–8). Given the higher barrier to resistance and decreased drug interactions of second-generation integrase inhibitors (dolutegravir, bictegravir), elvitegravir is rarely used.

c. Dolutegravir—Dolutegravir shows excellent potency and tolerability and is dosed once a day in most circumstances. It has been shown to be superior to efavirenz and darunavir. Unlike elvitegravir, dolutegravir does not require a boosting agent and has fewer drug-drug interactions. Similar to cobicistat, it inhibits tubular secretion of creatinine by the kidney, resulting in small increases in serum creatinine levels. The standard dosage used in treatment-naïve, integrase-naïve patients is 50 mg/day. It is available combined with abacavir and lamivudine in a single once a day tablet (Triumeq, Table 36–8). In patients receiving efavirenz or rifampin, the dose should be increased to 50 mg twice daily. It should also be dosed at 50 mg twice daily in integrase-experienced patients in whom dolutegravir resistance is documented or suspected. Indeed, when combined with other active medications, it has been shown to provide some activity in patients with integrase resistance who have not responded to prior raltegravir- or elvitegravir-containing regimens. Dolutegravir has demonstrated impressive results in clinical trials of treatment-naïve patients, in terms of effectiveness, tolerability, and high barrier to resistance, when compared with NNRTI, boosted PI, and raltegravir-containing regimens. Dolutegravir is coformulated in combination with rilpivirine (Juluca, Table 36–8) for use as a once-a-day (to be taken with a meal) treatment for patients who are virologically suppressed (viral load < 50 copies/mL) on a stable regimen for at least 6 months, with no history of treatment failures or resistance to either of the two agents. *A combination of dolutegravir-TDF and lamivudine is considered first-line or second-line therapy worldwide.*

d. Bictegravir—Bictegravir is dosed once daily, does not require boosting, and has a high barrier to resistance. It is dosed at 50 mg daily. It has been shown to be noninferior to dolutegravir. It is not available as a single agent but is marketed as a fixed-dose combination of bictegravir with emtricitabine and TAF (Biktarvy, Table 36–8).

e. Cabotegravir—Cabotegravir is an integrase inhibitor that has been approved for use in the United States, Canada, and in the European Union. Cabotegravir comes in two forms: an oral tablet and an injectable formulation. In both forms, it is intended to be given with rilpivirine. When given intramuscularly in combination with rilpivirine, the cabotegravir and rilpivirine are given as separate injections at the same time, one in each buttock. The first intramuscular loading doses are cabotegravir 600 mg and rilpivirine 900 mg. Thereafter, monthly intramuscular dosing is 400 mg of cabotegravir and 600 mg of rilpivirine. The advantage of this combination is that it is complete therapy for patients in whom the viral load is stable and suppressed (< 50 copies) on their current regimen, which is then stopped in favor of cabotegravir/rilpivirine. Additionally, the combination of cabotegravir 600 mg and rilpivirine 900 mg given every 8 weeks via injection has been approved. The most common side effect is injection site reaction.

5. Entry and fusion inhibitors—

a. Enfuvirtide—Enfuvirtide (Fuzeon) is known as a fusion inhibitor; it blocks the entry of HIV into cells by blocking the fusion of the HIV envelope to the cell membrane. The addition of enfuvirtide to an optimized antiretroviral regimen improved CD4 counts and lowered viral loads in heavily pretreated patients with multidrug-resistant HIV. Unfortunately, resistance to enfuvirtide develops rapidly in patients receiving a nonsuppressive treatment regimen. The dose is 90 mg by subcutaneous injection twice daily; unfortunately, painful injection site reactions develop in most patients, which makes long-term use problematic.

B. MARAVIROC—Maraviroc is a CCR5 co-receptor antagonist. Medications in this class prevent the virus from entering uninfected cells by blocking the CCR5 co-receptor. Before starting therapy, a viral tropism assay should be performed because this class of entry inhibitors is *active only against "CCR5-tropic virus."* This form of the HIV-1 virus tends to predominate early in infection, while so-called dual/mixed tropic virus (which utilizes either R5 or CXCR4 co-receptors) emerges later as infection progresses. Approximately 50–60% of previously treated people with HIV have circulating CCR5-tropic HIV. The medication has been shown to be effective in people with HIV who have CCR5-tropic virus and ongoing viral replication despite being heavily treated. The dose of maraviroc is 150–300 mg orally twice daily, based on the other medications the patient is taking at the time—in combination with a ritonavir-boosted PI, 150 mg daily of maraviroc has been used successfully. Common side effects are cough, fever, rash, musculoskeletal problems, abdominal pain, and dizziness; however, maraviroc is generally well tolerated with limited impact on serum lipids.

C. IBALIZUMAB—Ibalizumab is a monoclonal antibody that blocks the entry of HIV into the CD4 cell by blocking the CD4 receptor. Given as an intravenous infusion therapy along with other oral HIV medications, it is used as rescue therapy for patients with multidrug-resistant HIV that is not controlled by other treatments. It is given every 2 weeks and can now be given intravenously over 30 seconds. Common side effects include diarrhea, dizziness, nausea, rash, elevations in creatinine, and lymphopenia.

6. Attachment inhibitor—

FOSTEMSAVIR—The active metabolite of fostemsavir, temsavir, binds to the viral envelope glycoprotein 120, near to the CD4 binding site, such that the virus does not attach to the CD4 cells and cannot enter them. With its unique mechanism, it has no cross-resistance with other antiretrovirals. Unlike maraviroc, it is effective regardless of HIV-1 tropism. It is FDA-approved for use in heavily treatment-experienced adults with multidrug-resistant HIV-1 infection who are not responding to their current regimen. The dosage of fostemsavir is 600 mg orally twice daily, along with an optimized regimen of other antiretroviral medications. It should not be used in conjunction with medications that are strong P450 (CYP)3A inducers, such as rifampin, phenytoin, and St John's wort.

7. Capsid inhibitor—

LENACAPAVIR—Lenacapavir is a first-in-class capsid inhibitor that is very potent and can be given as a single subcutaneous injection every 26 weeks after two oral loading doses. Lenacapavir has been FDA-approved in combination with oral antiretrovirals with residual activity for those with multidrug-resistant HIV, based on the results of the CAPELLA study. Studies of lenacapavir in virologically suppressed patients in combination with other antiretrovirals is ongoing.

Segal-Maurer S et al; CAPELLA Study Investigators. Capsid inhibition with lenacapavir in multidrug-resistant HIV-1 infection. N Engl J Med. 2022;386:1793. [PMID: 35544387]

8. Constructing an initial regimen—Guidelines for starting ART are shown in Table 36–9. *The regimens with the strongest evidence all contain integrase inhibitors.* This reflects their high efficacy, high barrier to resistance, tolerability, low pill burden, and safety profile. The two best-tolerated, high barrier to resistance integrase inhibitors are bictegravir and dolutegravir and so they form the backbone of the recommended regimens. Integrase inhibitors are typically given with a backbone of two NRTIs (although see discussion of two-drug therapy below). With respect to NRTIs, the most commonly used combination is TDF or TAF with emtricitabine or lamivudine. *From an efficacy standpoint, there is no difference between TDF or TAF*; for patients on a boosted regimen (ie, one including cobicistat or ritonavir), those with renal dysfunction or osteoporosis or osteopenia (or risk for these conditions) should receive TAF. However, TAF is associated with increased weight gain and dyslipidemia, so TDF may be considered in individuals with obesity or dyslipidemia. Also, choosing between TDF and TAF may depend on convenience: which one is coformulated with other desired partner drugs. Emtricitabine and lamivudine are essentially the same from the point of view of efficacy and side effects. The next most commonly used two-drug NRTI backbone is abacavir and lamivudine (coformulated as part of Epzicom or with dolutegravir in Triumeq). Given the need to perform B^*5701 allele and hepatitis B testing, abacavir-containing regimens are not appropriate for rapid ART initiation.

The only two-drug regimen approved for initial ART is dolutegravir plus lamivudine, which is available as a single pill for once-a-day treatment (Dovato, Table 36–8). (All other recommended first-line initial regimens contain three medications, sometimes with a fourth agent as a booster.) This two-drug regimen is not recommended for patients with high HIV viral load (> 500,000 copies/mL), or for patients with HBV coinfection (because of development of resistance by the hepatitis B virus to lamivudine when used as monotherapy with possibility of severe flares of hepatitis), or for patients for whom the results from HIV resistance or HBV testing are not yet available. There is also concern about its use in patients with CD4 cell counts < 200/mL. Dolutegravir/rilpivirine (Juluca) and injectable cabotegravir/rilpivirine (Cabenuva) are FDA approved only in the setting of prior virologic suppression without prior treatment failure or drug resistance, although there are promising observational data regarding its use among patients who are not virologically suppressed due to adherence challenges to oral ART.

Studies have shown dolutegravir/abacavir/lamivudine to be superior to efavirenz/TDF/emtricitabine and have

Table 36–9. Recommended and alternative initial antiretroviral therapy regimens (listed in alphabetical order within categories).

Regimen	Advantages	Disadvantages
Recommended Initial Regimens		
Bictegravir + TAF + emtricitabine (Biktarvy)	Single pill once-a-day regimen Low risk of resistance Noninferior to dolutegravir	Less experience in heavily treated patients than with dolutegravir
Dolutegravir (50 mg daily)[1] + Either: emtricitabine/TDF or emtricitabine/TAF or lamivudine/TDF or lamivudine/TAF	Has activity in some patients with integrase resistance Once-a-day regimen Dolutegravir plus either abacavir/lamivudine or emtricitabine/TDF is superior to darunavir/ritonavir plus either of the NRTI backbones	No single tablet available When used in patients with integrase resistance or combined with certain other medications, requires twice-a-day dosing
Dolutegravir + abacavir + lamivudine (Triumeq)	Single pill once-a-day regimen Low risk of resistance Superior to Atripla Dolutegravir plus either abacavir/lamivudine or emtricitabine/TDF is superior to darunavir/ritonavir plus either of the NRTI backbones	Abacavir should be used only in HLA-B*5701-negative persons Should not be used in patients with hepatitis B coinfection When used in patients with integrase resistance or combined with certain other medications, requires twice-a-day dosing Fixed-dose combination should not be used in patients with creatinine clearance < 50 mL/min
Dolutegravir + lamivudine (Dovato)	Only recommended initial two-drug regimen Single pill once-a-day regimen	Not for use in patients with HIV RNA > 500,000 copies/mL, or patients initiating therapy during an opportunistic infection, or patients with hepatitis B coinfection, or patients in whom antiretroviral therapy is being started prior to results of HIV genotypic resistance testing or hepatitis B testing.
Other Integrase Inhibitor Regimens		
Raltegravir (400 mg twice daily or 1200 mg once daily) + Either: emtricitabine/TDF or emtricitabine/TAF or lamivudine/TDF or lamivudine/TAF	Fewest drug interactions of integrase inhibitors	Lower barrier to resistance than bictegravir and dolutegravir Requires twice-a-day dosing or taking two pills once a day No single tablet available
Alternative Initial Regimens That Are Non–Integrase Inhibitor-Based		
Darunavir (800 mg daily) with cobicistat + Either: emtricitabine/TDF or emtricitabine/TAF or lamivudine/TDF or lamivudine/TAF (boosted PI regimen)	Single tablet once-a-day regimen (with emtricitabine and TAF, Symtuza)	Cobicistat boosting causes similar drug-drug interactions as ritonavir; increases in serum creatinine (nonpathologic)

(*continued*)

Table 36–9. Recommended and alternative initial antiretroviral therapy regimens (listed in alphabetical order within categories). (continued)

Regimen	Advantages	Disadvantages
Darunavir (800 mg daily) with ritonavir (100 mg daily) boosting + Either: emtricitabine/TDF or emtricitabine/TAF or lamivudine/TDF or lamivudine/TAF (boosted PI regimen)	Potent boosted PI Can be given once daily Limited risk of resistance with poor adherence	Not available as a single tablet May cause rash in patients with sulfa allergy Ritonavir boosting required Has metabolic side effects
Doravirine with Either: emtricitabine/TDF or emtricitabine/TAF or lamivudine/TDF or lamivudine/TAF	Avoids the use of both integrase inhibitors and PIs Available as a single pill with lamivudine and TDF (Delstrigo) Does inhibit or induce the cytochrome P450 3A4 enzyme	In cases of viral virologic failure, NNRTI cross-resistance may develop.
Rilpivirine/emtricitabine/TDF (Complera) or with emtricitabine/TAF (Odefsey) Non-integrase, non-PI regimens	Single tablet once-a-day regimens Noninferior to Atripla in patients with baseline viral load < 100,000/mL Limited metabolic side effects	Requires taking with a meal Cannot be used with PPIs Use only in patients with viral loads < 100,000 copies/mL and CD4 counts > 200 cells/mcL Do not use in patients with viral loads > 100,000 copies/mL or CD4 counts < 200 cells/mcL

[1] Usual medication doses are supplied when not part of a fixed-dose preparation.

NNRTI, nonnucleoside reverse transcriptase inhibitor (eg, delavirdine, efavirenz, etravirine, nevirapine, rilpivirine); NRTI, nucleoside/nucleotide reverse transcriptase inhibitor (eg, abacavir, didanosine, emtricitabine, lamivudine, stavudine, tenofovir, zidovudine); PI, protease inhibitor; TAF, tenofovir alafenamide; TDF, tenofovir disoproxil fumarate.

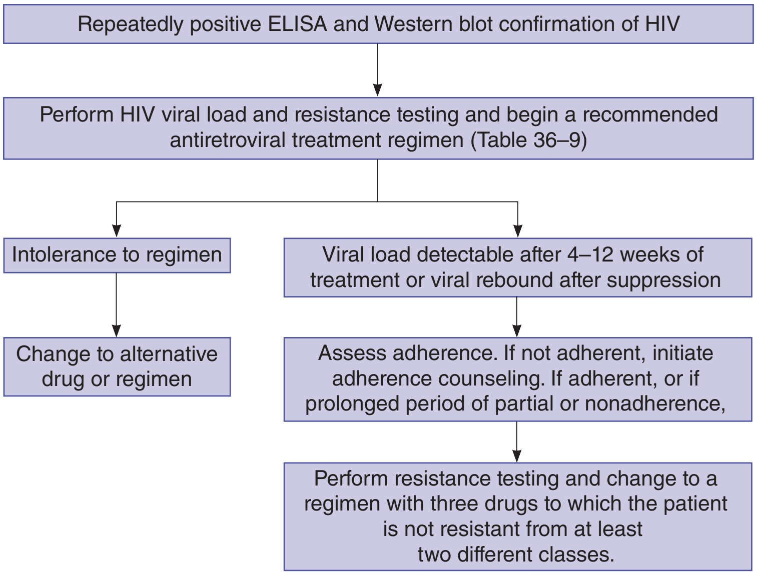
shown dolutegravir to be superior to ritonavir-boosted darunavir (both combined with either abacavir/lamivudine or TDF/emtricitabine). A network meta-analysis adjusting for NRTI backbone found that dolutegravir had superior efficacy in suppressing viral load compared with regimens containing ritonavir-boosted atazanavir, ritonavir-boosted darunavir, efavirenz, or ritonavir-boosted lopinavir. Discontinuation due to adverse events was also statistically lower with the dolutegravir regimens.

The emergence of generic antiretroviral medications can affect prescribing choices when equally effective regimens are available at different costs. For instance, for PrEP, the manufacturer of TDF/FTC and TAF/FTC will no longer allow patients to use their assistance program unless the patient is using branded TAF/FTC. There are generic versions available for abacavir, atazanavir, efavirenz, lamivudine, and TDF.

For patients who cannot take an integrase inhibitor, alternative regimens are recommended (Table 36–9).

Resistance testing should be performed prior to starting ART. Of people with newly diagnosed infections in some urban areas of the United States, 8–10% have transmitted drug resistance (most commonly to NNRTIs followed by NRTIs).

*The most important determinant of treatment efficacy is **adherence** to the regimen*. Therefore, it is vitally important that the regimen chosen be one to which the patient can easily adhere (Figure 36–7). In general, patients are more adherent if their medication regimens (Table 36–9) offer complete therapy in one pill that needs to be taken only once a day, do not require special timing with regard to meals, can be taken at the same time as other medications, do not require refrigeration or special preparation, and do not have bothersome side effects. Given the high level of effectiveness of recommended regimens, patients for whom the viral load does not fully suppress are likely to be encountering adherence challenges. Pharmacists and other specially trained clinicians can be very effective in helping patients improve their adherence by taking the time to understand why patients miss their medications and to problem solve (eg, take medicine at same time every day, keep a supply in the car or at work in case they forget). Demonstration projects are examining long-acting cabotegravir and rilpivirine as injectables in people challenged by adherence or viremia, with high virologic suppression achieved in one demonstration project in San Francisco, with 98% of the 129 starting with viremia achieving



Repeatedly positive ELISA and Western blot confirmation of HIV
Perform HIV viral load and resistance testing and begin a recommended antiretroviral treatment regimen (Table 36–9)
Intolerance to regimen
Viral load detectable after 4–12 weeks of treatment or viral rebound after suppression
Change to alternative drug or regimen
Assess adherence. If not adherent, initiate adherence counseling. If adherent, or if prolonged period of partial or nonadherence,
Perform resistance testing and change to a regimen with three drugs to which the patient is not resistant from at least two different classes.

▲ **Figure 36–7.** Approach to monitoring initial and subsequent antiretroviral therapy.

virologic suppression at 48 weeks compared with 99% in 241 who started with virologic suppression. In the ACTG5359/LATTITUDE study, participants with adherence challenges were provided financial incentives to achieve viral suppression using oral ART, and then were randomized to continue their oral regimen or switch to cabotegravir/rilpivirine. The long-acting ART arm experienced 7.2% cumulative risk of virologic failure vs 25.4% in the oral ART arm. The International Antiviral Society—USA and DHHS now recommend cabotegravir/rilpivirine among those at high risk of HIV progression who cannot take oral ART, with virus susceptible to both agents. For individuals with HIV resistant to rilpivirine, some clinicians are using cabotegravir and lenacapavir together off label. A case series of 34 individuals using this regimen at 4 academic medical centers achieved high virologic suppression (94%). For certain populations (eg, unstably housed individuals), specially tailored programs may be beneficial.

E. Monitoring Antiretroviral Treatment

1. Goals of monitoring ART—Monitoring of ART (Figure 36–7) has two goals: evaluate for *toxicity* and measure *efficacy* using objective markers to determine whether to maintain or change regimens. Laboratory evaluation for toxicity depends on the specific medications in the combination but generally should be done approximately every 3–6 months once a patient is on a stable regimen. Patients who are intolerant of their initial regimen should be changed to one of the other initial recommended or alternative regimens in Table 36–9. The second aspect of monitoring is to measure HIV viral load, the objective marker of efficacy. The HIV viral load should be repeated 2–4 weeks after the initiation or change of antiretroviral regimen and every 3–6 months thereafter in clinically stable patients. With integrase regimens, a two-log$_{10}$ reduction is expected within 2 weeks of starting therapy, and approximately 80% of patients will have undetectable HIV viral load at 1 month. *All patients should have undetectable viral loads by 3 months; if not, the usual problem is nonadherence* (see below). CD4+ counts are most useful in determining the immunologic response to ART, although the response can vary significantly, and determining whether opportunistic infection prophylaxis can be discontinued. CD4+ counts should be monitored approximately every 3–6 months in individuals newly initiating ART. For those who have consistently suppressed HIV viral loads over the first 1–2 years of therapy with a CD4+ count > 300 cells/mcL, monitoring can occur yearly, and is optional in those with CD4+ counts > 500 cells/mcL.

2. The challenge of medication adherence—In a patient who is adherent to an integrase inhibitor regimen, viral load should drop by 100-fold within 2 weeks. *For patients in whom viral loads do not decrease adequately, or who have viral rebound after suppression, the major question facing the clinician is whether the patient is nonadherent or has resistance to the regimen, or both.* Patients who are having trouble adhering to their treatment should receive adherence counseling. In patients who are adherent or who have missed enough doses to make resistance possible, resistance testing should be performed. Based on the results of resistance testing, if there is no treatment-emergent resistance, and the patient is tolerating the regimen well, the patient should continue the regimen with assessment of potential barriers to adherence (ie, mental health, substance use, medication coverage, or housing challenges). If resistance has emerged, the patient should be switched to a high-barrier-to-resistance regimen with at least two, but ideally three, active agents (ie, three-drug dolutegravir, bictegravir, or boosted darunavir-based regimen).

*Once ART has been initiated, it is **not** advisable to stop the therapy.* So-called drug holidays or structured treatment interruptions are not recommended because they have been shown to increase risk of AIDS-related complications, increase CD4 declines, and increase morbidity from non–AIDS-related complications (eg, MIs and liver failure).

3. The challenge of medication resistance—Resistance to HIV-1 medication has been documented for all currently available antiretrovirals. Although HIV medication resistance was common in the past, high-level resistance has been declining in the past few years, likely related to better tolerated, easier to use, and more efficacious antiretroviral agents. Resistance also occurs in patients who are ART-naïve but who are infected with a medication-resistant strain—called *"primary" or "transmitted" medication resistance.* Cohort studies of ART-naïve patients entering care in North America and Western Europe show that roughly 8–10% of people with a recent infection have a medication-resistant strain of HIV-1.

In addition to being part of a standard baseline evaluation, resistance testing is recommended for patients who are receiving ART and have suboptimal viral suppression (typically a viral load > 500 copies/mL is needed for resistance testing be performed). *Both **genotypic** and **phenotypic** resistance tests are commercially available, and in randomized controlled studies, genotypic resistance testing has been shown to result in improved short-term virologic outcomes compared to making treatment choices without resistance testing.* Furthermore, multiple retrospective studies have conclusively demonstrated that resistance tests provide prognostic information about virologic response to newly initiated therapy that cannot be gleaned from standard clinical information (ie, treatment history, examination, CD4 count, and viral load tests).

*Because of the complexity of resistance tests, many clinicians require **expert interpretation of results**.* In the case of genotypic assays, results may show that the pathologic variants that are selected for during ART are medication-specific or contribute to broad cross-resistance to multiple medications within a therapeutic class. An example of a medication-specific pathologic variant for the reverse transcriptase inhibitors would be the *M184V* pathologic variant that is selected for by lamivudine or emtricitabine therapy—this pathologic variant causes resistance only to those two medications. Conversely, the thymidine analog pathologic variants ("TAMs") of *M41L*, *D67N*, *K70R*, *L210W*, *T215Y/F*, and *T219Q/K/E* are selected for by either prior zidovudine or stavudine therapy, but cause resistance to all the medications in the class and often extend to the nucleotide inhibitor tenofovir when three or more of these TAMs are present. The combination of *M184V* and *K65R* is important to know as it causes resistance to all NRTIs except zidovudine and would typically necessitate change to an NRTI-sparing regimen. The most common pathologic variants associated with medication resistance and cross-resistance patterns for NRTIs, NNRTIs, PIs, and integrase inhibitors can be found at https://hivdb.stanford.edu (see specific references below). Phenotypic resistance testing can provide complementary data and is usually provided with an interpretation about susceptibility to the virus.

Resistance results may be misleading if a patient is not taking antiretroviral medications at the time of testing because the dominant virus is likely the wild-type, even if there are resistant viruses in the body that can become dominant with the selective pressure of antivirals. Thus, resistance results do not replace a careful history of what medications a patient has taken in the past and for how long. Also, the results of resistance testing should be viewed cumulatively—ie, if resistance is reported to an agent on one test, it should be presumed to be present thereafter even if subsequent tests do not give the same result.

Stanford University HIV Drug Resistance Database (https://hivdb.stanford.edu/) provides a genotypic resistance interpretation algorithm, HIVdb Program.

F. Constructing Antiretroviral Treatment Regimens for Patients with Resistance

In designing second-line regimens for patients with resistance to initial therapy, the goal is to identify three medications from at least two different classes to which the virus is not resistant. Even without resistance testing, certain forms of cross-resistance between medications within a class can be assumed. For example, the resistance patterns of raltegravir and elvitegravir are overlapping, and patients with treatment-emergent resistance to these regimens potentially harboring resistance to second-generation integrase inhibitors such as bictegravir and dolutegravir. Fostemsavir (an attachment inhibitor), ibalizumab (a monoclonal antibody), and lenacapavir (a subcutaneously administered capsid inhibitor) are specifically FDA approved for heavily treated adults with multidrug-resistant HIV who are not responding to their existing regimen. They are used in combination with other antiretroviral drugs.

In constructing regimens, toxicities should be nonoverlapping and agents that are either virologically antagonistic or incompatible in terms of drug-drug interactions should be avoided. For example, dolutegravir and etravirine should not be coadministered without inclusion of a ritonavir-boosted PI, as etravirine will reduce the plasma concentrations of dolutegravir. The combination of TDF and boosted PIs should ideally be avoided given the potential for increased tenofovir toxicity with this regimen. Coformulated TAF and boosted PI regimens (ie, emtricitabine/TAF/darunavir or Symtuza) are preferred in this setting given these are the only formulations where a lower dose of TAF is available (10 mg versus typical 25 mg dose). Lamivudine and emtricitabine are very similar medications and so are not used together.

Given the availability of new class medications and new generation medications, *a combination of ART can successfully treat virtually all patients—no matter how much resistance is present.*

▶ Course & Prognosis

With improvements in therapy, patients who have access to effective regimens and are adherent to treatment should have life spans that approach the mean. A population-based study conducted in Denmark found that people aged 25 years with HIV without hepatitis C had a life expectancy similar to that of a 25-year-old without HIV. Unfortunately, there are racial and ethnic disparities in the uptake of ART. *Studies consistently show disparities in uptake and maintenance of ART among patients with HIV who self-identify as Black and those with housing insecurity or who inject recreational drugs*. For patients whose disease progresses even though they are receiving appropriate treatment, palliative care must be provided (see Chapter 5), with attention to pain control, spiritual needs, and family (biologic and chosen) dynamics.

When to Refer

- People with HIV in whom viral loads cannot be fully suppressed on one of the initial recommended regimens should be treated in consultation with a specialist.
- Specialty consultation is particularly important for those patients with detectable viral loads on ART; those intolerant of standard medications; those in need of systemic chemotherapy; and those with complicated opportunistic infections, particularly when invasive procedures or experimental therapies are needed.

When to Admit

Admit patients with opportunistic infections who are acutely ill (eg, who are febrile, who have had rapid change of mental status, or who are in respiratory distress) or who require intravenous medications.

Viral & Rickettsial Infections

John Szumowski, MD, MPH
Tyler Brehm, MD
Jishna Shrestha, MBBS
Wayne X. Shandera, MD

Over the last few decades, the recognition and impact of viral and rickettsial diseases have increased dramatically—especially following COVID-19. Emerging and re-emerging, clinically important viruses and rickettsial/tick-borne pathogens include those that have adapted to new environments because of travel and importation (eg, West Nile virus, chikungunya, mpox), climate change, and expanded vector ranges (eg, dengue, Zika, Japanese encephalitis, tick-borne encephalitis viruses, *Ehrlichia*), and tightening of human-animal interfaces (eg, avian influenza, coronaviruses, Ebola, murine typhus). The most notable new viral pathogen to enter human populations was SARS-CoV-2, the causative agent of COVID-19. The global scientific community has responded to many of these threats by working together to develop new diagnostics, therapeutics, vaccines, and public health interventions and improve access to old ones.

For viral pathogens, novel immunotherapies have been successful against some (eg, CAR T-cell therapy for cytomegalovirus in immunocompromised patients), and novel and repurposed antiviral agents are now widely available for others (remdesivir, molnupiravir, nirmatrelvir/ritonavir for SARS-CoV-2). Novel vaccines and therapeutics have been recently developed for RSV for patients 60 years and older, pregnant women, and neonates. In contrast, older, well-known viruses (eg, rabies, arboviruses, common cold coronaviruses) continue to cause extensive and sometimes severe disease in the absence of new therapeutic and preventive agents. Less attention has been paid to rickettsial diseases, although pathogens such as *Rickettsia rickettsii* and *R typhi* infect increasingly large swaths of the population. Perhaps as important as effective diagnostics, therapeutics, and vaccines, dedicated attention to environmental and climate issues is urgently needed to control and prevent diseases due to new, variant, and re-emerging viral and rickettsial pathogens. Our knowledge of these pathogens is advancing rapidly because of exciting technological leaps in vaccinology, multiomics (proteomics, transcriptomics, genomics, metabolomics), and diagnostics.

VIRAL DISEASES

HUMAN HERPESVIRUSES

1. Herpesviruses 1 & 2

ESSENTIALS OF DIAGNOSIS

- Spectrum of illness: stomatitis, urogenital lesions, Bell palsy, encephalitis.
- Variable intervals between exposure and clinical disease since herpes simplex virus (HSV) causes both primary and reactivation disease.

General Considerations

HSV-1 and HSV-2 affect primarily the oral and genital areas, respectively (but can cause disease at either site). Most persons with HSV-2 infection in the United States are unaware they are infected. Asymptomatic shedding of either virus is common, but it is more common with HSV-2 and from genital areas. Most infected individuals shed virus at least once a month, which may contribute to transmission. Individuals with asymptomatic HSV-2–infection shed the virus less often than those with symptomatic infection. Total and subclinical shedding of HSV-2 virus decreases after the first year of initial infection, although viral shedding continues for years thereafter.

HSV-2 seropositivity is associated with higher risk of HIV acquisition, and HSV-2 reactivates more often in advanced HIV infection. HIV replication is increased by interaction with HSV proteins. Suppression of HSV-2 decreases HIV plasma levels and genital tract shedding of HIV, which can contribute to a reduction in the sexual transmission of HIV.

Clinical Findings

A. Symptoms and Signs

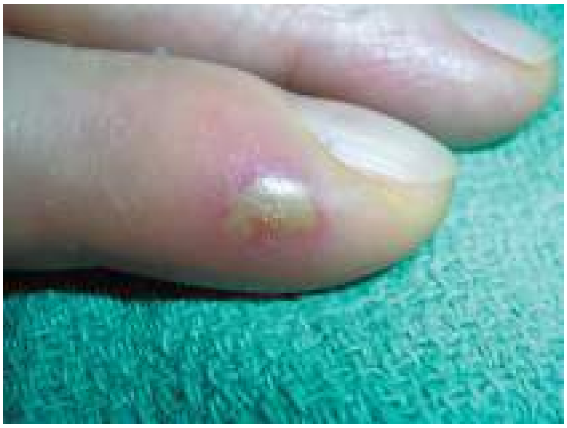
1. Mucocutaneous disease—See Chapter 6 for HSV-1 mucocutaneous disease ("**herpes labialis**" or "**gingivostomatitis**"). Digital lesions (herpetic **whitlow**) (Figure 37–1) are an occupational hazard in medicine and dentistry. Contact sports (eg, wrestling) are associated with skin infections ("**herpes gladiatorum**").

Vesicles form moist, painful ulcers after several days and epithelialize over 1–2 weeks if untreated. Primary infection is usually more severe than recurrences but may be asymptomatic. Recurrences often involve fewer lesions, tend to be labial, heal faster, and may be triggered by stress, fever, infection, sunlight, and chemotherapy.

HSV-2 lesions largely involve the genital tract. The virus typically remains latent in the presacral ganglia, and shedding of HSV-2 can occur for years after acquisition (see Chapter 6). Occasionally, lesions arise in the perianal region or on the buttocks and upper thighs. Dysuria, cervicitis, and urinary retention may occur in women. Urethritis may occur in men. Proctitis and extensive, ulcerating, sacral lesions may be presenting symptoms in patients with HIV with low CD4 counts.

2. Ocular disease—HSV can cause uveitis, keratitis, blepharitis, and keratoconjunctivitis (see Chapter 7). Lesions limited to the epithelium usually heal without affecting vision, whereas stromal involvement can cause uveitis, scarring, and eventually blindness. HSV is the second most common infectious cause of acute retinal necrosis, after varicella-zoster virus (VZV).

3. Neonatal and congenital infection—HSV-1 or HSV-2 can infect the fetus and induce congenital malformations (organomegaly, bleeding, and CNS abnormalities). Neonatal transmission during delivery is more common than intrauterine infection. The global rate of neonatal herpes is estimated to be about 10 cases per 100,000 live births. Maternal infection during the third trimester is associated with the highest risk of neonatal transmission, but about 70% of these infections are asymptomatic or unrecognized. Invasive fetal monitoring and vacuum or forceps delivery increase the risk of herpesvirus transmission. Neonatal disease can present primarily with cutaneous findings (involving skin, eyes, and mouth) but can also cause disseminated disease, including CNS involvement.



▲ **Figure 37–1.** Herpetic whitlow. (Reproduced with permission from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

4. CNS disease—Traditionally, herpes simplex encephalitis is associated with HSV-1 infection and aseptic meningitis with HSV-2 infection. Both viruses, however, can cause encephalitis and may affect both immunocompromised and immunocompetent persons. Encephalitis presents with nonspecific symptoms: a flu-like prodrome followed by headache, fever, behavioral and speech disturbances, and focal or generalized seizures. The temporal lobe is often involved. Untreated disease and presentation with coma are associated with high mortality. Ischemic stroke, although infrequent, can complicate the course of HSV meningitis or encephalitis or can happen in isolation due to HSV-induced cerebral vasculitis. Many survivors suffer neurologic sequelae, which are observed more frequently among patients with HSV-1 infection. While primary HSV infection may present with aseptic meningitis, HSV-2 is also associated with benign recurrent lymphocytic (Mollaret) meningitis.

5. Disseminated infection—Disseminated HSV infection occurs most often in immunosuppression, either primary or iatrogenic, or rarely with pregnancy. In disseminated disease, skin lesions are not always present. Disseminated skin lesions are a particular complication in patients with atopic eczema (**eczema herpeticum**) and burns. Elevated hepatocellular enzymes suggest hepatic involvement, which may cause severe liver disease (see below).

6. Bell palsy—HSV-1 is a cause of Bell palsy (facial nerve paralysis) (see also Chapter 27).

7. Esophagitis and proctitis—HSV-1 can cause esophagitis in immunocompromised patients, particularly those with advanced HIV. The lesions are smaller and deeper than those observed in patients with cytomegalovirus (CMV) esophagitis. Rarely HSV esophagitis is accompanied by significant upper GI hemorrhage. Proctitis occurs mainly in men who have sex with men.

8. Erythema multiforme—HSV infections are a leading cause of erythema multiforme minor ("**herpes-associated erythema multiforme**") and a more severe skin condition, Stevens-Johnson syndrome/toxic epidermal necrolysis (see also Chapter 6).

9. Hepatitis—HSV infection causes approximately 1% of cases of acute liver failure, particularly in pregnant patients and those with immunosuppression. HSV hepatitis may not be associated with a rash. The mortality of fulminant hepatitis is nearly 75%, necessitating a low clinical suspicion for HSV in these cases.

10. Pneumonitis—Pulmonary disease is uncommon and noted primarily in heavily immunocompromised persons (such as persons with hematologic malignancies), where it is associated with high mortality. In addition to causing tracheitis, HSV may manifest as focal pulmonary disease or bilateral interstitial pneumonitis.

B. Laboratory Findings

1. Mucocutaneous disease—See Chapter 6.

2. Ocular disease—Herpes keratitis is diagnosed by branching (dendritic) ulcers that stain with fluorescein. The extent of epithelial injury in herpes keratitis correlates well with PCR positivity. Uveitis from HSV is often diagnosed clinically, although PCR assays (including a multiplex assay that includes VZV) on anterior chamber aspirated material may assist in making the diagnosis.

3. Encephalitis and meningitis—CSF typically shows a lymphocyte-predominant pleocytosis and elevated protein; RBCs or xanthochromia also may be noted. CSF findings may be atypical in immunosuppressed patients. HSV PCR of the CSF is a rapid, sensitive, and specific tool for early diagnosis and can be included in a multiple rapid array panel. HSV CSF PCR is rarely negative when tested very early in the illness, and it should be repeated after 3–5 days if clinical suspicion persists. Viral culture has limited sensitivity, and assay turnaround times are longer than PCR testing. MRI brain may demonstrate increased signal in the temporal and frontal lobes. Temporal lobe seizure foci may be shown on electroencephalograms (EEGs).

4. Esophagitis, proctitis, and other GI disease—Esophagitis is diagnosed by endoscopic biopsy with PCR and cultures. Proctitis may be diagnosed by rectal swab for PCR or culture. Complicated cases may require biopsy.

5. Pneumonia—Pneumonia is diagnosed by clinical, pathologic, and radiographic findings. The CT findings include diffuse or multifocal areas of ground-glass attenuation or consolidative changes or both and are best confirmed using HRCT techniques. Positive HSV PCR from respiratory specimens usually represents contamination from oral HSV reactivation, especially in immunocompetent patients. Tissue biopsy demonstrating viral inclusions provides stronger evidence for pneumonia but is infrequently done.

6. Disseminated disease—In addition to the organ-specific testing noted above, blood PCR may be positive.

Prevention

Multiple interventions should be considered to reduce the risk of HSV transmission. These include suppressive antiviral therapy for the infected individual (see above and also Chapter 6), patient counseling, and use of barrier protection such as condoms. Disclosure to sexual partners of HSV-seropositive status is associated with about a 50% reduction in HSV-2 acquisition. Male circumcision is also associated with a lower incidence of acquiring HSV-2 infection.

Standard precautions should be used by healthcare personnel caring for persons with active HSV infection. Contact precautions (eg, use of a gown) should be employed in cases with more extensive mucocutaneous disease until herpetic lesions are dry and crusted. Staff with active lesions (eg, whitlows) should not have contact with patients. No herpes vaccine is publicly available, although several vaccine candidates have undergone clinical trials.

Treatment & Prophylaxis

Medications that inhibit replication of HSV-1 and HSV-2 include acyclovir and related compounds (famciclovir, valacyclovir), foscarnet, cidofovir, and trifluridine and vidarabine (both for keratitis) (Table 37–1). Agents under study include helicase-primase inhibitors pritelivir and amenamevir, which have activity against VZV as well as HSV. Pritelivir is being further evaluated in a phase 3 trial for treating acyclovir-resistant mucocutaneous HSV in immunocompromised patients. Brincidofovir, a lipid conjugate of cidofovir, showed in vitro activity against HSV/VZV and was effective in one retrospective study in hematopoietic cell transplant recipients as HSV/VZV prophylaxis; however, further clinical trial data are needed.

A. Mucocutaneous Disease

See Chapter 6.

B. Keratitis and Uveitis

For treating acute epithelial keratitis, oral antiviral agents such as valacyclovir or famciclovir are first-line therapies (see Chapter 7). Topical corticosteroids may exacerbate the infection, although systemic corticosteroids may help with selected cases of stromal infection. Long-term treatment (> 1 year) with acyclovir at a dosage of 800 mg/day orally decreases recurrence rates of keratitis, conjunctivitis, or blepharitis due to HSV.

C. Neonatal Disease

Counseling (but not serologic screening) should be offered to pregnant mothers. The use of maternal antenatal suppressive therapy with acyclovir (400 mg orally three times daily) or valacyclovir (500 mg twice daily) beginning at 36 weeks' gestation decreases the presence of detectable HSV, the rates of recurrence at delivery, and the need for cesarean delivery. Cesarean delivery is recommended for pregnant persons with active genital lesions or typical prodromal symptoms. Infants with proven or suspected HSV should receive treatment with intravenous acyclovir (20 mg/kg every 8 hours for 14 days, extended to 21 days with CNS involvement). Management of neonatal herpes is beyond the scope of this chapter, and cases should be managed with assistance of a pediatric infectious diseases specialist.

D. Encephalitis and Meningitis

Because of the need for rapid treatment to decrease mortality and neurologic sequelae, intravenous acyclovir (10 mg/kg every 8 hours for 10 days or more, adjusting for kidney disease) should be started in those patients with suspected HSV encephalitis, *stopping only if another diagnosis is established*. If the PCR of CSF is negative but clinical suspicion remains high, an LP should be repeated and acyclovir continued. Note that the recommended duration of therapy is longer (14–21 days) for immunosuppressed patients. Acyclovir resistance in herpes simplex encephalitis has been reported but is unusual. Long-term neurologic sequelae of HSV encephalitis are common, and relapse is recognized.

Table 37–1. Agents for viral infections (listed in alphabetical order).[1]

Drug	Dosing[2]	Spectrum	Toxicities
Acyclovir	**HSV and VZV infections:** 400 mg orally three times daily or 200 mg orally five times daily; 10 mg/kg intravenously every 8 hours (total 30 mg/kg/day) for 7–10 days **Acute herpes encephalitis:** 10 mg/kg intravenously every 8 hours (total 30 mg/kg/day) for 14–21 days	HSV, VZV	Neurotoxic reactions, reversible kidney dysfunction, local reactions
Baloxavir	< 80 kg: 40 mg orally as a single dose ≥ 80 kg: 80 mg orally as a single dose	Influenza A and B strains	Diarrhea, vomiting, and bronchitis
Cidofovir	5 mg/kg intravenously weekly for 2 weeks, then every other week	CMV	Neutropenia, kidney disease, ocular hypotonia
Famciclovir	**Acute VZV:** 500 mg orally three times daily for 7 days **Genital or cutaneous HSV-1/HSV-2:** 250 mg three times daily for 7–10 days; 125 mg twice daily for 5 days for recurrences (500 mg twice daily for 5–10 days if HIV-positive)	HSV, VZV	Early angioedema; later rarely, GI symptoms, headaches, rashes
Foscarnet	**Induction:** 90 mg/kg intravenously every 12 hours or 60 mg/kg intravenously every 8 hours for 14–21 days **Maintenance:** 90–120 mg/kg intravenously once daily **HSV:** 40 mg/kg/dose intravenously every 8 to 12 hours for 14–21 days	HSV resistant to acyclovir, CMV, VZV, HIV-1	Nephrotoxicity, genital ulcerations, calcium disturbances
Ganciclovir	**Induction:** 5 mg/kg intravenously every 12 hours for 14–21 days **Maintenance:** 6 mg/kg/day intravenously for 5 days each week	CMV	Neutropenia, thrombocytopenia, CNS side effects
Idoxuridine (not available in the United States)	Topical, 0.1% every 1–2 hours for 3–5 days	HSV keratitis	Local reactions
Interferon alfa-2b	**HBV infection:** 10 million units subcutaneously three times weekly or 5 million units daily[1] **Condylomata:** 1 million units intralesionally in up to five warts three times weekly for 3 weeks	HBV, HCV, HPV	Influenza-like syndrome, myelosuppression, neurotoxicity
Interferon alfa-n3	**Refractory or recurring external condylomata acuminata:** 0.05 mL (250,000 units) per wart intralesionally twice weekly for up to 8 weeks; 0.5 mL (2.5 million units) is the maximum dose per treatment session	HPV, HCV	Local reactions Influenza-like syndrome, myelosuppression, neurotoxicity
Nirmatrelvir/ritonavir	300/100 mg orally twice daily for 5 days	SARS-CoV-2	Adjust for renal dysfunction, multiple drug interactions
Oseltamivir	75 mg orally twice daily for 5 days	Influenza A and B	Adjust for renal dysfunction
Palivizumab	15 mg/kg intramuscularly every month in RSV season	RSV	Upper respiratory infection symptoms
Penciclovir	Topical 1% cream every 2 hours during waking hours for 4 days	HSV	Local reactions
Peramivir	600 mg intravenously as a single dose	Uncomplicated influenza A	Nausea, vomiting, diarrhea, neutropenia
Remdesivir	200 mg intravenously on day 1 followed by 100 mg intravenously once daily for 4 days for non-ICU patients, 9 more days for ICU patients	SARS-CoV-2	Transaminitis, fatigue, headaches, nausea
Ribavirin	**RSV infection:** one vial (6 g) dissolved and delivered through a small particle aerosol generator (SPAG-2) over a continuous 12- to 18-hour period daily for 5 consecutive days	RSV, severe influenza A or B, Lassa fever	Wheezing, hemolytic anemia
Trifluridine	Topical, 1% drops every 2 hours during waking hours (maximum 9 drops per day)	HSV keratitis	Local reactions

(*continued*)

Table 37–1. Agents for viral infections (listed in alphabetical order).[1] (continued)

Drug	Dosing[2]	Spectrum	Toxicities
Valacyclovir	**Acute VZV:** 1 g orally three times daily for 7 days **Primary genital HSV-1/HSV-2:** 1 g orally twice daily for 7–10 days **Recurrent genital HSV-1/HSV-2:** 500 mg orally twice daily for 3 days or 1 g orally once daily for 5 days **Suppressive therapy:** 1 g orally daily; 500 mg orally daily if fewer than 9 recurrences/year (Dose depends on immune status and number of recurrences.)	VZV, HSV	Thrombotic thrombocytopenic purpura or hemolytic-uremic syndrome in AIDS
Valganciclovir	900 mg orally twice daily for 3 weeks; 900 mg daily as maintenance	CMV	See ganciclovir
Zanamivir	Two inhalations (10 mg) twice daily for 5 days	Uncomplicated influenza A and B	Bronchospasm in patients with asthma

Sources: Data from Drugs.com and Lexicomp Online.

[1] Agents used exclusively in the management of HIV infection and AIDS are found in Chapter 36. Agents used in the management of HBV and HCV infections are found in Chapter 16.

[2] Dosing varies considerably by indication and may require adjustment based on patient's clinical state and type of viral infection. Consultation with a pharmacist is recommended.

CMV, cytomegalovirus; HBV, hepatitis B virus; HCV, hepatitis C virus; HSV, herpes simplex virus; VZV, varicella-zoster virus.

The role for antiviral therapy of aseptic meningitis in immunocompetent persons remains uncertain, as the condition is typically self-limiting; early transition to oral antiviral therapy can be considered in cases where treatment is pursued. Long-term oral prophylaxis with valacyclovir, however, does not appear to prevent recurrences of aseptic meningitis with HSV-2.

E. Disseminated Disease

Disseminated disease responds best to parenteral acyclovir when treatment is initiated early.

F. Bell Palsy

While steroids have been demonstrated to improve time to clinical recovery, the role for antiviral therapy in cases of Bell palsy is less clear. Antivirals are not typically recommended but are nevertheless sometimes considered in cases of more severe disease.

G. Esophagitis and Proctitis

Patients with severe disease should receive intravenous acyclovir (5–10 mg/kg every 8 hours) and can be transitioned to oral antiviral therapy (acyclovir, valacyclovir, or famciclovir) once they are able to swallow and when absorption is felt to be adequate. Duration of therapy depends on resolution of symptoms, typically at least 5 days. Secondary prophylaxis pending immune recovery is typically recommended in immunocompromised persons with following an episode of severe disease or with frequent recurrences.

H. Erythema Multiforme

Suppressive therapy with oral acyclovir (400 mg twice a day for 6 months) decreases the recurrence rate of HSV-associated erythema multiforme. Valacyclovir (500 mg orally twice a day) may be effective in cases unresponsive to acyclovir.

2. Varicella (Chickenpox) & Herpes Zoster (Shingles)

ESSENTIALS OF DIAGNOSIS

- **Varicella rash:** pruritic, centrifugal, papular changing to vesicular ("dew drops on a rose petal"), pustular, and finally crusting.
- **Zoster rash:** tingling, pain, eruption of vesicles in a dermatomal distribution, evolving to pustules and then crusting.

General Considerations

VZV manifests as chickenpox (varicella) following primary infection and as shingles (herpes zoster) following reactivation.

Chickenpox generally presents during childhood and has an incubation period of 10–20 days (average 2 weeks). It is highly contagious, spreading by inhalation of infective droplets or contact with lesions.

The incidence and severity of herpes zoster ("**shingles**"), which *affects up to 30% of persons during their lifetime*, increase with age due to an age-related decline in immunity against VZV. More than half of all patients in whom herpes zoster develops are older than 60 years, and the incidence of herpes zoster reaches 10 cases per 1000 patient-years by age 80 (by which time 50% are infected with VZV). The annual incidence in the United States of 1 million cases per year is increasing as the population ages. Patients who are immunocompromised as a result of advanced HIV, malignancy, transplantation status, or other immunosuppressive therapies are also at increased risk of zoster and zoster-related complications such as disseminated disease.

Clinical Findings

A. Varicella

1. Symptoms and signs—Fever and malaise are mild in children and more marked in adults. The pruritic rash begins prominently on the face, scalp, and trunk and later involves the extremities (Table 37–2). The macular/papular rash evolves within a few hours to vesicles that become pustular and eventually form crusts (Figure 37–2) (Figure 37–3). New lesions may erupt for 1–5 days, so different stages of the eruption are usually present simultaneously. The crusts slough in 7–14 days. The vesicles and pustules are superficial and elliptical, with slightly serrated borders. Although the disease is often mild, complications (such as secondary bacterial infection, pneumonitis, and encephalitis) occur in ~1% of cases and often lead to hospitalization.

Varicella is more severe in older patients and immunocompromised persons (including pregnancy). In the latter, atypical presentations, including widespread dissemination in the absence of skin lesions, are often described. After the primary infection, the virus remains dormant in cranial nerve sensory ganglia and spinal dorsal root ganglia. *Latent VZV will reactivate as herpes zoster in about 30% of persons.*

2. Laboratory findings—Leukopenia and subclinical transaminase elevation are often present, and thrombocytopenia occasionally occurs. Diagnosis is usually made clinically, with confirmation by direct immunofluorescent antibody staining or PCR of scrapings from lesions or CSF, both of which are more sensitive than culture. The exception is VZV vasculopathy, which can be diagnosed via anti-VZV IgG detection in the CSF with a reduced serum/CSF ratio. Note that anti-VZV **IgG** will typically become detectable in the CSF after 2 weeks of illness, while VZV DNA may be detectable only for the first 2 weeks of infection. Although elevation of varicella IgM is occasionally used to diagnose a primary VZV infection, the assay has poor performance and is generally not recommended. A varicella skin test and interferon gamma (IFN-γ) enzyme-linked immunospot (ELISPOT) can screen for VZV susceptibility.

B. Herpes Zoster

Herpes zoster ("shingles") usually occurs among adults, but cases are reported among infants and children. Shingles incidence rises markedly with age because of immunosenescence and loss of specific immunity to VZV, with rates of 8 to 12 per 1000 person-years in individuals older than 80 years. Skin lesions typically develop into clusters of vesicles over 3–5 days and can be painful or pruritic. Superficial sensory symptoms such as pain are often severe and commonly *precede* the appearance of rash by several days. Lesions follow a dermatomal distribution, with thoracic and lumbar roots being the most common. In most cases, a single unilateral dermatome is involved, but occasionally, neighboring and distant areas are involved. If lesions cover three or more dermatomes, disease is considered to be *disseminated*. Lesions eventually dry and crust over; in untreated immunocompetent individuals they take 2–4 weeks to heal and can leave hyperpigmented macular scars. Lesions on the tip of the nose, inner corner of the eye, and root and side of the nose **(Hutchinson sign)** indicate involvement of the trigeminal nerve **(herpes zoster ophthalmicus).** Facial palsy and lesions of the external ear with or without tympanic membrane involvement, vertigo, tinnitus, or deafness signify geniculate ganglion involvement **(Ramsay Hunt syndrome** or **herpes zoster oticus).** Shingles is a common and serious complication among immunosuppressed patients.

Complications

A. Varicella

Secondary bacterial skin superinfections, particularly with group A *Streptococcus* and *Staphylococcus aureus*, are the most common complications. Cellulitis, erysipelas, and scarlet fever are described. Bullous impetigo and necrotizing fasciitis are less often seen. Other associations with varicella include epiglottitis, necrotizing pneumonia, osteomyelitis, septic arthritis, epidural abscess, meningitis, endocarditis, pancreatitis, giant cell arteritis, IBD, and purpura fulminans.

Interstitial VZV pneumonia is more common in adults (especially those who smoke cigarettes, patients with HIV, and pregnant persons) and may result in acute respiratory distress syndrome. After healing, numerous densely calcified lesions are seen throughout the lung fields on CXRs.

Historically, neurologic complications developed in about 1 in 2000 children (cerebellar ataxia in 1:4000, specifically). A limited course and complete recovery are the rule. Encephalitis is similarly infrequent, occurs mostly in adults, and is characterized by delirium, seizures, and focal neurologic signs. The rates for both mortality and long-term neurologic sequelae are about 10%. Ischemic strokes in the wake of acute VZV infection present at a mean of 4 months after rashes (highest relative risk within 1 month after infection) and may be due to an associated vasculitis. Multifocal encephalitis (described without a rash in solid organ transplant recipients), ventriculitis, myeloradiculitis, arterial aneurysm formation, Ramsay Hunt syndrome, optic neuritis (with zoster ophthalmicus), and arteritis are also described in immunosuppressed individuals, especially those with HIV. When seizures develop in immunosuppressed patients, especially those taking corticosteroids, disseminated zoster should be considered.

Clinical hepatitis is uncommon and mostly presents in the immunosuppressed patient but can be fulminant and fatal. **Reye syndrome** (fatty liver with encephalopathy) also rarely complicates varicella (and other viral infections, especially influenza B virus), usually in childhood, and is associated with aspirin therapy (see Influenza, below).

Table 37–2. Diagnostic features of some acute exanthems (listed in alphabetical order).

Disease	Prodromal Signs and Symptoms	Nature of Eruption	Other Diagnostic Features	Laboratory Tests
Chikungunya fever	2–4 (sometimes 1–12) days, fever, headaches, abdominal complaints, myalgias, arthralgias.	Maculopapular, centrally distributed, pruritus, can be bullous with sloughing in children, occasional facial edema and petechiae.	History of mosquito bites, epidemiologic factors.	ELISA-based IgM or IgG (fourfold increase in titers); PCR and cultures are infrequently available.
Eczema herpeticum	None.	Vesiculopustular lesions in area of eczema.		HSV isolated in cell culture. Multinucleated giant cells in smear of lesion.
Ehrlichiosis	Headache, malaise.	Rash in one-third, similar to Rocky Mountain spotted fever.	Pancytopenia, elevated liver biochemical tests.	PCR, immunofluorescent antibody.
Enterovirus infections	1–2 days of fever, malaise.	Maculopapular rash resembling rubella, rarely papulovesicular or petechial.	Aseptic meningitis.	Virus isolation from stool or CSF; complement fixation titer rise.
Erythema infectiosum (erythroparvovirus)	None. Usually in epidemics.	Red, flushed cheeks; circumoral pallor; maculopapules on extremities.	“Slapped face” appearance.	WBC count normal.
Exanthema subitum (HHV-6, 7; roseola)	3–4 days of high fever.	As fever falls, pink maculopapules appear on chest and trunk; fade in 1–3 days.		WBC count low.
Infectious mononucleosis (EBV)	Fever, adenopathy, sore throat.	Maculopapular rash resembling rubella, rarely papulovesicular.	Splenomegaly, tonsillar exudate.	Atypical lymphocytes in blood smears; heterophile agglutination (Monospot test).
Kawasaki disease	Fever, adenopathy, conjunctivitis.	Cracked lips, strawberry tongue, maculopapular polymorphous rash, peeling skin on fingers and toes.	Edema of extremities. Angiitis of coronary arteries.	Thrombocytosis, electrocardiographic changes.
Measles (rubeola)	3–4 days of fever, coryza, conjunctivitis, and cough.	Maculopapular, brick red; begins on head and neck; spreads downward and outward, in 5–7 days rash brownish, desquamating. See Atypical measles, above.	Koplik spots on buccal mucosa.	WBC count low. Virus isolation in cell culture. Antibody tests by hemagglutination inhibition or neutralization.
Meningococcemia	Hours of fever, vomiting.	Maculopapules, petechiae, purpura.	Meningeal signs, toxicity, shock.	Cultures of blood, CSF. WBC count high.
Rocky Mountain spotted fever	3–4 days of fever, vomiting.	Maculopapules, petechiae, initial distribution centripetal (extremities to trunk, including palms).	History of tick bite.	Indirect fluorescent antibody; complement fixation.
Rubella	Little or no prodrome.	Maculopapular, pink; begins on head and neck, spreads downward, fades in 3 days. No desquamation.	Lymphadenopathy, postauricular or occipital.	WBC count normal or low. Serologic tests for immunity and definitive diagnosis (hemagglutination inhibition).
Scarlet fever	One-half to 2 days of malaise, sore throat, fever, vomiting.	Generalized, punctate, red; prominent on neck, in axillae, groin, skin folds; circumoral pallor; fine desquamation involves hands and feet.	Strawberry tongue, exudative tonsillitis.	Group A β-hemolytic streptococci in cultures from throat; antistreptolysin O titer rise.
Typhus	3–4 days of fever, chills, severe headaches.	Maculopapules, petechiae, initial distribution centrifugal (trunk to extremities).	Endemic area, lice.	Complement fixation.

(*continued*)

Table 37–2. Diagnostic features of some acute exanthems (listed in alphabetical order). (continued)

Disease	Prodromal Signs and Symptoms	Nature of Eruption	Other Diagnostic Features	Laboratory Tests
Varicella (chickenpox)	0–1 day of fever, anorexia, headache.	Rapid evolution of macules to papules, vesicles, crusts; all stages simultaneously present; lesions superficial, distribution centripetal.	Lesions on scalp and mucous membranes.	Specialized complement fixation and virus neutralization in cell culture. Fluorescent antibody test of smear of lesions.

EBV, Epstein-Barr virus; EM, electron microscopy; HHV, human herpesvirus; HSV, herpes simplex virus; Ig, immunoglobulin.

When contracted during the first or second trimesters of pregnancy, varicella carries a minuscule risk of congenital malformations, including cicatricial lesions of an extremity, growth retardation, microphthalmia, cataracts, chorioretinitis, deafness, and cerebrocortical atrophy. If varicella develops around the time of delivery, the newborn is at risk for disseminated disease.

B. Herpes Zoster

Postherpetic neuralgia occurs in 10–13% of patients who have herpes zoster and are older than 60 years. The pain can be prolonged and debilitating. Risk factors for postherpetic neuralgia include advanced age, female sex, the presence of a prodrome, obstructive sleep apnea, and severity of rash or pain.

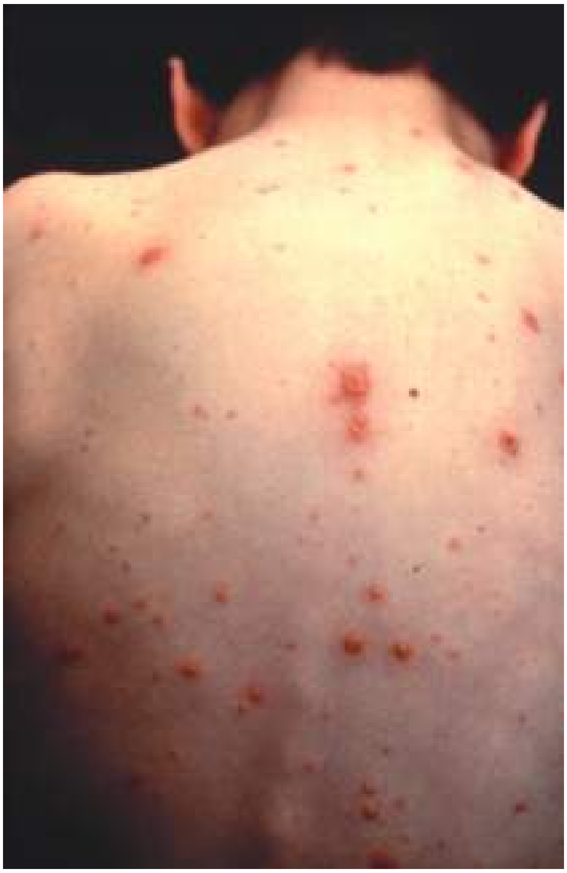

Figure 37–2. Primary varicella (chickenpox) skin lesions. (Public Health Image Library, CDC.)

Other complications include the following: (1) bacterial skin superinfections; (2) herpes zoster ophthalmicus, which occurs with involvement of the trigeminal nerve, is a *sight-threatening complication* (especially when it involves the iris), and is a marker for vasculopathic stroke over the ensuing year with the highest risk in the month immediately following the herpes zoster episode; (3) rarely, unilateral ophthalmoplegia; (4) keratitis; (5) involvement of the geniculate ganglion of cranial nerve VII as well as cranial nerves V, VIII, IX, and X; (6) aseptic meningitis; (7) peripheral motor neuropathy; (8) transverse myelitis, which can become chronic; (9) encephalitis; (10) acute cerebellitis; (11) stroke; (12) vasculopathy; (13) acute retinal necrosis; (14) progressive outer retinal necrosis (largely among patients with HIV); (15) temporal arteritis; and (16) sacral meningoradiculitis (Elsberg syndrome). Visceral dissemination in immunocompromised patients is rare and fatal over half the time. VZV is a major cause of Bell palsy in patients who are HSV seronegative.

Diagnosis of neurologic complications generally requires the detection of VZV DNA in CSF or the

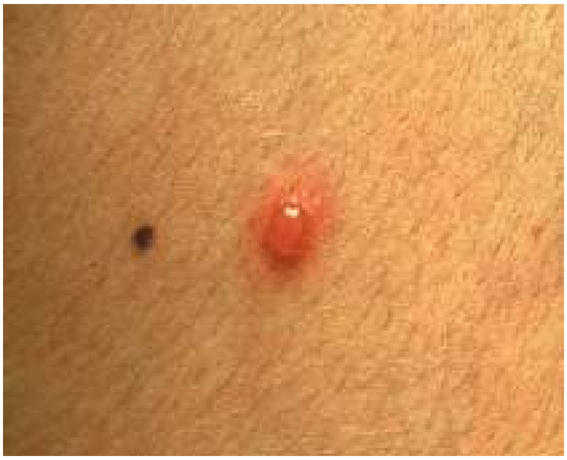

Figure 37–3. Chickenpox (varicella) with classic "dew drop on rose petal" appearance. (Reproduced with permission from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

detection of VZV DNA in tissue. The exception is VZV vasculopathy, which can be diagnosed via VZV antibodies (see Laboratory findings, above). **Zoster sine herpete** (pain without rash) can also be associated with most of the above complications. A molecular assay can help distinguish HSV from VZV for patients with keratitis.

Varicella-zoster increases maternal and fetal morbidity, and pregnant persons should be advised to avoid exposure to VZV.

Prevention

Healthcare workers should be screened for varicella and vaccinated if seronegative. Patients with active varicella or herpes zoster are promptly separated from seronegative patients. For patients with varicella, airborne and contact isolation is recommended, whereas for those with zoster, contact precautions are sufficient. However, airborne precautions should be added if disease affects three or more dermatomes. For immunosuppressed patients with zoster, precautions should be the same as if the patient had varicella. Exposed serosusceptible patients should be placed in isolation and exposed serosusceptible employees should stay away from work for 8–21 days after exposure. Healthcare workers with zoster should receive antiviral agents during the first 72 hours of disease and withdraw from work until lesions are crusted. The need for postexposure prophylaxis should be assessed.

A. Varicella

1. Vaccination—Universal childhood vaccination against varicella is effective. The varicella vaccine is *live and attenuated*, safe, and > 98.1% effective when given after 13 months of age. A single antigen live attenuated vaccine (VARIVAX, VARILRIX) or a quadrivalent measles, mumps, rubella, and varicella (MMRV) vaccine (ProQuad) is available (the combination is immunogenic). The first dose of the single antigen vaccine should be administered at 12–18 months of age and the second at 4–6 years. Alternatively, the MMRV vaccine can be given as a first dose at 12–15 months of age and the second dose before elementary school entry. *Aspirin should be avoided for at least 6 weeks after vaccination because of the risk of Reye syndrome.* The single antigen vaccine is safe and well tolerated, but the quadrivalent MMRV vaccine is associated with a small risk of febrile seizures 5–12 days after vaccination among infants aged 12–23 months. Because of this risk, the CDC recommends using separate varicella and MMR vaccines for the first dose in children younger than 48 months old. Rashes, when secondary to the varicella vaccine, appear 15–42 days after vaccination. Rare cases of keratitis are associated with zoster and varicella vaccines.

For serosusceptible individuals older than 13 years, two doses of varicella vaccine (single antigen) administered 4–8 weeks apart are recommended. For those who previously received a single dose, a *catch-up second dose* is advised, especially in the epidemic setting (where it is effective when given during the first 5 days postexposure). Household contacts of immunocompromised patients should adhere to these recommendations. Susceptible pregnant persons (who should not be vaccinated with live varicella or zoster vaccines during pregnancy) must receive the first dose of single antigen vaccine before discharge after delivery and the second dose 4–8 weeks later. The Advisory Committee on Immunization Practices (ACIP) recommends administration of the single-antigen varicella vaccine as two doses 3 months apart to children living with HIV aged 12 months or older with CD4 cell percentage > 15% and adolescents and adults with CD4 cell counts 200/mcL or higher (regardless of age).

The vaccine may also be given to patients with impaired humoral immunity, to patients receiving corticosteroids, to pediatric oncology patients receiving chemotherapy, and to patients with juvenile rheumatoid arthritis who receive methotrexate. Patients receiving high doses of corticosteroids for > 2 weeks may be vaccinated a month after discontinuing the therapy. Patients with leukemia, lymphoma, or other malignancies whose disease is in remission and who have not undergone chemotherapy for at least 3 months may be vaccinated. Kidney and liver transplant patients should be vaccinated if they are susceptible to varicella.

The incidence of varicella in the United States is significantly reduced with the varicella vaccine. Although uncommon, the varicella vaccine, like any of the live varicella-zoster vaccines, can potentially reactivate and cause clinical disease. Vaccination against varicella is thought to provide less protection against future zoster than natural varicella infection. The incidence of varicella-associated group A streptococcal infection and varicella neurologic complications are both diminished with the advent of varicella vaccination.

The FDA no longer maintains a registry for exposed pregnant persons because of the low rate of such incidents and the general safety of varicella vaccines. Incidents can be reported to Merck (877-888-4231) or through the Vaccine Adverse Events Registry System Vaccine (https://vaers.hhs.gov/index).

2. Postexposure—Postexposure vaccination is recommended for unvaccinated persons without other evidence of immunity. **Varicella-zoster immune globulin** available in the United States only as VariZIG should be considered for susceptible exposed patients (for up to 10 days after exposure but as soon as feasible) who should not receive the vaccine, including immunosuppressed patients, neonates from mothers with varicella around the time of delivery, exposed premature infants born from serosusceptible mothers at > 28 weeks' gestation, and neonates born at < 28 weeks' gestation regardless of maternal serostatus. Varicella and zoster vaccines are not recommended for pregnant persons.

No controlled studies have evaluated the use of acyclovir in this setting. VariZIG is given by intramuscular injection in a dosage of 125 IU/10 kg, to a maximum of 625 IU with a weight-based (2-kg cutoff) minimum dose of 62.5 or 125 IU), with a repeat identical dose in 3 weeks if a high-risk patient remains exposed. VariZIG has no place in therapy of established disease; however, it reduces severity of varicella in high-risk children or adults (ie, those with impaired immunity and infants exposed peripartum) if given within 4 days of exposure. Varicella vaccination should be delayed at least 5 months after VariZIG administration. If VariZIG is unavailable, standard pooled intravenous immunoglobulin (IVIG) (400 mg/kg given in one dose) can be given. Acyclovir (40–80 mg/kg) for 5 days or the varicella vaccine (if not contraindicated) can also be given as postexposure prophylaxis within 3 days of exposure. Either of these options offers an efficacy of 70–85% compared with 90% efficacy for VariZIG.

Further information may be obtained by calling the CDC's Immunization Information Hotline (1-800-232-4636).

B. Herpes Zoster

Shingrix, HZ/su (GlaxoSmithKline Biologicals), an adjuvanted recombinant subunit vaccine, is approved by the FDA for VZV and is recommended for immunocompetent individuals aged 50 years or older, as well as for adults aged 19 years or older who are or will be immunodeficient or immunosuppressed because of disease or therapy (including people living with HIV). *Shingrix is preferred over the older live attenuated VZV vaccine* (Zostavax, no longer available in the United States). Shingrix is particularly effective in reducing the incidence of herpes zoster infection and postherpetic neuralgia in adults aged 70 years or older; immunosenescence to the vaccine does not appear to occur in older patients; strong, persistent immune responses are seen > 7 years after initial vaccination. Vaccine efficacy has ranged from 70% to 100% in different studies over a follow-up period of 2–7 years, with more rapidly waning efficacy seen in patients who only received one dose (48% by year 3). Shingrix is safe in persons with HIV and with immune restoration (typically CD4 cell counts > 50/mcL), recipients of autologous stem cell transplants, and adults with autoimmune disease taking immunosuppressive therapy. However, it may be less efficacious in immunocompromised hosts, as reported in patients taking corticosteroids at the time of immunization.

Even if the person has had a prior episode of herpes zoster, Shingrix vaccine has efficacy and should be administered. No specific recommendations exist regarding how long to wait between a zoster outbreak and administering the vaccine; the CDC recommends waiting until the outbreak has resolved, and other experts suggest waiting up to a year as herpes zoster itself will boost VZV-specific immunity for several years. Concurrent administration of the adjuvanted recombinant subunit VZV vaccine with pneumococcal vaccine, adjuvanted influenza vaccine (Fluad), and/or COVID-19 vaccines is safe. The CDC recommends that recombinant and adjuvanted vaccines, such as Shingrix, be administered concomitantly with other adult vaccines at different anatomic sites.

If a varicella vaccine is mistakenly administered to an adult instead of the adjuvanted recombinant subunit vaccine zoster vaccine, the dose should be considered invalid, and the patient should be administered a dose of zoster vaccine at the same visit. The zoster vaccine cannot be used in children in place of varicella vaccine; if the vaccine is accidentally given to a child, the event should be reported to the CDC. If Zostavax is administered to an adult when Shingrix is indicated, the Shingrix series can be initiated 8 weeks later.

A new herpes zoster mRNA vaccine (ZOSAL) has shown superior vaccine immunity and safety profile compared to Shingrix in mice and rhesus macaques, but it has yet to be studied in humans.

Treatment

A. General Measures

In general, patients with varicella should be isolated until primary lesions have crusted. Pruritus can be relieved with antihistamines, calamine lotion, and colloidal oatmeal baths. Fever can be treated with acetaminophen (*not* aspirin). Fingernails can be closely cropped to avoid skin excoriation and infection. Hospitalized individuals with open, disseminated herpes zoster skin lesions (ie, lesions that cross three or more dermatomes) should be placed on both contact and airborne isolation until lesions crust over.

B. Antiviral Therapy

1. Varicella—Uncomplicated disease in otherwise healthy children and adolescents does not require antiviral therapy. Acyclovir, 20 mg/kg (max 800 mg per dose) orally four times daily for 5–7 days, should be given within the first 24 hours after the onset of varicella rash and should be considered for patients older than 12 years, secondary household contacts (disease tends to be more severe in secondary cases), patients with chronic cutaneous and cardiopulmonary diseases, and children receiving long-term therapy with salicylates (to decrease the risk of Reye syndrome). Famciclovir is not approved for anyone under 18 years of age. Valacyclovir can be given for patients 2 and older at a dose of 20 mg/kg (max 1000 mg) three times daily for 5 days. Children under 2 should be treated with acyclovir, as the safety of valacyclovir has not been established for this age group. There is no consensus dosing for acyclovir for this age group.

In immunocompromised patients, in pregnant persons during the third trimester, and in patients with extracutaneous disease (encephalitis, pneumonitis), antiviral therapy with high-dose intravenous acyclovir (30 mg/kg/day in three divided doses intravenously for at least 7 days, 10 days for encephalitis) *should be started once the diagnosis is suspected*. The oral alternative is 800 mg four times daily for 5–10 days, based on the disease state treated. Corticosteroids may be useful in the presence of pneumonia. Prolonged prophylactic acyclovir is important to prevent VZV reactivation in profoundly immunosuppressed patients. Adjuvant treatment with VSV-specific immunoglobulins for patients with pneumonia is advocated by some experts.

2. Herpes zoster—For uncomplicated herpes zoster, valacyclovir or famciclovir is preferable to acyclovir due to dosing convenience and higher drug levels in the body (Table 37–1). *Therapy should start within the first 72 hours of the onset of the lesions* and be continued until the lesions have all crusted over (typically 7–14 days). Bromovinyl deoxyuridine (Brivudine) is another therapy for herpes zoster used primarily in Europe (not available in the United States). *Antiviral therapy reduces the duration of herpetic lesions and associated episodes of acute pain but does not decrease the risk of postherpetic neuralgia.* Corticosteroids (a tapering course, eg, starting at prednisone 60 mg/day, for 2–3 weeks or methylprednisolone 24 mg/day for 1–2 weeks) are safe in immunocompetent patients and may be useful in the acute management of disease to hasten the resolution of zoster-related pain.

Intravenous acyclovir is used for extradermatomal complications of zoster. Adjunctive therapy may be considered in retinal disease (eg, vitreal foscarnet infections) and acute herpes zoster (eg, sorivudine, a topical antiviral). In cases of prolonged or repeated acyclovir use, immunosuppressed patients may require a switch to intravenous foscarnet due to the development of acyclovir-resistant VZV infections.

C. Treatment of Postherpetic Neuralgia

Once established, postherpetic neuralgia is difficult to treat, and less than half of patients achieve adequate pain relief. This condition may respond to neuropathic pain agents such as gabapentin or lidocaine patches. Tricyclic antidepressants and capsaicin cream are also widely used and effective; use of opioids in managing neuropathic pain is controversial and based on limited evidence, and their long-term use should be avoided. The epidural injection of corticosteroids and local anesthetics appears to modestly reduce herpetic pain at 1 month but, as with oral corticosteroids, is not effective for prevention of long-term postherpetic neuralgia. Transcutaneous electrical nerve stimulation or pulsed radiofrequency is reportedly successful. Gabapentin appears to show efficacy as a preventive medication in reducing the risk of postherpetic neuralgia in patients with diabetes and neuropathy. Duloxetine initiated during the initial outbreak may also reduce pain scores at 12 weeks, although randomized, *placebo-controlled* studies on this are lacking. Available evidence suggests that vaccination with the recombinant zoster vaccine (Shingrix; see Herpes Zoster section under Vaccination, below) significantly reduces the duration of herpes zoster–related pain.

▶ Prognosis

The total duration of varicella from onset of symptoms to disappearance of crusts rarely exceeds 2 weeks. Fatalities are rare except in immunosuppressed patients, where in hospitalized patients it was as high as 8% in one French cohort study.

Herpes zoster resolves in 2–6 weeks. Antibodies persist longer and at higher levels than with primary varicella. Eye involvement with herpes zoster necessitates periodic future examinations.

3. Epstein-Barr Virus & Infectious Mononucleosis

ESSENTIALS OF DIAGNOSIS

- Malaise, fever, and sore throat.
- Palatal petechiae, lymphadenopathy, splenomegaly; occasionally, a maculopapular rash.
- Positive heterophile agglutination test (Monospot).
- Atypical large lymphocytes in blood smear; lymphocytosis.
- Complications: hepatitis, myocarditis, neuropathy, encephalitis, airway obstruction from adenitis, hemolytic anemia, thrombocytopenia.

▶ General Considerations

Epstein-Barr virus (EBV) is one of the most ubiquitous human viruses, infecting > 95% of adults worldwide. **Infectious mononucleosis** is a common manifestation of EBV and may occur at any age following primary infection. In the United States, the incidence of EBV infection is declining, although it remains high for those 12–19 years old. In low- and middle-income countries, infectious mononucleosis occurs at younger ages and tends to be less symptomatic. EBV is largely transmitted by saliva but can also be recovered from genital secretions. Saliva may remain infectious for 6 months or longer after symptom onset. Although infectious mononucleosis is generally a benign condition, EBV has also been linked to malignancies and other chronic conditions, as discussed further below.

▶ Clinical Findings

A. Symptoms and Signs

The early phase of infectious mononucleosis is classically marked by fever, sore throat, fatigue, malaise, anorexia, and myalgia. Physical findings include lymphadenopathy (discrete, nonsuppurative, slightly painful, especially along the posterior cervical chain), transient upper lid edema (**Hoagland sign**), and splenomegaly (in up to 50% of patients and sometimes massive). A maculopapular or petechial rash may occur in 20% of patients; historically rash was associated with ampicillin treatment but appears to be less common in more recent reports. Conjunctival hemorrhage, soft palate petechiae, tonsillar exudates, and uvular edema also may be noted.

Other manifestations include hepatitis, interstitial pneumonitis (sometimes with pleural involvement), cholestasis, gastritis, kidney disease (mostly interstitial nephritis), and epiglottitis. Involvement of the nervous system is uncommon (1–5% of cases) and can manifest in diverse ways such as aseptic meningitis, encephalitis, cerebellitis, peripheral and optic neuritis, transverse myelitis, or Guillain-Barré syndrome. Airway obstruction from lymph node enlargement can occur. Complications of acute disease are more common among older adults.

B. Laboratory Findings

An initial phase of granulocytopenia is followed within 1 week by lymphocytic leukocytosis with atypical lymphocytes (larger than normal mature lymphocytes that may demonstrate irregular shape) constituting > 10% of the leukocyte count. Hemolytic anemia occurs occasionally, as does thrombocytopenia.

Diagnosis is typically made based on characteristic manifestations and serologic evidence of infection. Historically, heterophile antibody tests (eg, Monospot) were used. However, the Monospot test suffers from limited sensitivity—particularly in younger children and early in infection—and has been largely replaced with EBV-specific serologic panels. During acute illness, immunoglobulin M (IgM) antibody to EB virus capsid antigen (VCA) rises and falls, and immunoglobulin G (IgG) antibody to VCA rises and persists for life. Antibodies (IgG) to EBV nuclear antigen (EBNA) appear after 4 weeks of onset and persist thereafter. Absence of IgG and IgM VCA or the presence of IgG EBNA should make one reconsider the diagnosis of acute EBV infection.

EBV PCR testing is available but does *not* have a role in the routine evaluation of a patient being evaluated for possible infectious mononucleosis.

Differential Diagnosis

CMV infection, toxoplasmosis, acute HIV infection, secondary syphilis, HHV-6 infection, rubella, and drug hypersensitivity reactions (eg, to the anticonvulsants carbamazepine or phenytoin) may mimic infectious mononucleosis due to EBV, but exudative pharyngitis is usually absent and the heterophile antibody tests are negative. With acute HIV infection, rash and mucocutaneous ulceration are common but atypical lymphocytosis is much less common. Heterophile-negative infectious mononucleosis with nonsignificant lymphocytosis (especially if rash or mucocutaneous ulcers are present) should prompt investigation for acute HIV infection. CMV, toxoplasmosis, and, on occasion, EBV can cause heterophile-negative infectious mononucleosis with atypical lymphocytosis. *Mycoplasma* infection may also present as pharyngitis, though lower respiratory symptoms usually predominate.

The differential diagnosis of acute exudative pharyngitis includes gonococcal and streptococcal infections, and infections with adenovirus and herpes simplex. Head and neck soft tissue infections (pharyngeal and tonsillar abscesses) may occasionally be mistaken as the lymphadenopathy of mononucleosis.

Complications

Splenic rupture (0.5–1%) is a rare but dramatic complication, and a history of preceding trauma can be elicited in 50% of the cases. Acalculous cholecystitis, fulminant hepatitis with massive necrosis, pericarditis, myocarditis, and hemophagocytic lymphohistiocytosis (HLH) also are infrequent complications of acute EBV infection. Additional EBV-associated conditions are discussed below.

Treatment

A. General Measures

More than 95% of patients with acute EBV-associated infectious mononucleosis recover without specific therapy. Treatment is supportive. Antiviral therapy targeting EBV has not shown clinical benefit, possibly due to absent viral DNA polymerase expression during latent infection. Corticosteroid therapy, although widespread, is *not* recommended in uncomplicated cases; its use is reserved for impending airway obstruction from enlarged lymph nodes, hemolytic anemia, and severe thrombocytopenia. The value of corticosteroid therapy in impending splenic rupture, pericarditis, myocarditis, and nervous system involvement is less well established. Ampicillin and amoxicillin are traditionally avoided with concomitant EBV because of the frequent association with rash (90%); if rash occurs, it does not preclude future challenge with amoxicillin or ampicillin.

B. Treatment of Complications

Hepatitis, myocarditis, and encephalitis are treated symptomatically. Splenic rupture is associated with vigorous physical activity and requires splenectomy. *Patients should avoid contact or collision sports for at least 4 weeks to decrease the risk of splenic rupture (even if splenomegaly is not detected by physical examination, which can be insensitive).*

Prognosis

In uncomplicated cases, fever disappears in 10 days and lymphadenopathy and splenomegaly in 4 weeks. The debility sometimes lingers for 2–3 months.

Death is uncommon and is usually due to splenic rupture, hypersplenic phenomena (severe hemolytic anemia, thrombocytopenic purpura), or encephalitis.

4. Other EBV-Associated Conditions

Persons living with HIV, particularly at lower CD4 counts, may have **oral hairy leukoplakia**. This condition is generally asymptomatic and can be mistaken for oral candidiasis. It classically affects the lateral aspect of the tongue and, unlike candidiasis, does not scrape off with a tongue blade.

EBV is also associated with multiple malignancies, including nasopharyngeal carcinoma, Burkitt lymphoma (particularly endemic and HIV-associated types), a subset of Hodgkin lymphomas, and primary CNS lymphoma among others. Antiviral therapy has not shown benefit in these cases. Immunosuppression should be reduced if possible, and persons with HIV should be started on antiretroviral therapy.

Both solid organ and stem cell transplant recipients are at risk for **posttransplant lymphoproliferative disorder (PTLD)**. EBV-driven B cell proliferation is responsible for up to 50% of PTLD cases. Clinical presentation can vary from asymptomatic disease to acute illness, and PTLD can involve the allograft, lymph nodes, and other extranodal tissues such as the gastrointestinal tract and the central nervous system. In addition to reduction of immunosuppression, B cell–targeted therapies such as rituximab are commonly used in these cases. There has also been interest in studying the role of EBV in multiple chronic conditions, though demonstrating causality has been challenging. Recent work has demonstrated a potential mechanism (molecular mimicry) that suggests a causal link between EBV infection and some cases of multiple sclerosis.

When to Admit

Presence of severe complications of EBV disease including the following:

- Acute meningitis, encephalitis, or Guillain-Barré syndrome.
- Severe thrombocytopenia; significant hemolysis.
- Potential splenic rupture.
- Airway obstruction from severe adenitis.
- Pericarditis.
- Abdominal findings mimicking an acute abdomen.

5. Cytomegalovirus Disease

ESSENTIALS OF DIAGNOSIS

- Mononucleosis-like syndrome.
- Frequent pathogen seen in populations with compromised cellular immunity, such as transplant recipients.
- Diverse clinical syndromes in HIV (retinitis, esophagitis, colitis, encephalitis).
- Important infectious cause of congenital abnormalities.

General Considerations

CMV infection is common. In high-income countries, the seroprevalence in adults is about 60–80%; it is even higher in low- and middle-income countries. Transmission occurs through sexual contact, receipt of blood products, or transplantation. In pediatric cases, important routes of transmission include close contact (as in daycare centers), breastfeeding, and intrauterine transmission. *Most CMV infections are asymptomatic*. Severe disease occurs primarily in immunocompromised persons, including those post–organ transplant, with advanced HIV, and with IBD.

Three recognizable clinical syndromes exist: (1) perinatal disease and CMV inclusion disease, (2) diseases in immunocompetent persons, and (3) diseases in immunocompromised persons. Congenital CMV infection is the most common congenital infection in high-income countries (about 0.6% of live births, with higher rates in underdeveloped areas and among lower socioeconomic groups). Transmission is much higher from mothers with primary disease than those with reactivation (40% versus 0.2–1.8%). About 10% of infected newborns will be symptomatic with CMV inclusion disease.

In immunocompetent persons, acute CMV infection is the most common cause of the mononucleosis-like syndrome with negative heterophile antibodies. In critically ill immunocompetent adults, CMV reactivation is associated with prolonged hospitalization and death.

CMV is usually disseminated in persons with compromised cellular immunity, leading to several different clinical manifestations, described below. Solid organ and bone marrow transplant patients are at highest risk for disease from CMV reactivation for a year after allograft transplantation (but especially during the first 100 days post-transplantation) and in particular when graft-versus-host disease is present. For solid organ transplant recipients, the risk is increased when the donor is CMV-seropositive and the recipient is seronegative. Other the other hand, for patients undergoing stem cell transplantation, the risk of CMV reactivation and CMV disease is highest in cases of CMV-seronegative donor and seropositive recipient. Depending on the serostatus of the donor and recipient, disease may present as primary infection or reactivation. The risk of CMV disease is proportionate to the degree of immunosuppression and manifestations may differ by the cause. CMV may contribute to transplanted organ dysfunction, which often mimics organ rejection.

Clinical Findings

A. Symptoms and Signs

1. Perinatal disease and CMV inclusion disease—CMV inclusion disease in infected newborns is characterized by hepatitis, thrombocytopenia, microcephaly, periventricular CNS calcifications, mental retardation, and motor disability. Hearing loss develops in > 50% of infants who are symptomatic at birth, making CMV a leading cause of pediatric hearing loss. Most infected neonates are asymptomatic, but neurologic deficits may ensue later in life, including hearing loss in 15% and cognitive impairment in 10–20%. Perinatal infection acquired through breastfeeding or blood products typically has a benign clinical course.

2. Disease in immunocompetent persons—Symptomatic disease in uncommon among immunocompetent adults. Acute CMV infection may present as a mononucleosis-like illness with fever, malaise, myalgias, arthralgias, and splenomegaly. In comparison with EBV-associated mononucleosis, in CMV infection exudative pharyngitis or cervical lymphadenopathies are uncommon whereas cutaneous rashes are common. The mean duration of symptoms is 7–8 weeks. Complications include mucosal GI damage, encephalitis, hepatitis, thrombocytopenia, Guillain-Barré syndrome, pericarditis, and myocarditis. A mononucleosis-like syndrome due to CMV can also occur post-splenectomy, often years later, and is associated with a protracted fever, marked lymphocytosis, and impaired anti-CMV IgM response.

3. Disease in immunocompromised persons—Distinguishing between CMV *infection* (with evidence of CMV replication) and CMV *disease* (evidence for systemic symptoms or organ invasion by pathologic diagnosis) is important. In addition to patients with HIV, transplant recipients (solid organ or hematopoietic stem cell) show a broad spectrum of disease including ocular, GI (eg, colitis, esophagitis, and acute cholecystitis), kidney, and CNS disease.

A. CMV RETINITIS—A funduscopic examination reveals neovascular, proliferative lesions ("pizza-pie" retinopathy). Immune restoration with ART is associated with CMV vitritis and cystoid macular edema.

B. GI AND HEPATOBILIARY CMV—Esophagitis presents with odynophagia. Gastritis can occasionally cause bleeding, and small bowel disease may mimic IBD or may present as ulceration or perforation. Colonic CMV disease causes diarrhea, hematochezia, abdominal pain, fever, and weight loss and may mimic IBD. CMV hepatitis causes a range of liver pathology from asymptomatic transaminase elevation with primary CMV infection to acute liver failure.

C. RESPIRATORY CMV—CMV pneumonitis is characterized by cough, dyspnea, and relatively little sputum production. Co-infection with *Pneumocystis jirovecii* can be seen.

D. NEUROLOGIC CMV—Neurologic syndromes associated with CMV include polyradiculopathy, transverse myelitis, ventriculoencephalitis, and encephalitis. These manifestations are more prominent in patients with advanced HIV in whom the encephalitis has a subacute onset.

B. Laboratory Findings

1. Mothers and newborns—Congenital CMV disease is confirmed by the presence of the virus in amniotic fluid or an IgM assay from fetal blood. Amniocentesis is less reliable before 21 weeks' gestation (due to inadequate fetal urinary development and release into the amniotic fluid), but amniocentesis is associated with greater risk when performed after 21 weeks' gestation. PCR assays or culture of the newborn's urine, saliva, or blood specimens obtained during the first 3 weeks of life are used to diagnose congenital CMV infection.

2. Immunocompetent persons—The acute mononucleosis-like syndrome is characterized by initial leukopenia; within 1 week, it is followed by absolute lymphocytosis with atypical lymphocytes. Abnormal liver biochemical tests are common in the first 2 weeks of the disease (often 2 weeks after the fever). Detection of CMV DNA, specific IgM, or a fourfold increase of specific IgG levels supports the diagnosis of acute infection.

3. Immunocompromised persons—Tissue biopsy is the gold standard for diagnosing CMV end-organ disease, though it is not always feasible. In CMV retinitis, however, clinical exam findings in a typical host (eg, patient with advanced AIDS) are sufficient to make a presumptive diagnosis. Fluid cultures may lack specificity, as viral shedding is common in immunocompromised persons. Serologic testing has limited utility given high baseline seropositivity in many populations. However, among patients with HIV, a negative CMV IgG lowers the likelihood of CMV disease.

PCR testing has proved useful for the diagnosis of CMV in immunocompromised populations. Blood/plasma PCR testing can be challenging to interpret given frequency of herpes virus viremia in association with serious illness and immunocompromise. Nevertheless, quantitative PCR testing is commonly used in transplant recipients to guide treatment and prevention. Serial PCR should be compared using the same specimen type (ie, whole blood or plasma). CSF should be sent for CMV PCR in cases of suspected neurologic involvement.

C. Imaging

The CXR findings of CMV pneumonitis are consistent with interstitial pneumonia.

D. Biopsy

Tissue confirmation is especially useful in diagnosing CMV pneumonitis and CMV GI disease; the diagnosis of colonic CMV disease is made by mucosal biopsy showing characteristic CMV histopathologic findings of intranuclear ("owl's eye") and intracytoplasmic inclusions. When biopsy does not yield diagnostic findings but CMV colitis is suspected, CMV DNA PCR might help identify additional cases.

▶ Prevention

Primary prevention is best accomplished by good hand hygiene and use of barrier methods during sexual activity.

A major source of CMV for pregnant persons is their own young children, particularly those in childcare. Measures to decrease their risk of contracting primary CMV include practicing hand hygiene after changing diapers and after contact with respiratory secretions, as well as avoiding sharing utensils, food, and cleansing objects that have been in contact with children's secretions.

Antiretroviral therapy is effective in preventing CMV disease among patients with HIV. While secondary prophylaxis is routine following an episode of CMV retinitis pending CD4 reconstitution, primary prophylaxis is not recommended.

The use of leukocyte-depleted blood products effectively reduces the incidence of CMV disease in patients who have undergone transplantation. Prophylactic and preemptive strategies (eg, antiviral agents only when antigen detection or PCR assays show evidence of active CMV replication) appear equally effective in preventing invasive disease and mortality after hematopoietic stem cell transplant. The appropriate management of transplant patients is based on the serostatus of the donor and the recipient. All effective anti-CMV therapies can serve as prophylactic agents for CMV-seropositive transplants or for CMV-seronegative recipients of CMV-positive organ transplants. In addition to valganciclovir, letermovir is useful in prophylaxis against CMV infections in adult allogenic hematopoietic stem cell transplant recipients. It is given as 480 mg orally daily with dose adjustments for cyclosporine administration and for advanced kidney dysfunction. Recommended duration of CMV prophylaxis in posttransplant patients and in other immunocompromised patients varies by the type of transplant.

CMV immune globulin is used in some centers as part of the prophylaxis in kidney, liver, and lung transplantation patients.

Treatment & Prognosis

In immunocompetent persons, CMV infection is usually self-limited, and no specific antiviral therapy is needed. In contrast, in immunocompromised persons, treatment of CMV disease is necessary. CMV disease in immunocompromised patients is generally treated initially with intravenous ganciclovir (5 mg/kg every 12 hours, adjusted for kidney function). Oral valganciclovir (900 mg every 12 hours, adjusted for kidney function) is an acceptable alternative in patients with non–life-threatening disease.

Foscarnet and cidofovir are reserved for treatment of resistant CMV infections due to their toxicities and requirement for parenteral administration. Maribavir is a recently available oral option for CMV viremia clearance and symptom control in patients with posttransplant refractory CMV infection.

CMV infections in immunosuppressed patients require a reduction of immunosuppression when possible. Persons living with HIV should be started on antiretroviral therapy, although a short delay due to concern for immune reconstitution inflammatory syndrome (IRIS) can be considered in cases of retinitis or CNS disease. Therapy for CMV retinitis is maintained until there is sustained CD4 recovery > 100 cells/mcL and retinal lesions appear quiescent; a decision to stop CMV therapy should involve ophthalmology input. The use of secondary prophylaxis following CMV disease without retinal involvement is more individualized and takes into account the extent of disease and immune reconstitution.

Treatment of CMV retinitis is discussed in Chapter 7.

When to Refer

- Patients with advanced HIV with retinitis, esophagitis, colitis, hepatobiliary disease, or encephalitis.
- Transplant recipients

When to Admit

- Concern for severe manifestations such as inability to swallow, severe abdominal pain, or altered mental status.
- Initiation of intravenous anti-CMV agents.

6. Human Herpesviruses 6, 7, & 8

HHV-6 is a B-cell lymphotropic virus that is the principal cause of **exanthema subitum** (roseola infantum, sixth disease). Infection during pregnancy and congenital transmission is recognized. Primary HHV-6 infection occurs most commonly in children under 2 years of age and is a major cause of infantile febrile seizures. Primary infection in immunocompetent adults is uncommon but can produce a mononucleosis-like illness. Other manifestations in immunocompetent persons such as encephalitis, myocarditis or hepatitis are unusual. HHV-6 is on occasion also associated with drug-induced hypersensitivity syndromes.

Most cases of HHV-6 reactivation occur in immunocompromised persons. Reactivation is associated with graft rejection, graft-versus-host disease, and bone marrow suppression in transplant patients and with encephalitis and pneumonitis in patients with advanced HIV. In recipients of hematopoietic stem cell transplants, HHV-6 may cause fever. It is also associated with limbic encephalitis, particularly among recipients of umbilical cord hematopoietic cell transplants. Temporal lobe abnormalities are common on MRI in these cases.

Diagnosis in immunocompromised patients is typically made via PCR. This testing can be challenging to interpret, as some patients have chromosomally integrated HHV6 accounting for viremia; infectious diseases consultation is advised. Ganciclovir, cidofovir, and foscarnet have in vitro activity against HHV-6, although optimal therapy remains uncertain.

HHV-8 (see also Chapter 36) is associated with a spectrum of disease including Kaposi sarcoma, primary effusion lymphoma, and multicentric Castleman disease (MCD), among others. HHV-8 infection is endemic in Africa; transmission seems to be primarily horizontal in childhood from intrafamilial contacts. In the United States, on the other hand, sexual transmission (particularly among men having sex with men) is thought to be most important. Although HHV-8 related malignancies are often associated with HIV infection, Kaposi sarcoma is also well described in solid organ transplant recipients and noted in other patient populations. Antiviral therapy targeting KSHV has not demonstrated efficacy in associated malignancies.

MAJOR VACCINE-PREVENTABLE VIRAL INFECTIONS

1. Measles

ESSENTIALS OF DIAGNOSIS

- Onset of prodrome 7–18 days after exposure in an unvaccinated patient.
- Prodrome: fever, coryza, cough, conjunctivitis, malaise, irritability, photophobia, Koplik spots.
- Rash: brick red, maculopapular; appears 3–4 days after onset of prodrome; begins on the face and proceeds "downward and outward," affecting the palms and soles last.
- Leukopenia.

General Considerations

Measles is a reportable acute systemic paramyxoviral infection transmitted by direct contact with infectious droplets or by airborne spread. It is highly contagious with communicability greatest during the pre-eruptive and catarrhal stages but continues 4 days after the appearance of rash. Millions of doses of measles vaccines were postponed or missed from 2020 to 2022 due to COVID-19 related delays in medical care. Missed vaccines and increasing vaccine hesitancy have increased the number of measles cases seen worldwide over recent years. In 2023, the WHO estimates there were 10,341,000 cases of measles worldwide and 136,000 deaths, mostly in children.

The WHO previously considered measles eliminated in most countries worldwide, including the Americas. Though effective vaccination averted 60.3 million global measles deaths between 2000 and 2023, reduced measles vaccination rates during the COVID-19 pandemic have led to a resurgence of the disease. Measles outbreaks are occurring worldwide; the countries reporting the highest number of measles cases between February 2024 and July 2024, in order, were Iraq (24,191 cases), Ethiopia, Kazakhstan, Pakistan, Yemen, India, Russian Federation, Kyrgyzstan, Romania, and Azerbaijan (8570 cases). There was a 43% increase in measles deaths from 2021 to 2022 (from 95,000 to 136,200). Measles deaths were reported to decrease by about 8% in 2023, primarily attributable to an increased number of cases occurring in countries with lower risk for death.

Most measles cases in the United States were formerly imported. However, a number of measles outbreaks have been reported in the United States in 2023–2024 due to lower vaccination rates, with a notable increase in parents filing for medical or religious exemptions to childhood vaccines from the 2019–2020 school year to the 2021–2022 school year. More measles cases were reported in the first 3 months of 2024 in the United States than in the entirety of 2023. As of November 21, 2024, a total of 280 measles cases were reported by 32 US jurisdictions. There have been 16 outbreaks (defined as 3 or more related cases) in 2024 in the United States, up from 4 in 2023. During the 2022–2023 school year, coverage for measles vaccines among children was lower than in previous years, now at 93.1%. This level of vaccination coverage and resultant measles outbreaks in the United States is threatening the status of measles elimination in the country (declared in 2000).

Clinical Findings

A. Symptoms and Signs

The incubation period for measles is 10–14 days. The illness starts with a prodromal phase manifested by high-grade fever (often as high as 40–40.6°C), malaise, coryza (nasal obstruction, sneezing, and sore throat resembling upper respiratory infections), persistent cough, and conjunctivitis (redness, swelling, photophobia, and discharge). These symptoms intensify over 2–4 days before onset of the rash and peak on the first day of the rash. The fever persists through the early rash (about 5–7 days) (Table 37–2).

The characteristic measles rash appears on the face and behind the ears. Initial lesions are pinhead-sized papules that coalesce to form a brick-red, irregular, blotchy maculopapular rash. The rash spreads to the trunk and extremities, including the palms and soles. It lasts for 3–7 days and fades in the same manner it appeared. Other findings include pharyngeal erythema, tonsillar exudate, moderate generalized lymphadenopathy, and, at times, splenomegaly.

Koplik spots (small, irregular, and red with whitish center on the mucous membranes) are pathognomonic of measles (Figure 37–4). They appear about 2 days before the rash and last 1–4 days as tiny "table salt crystals" on the palatal or buccal mucosa opposite the molars.

B. Laboratory Findings

Leukopenia is usually present unless secondary bacterial complications exist. A lymphocyte count under 2000/mcL (2.0×10^9/L) is a poor prognostic sign. Thrombocytopenia and proteinuria are common.

Detection of IgM measles antibodies with ELISA or a fourfold rise in serum hemagglutination inhibition antibody

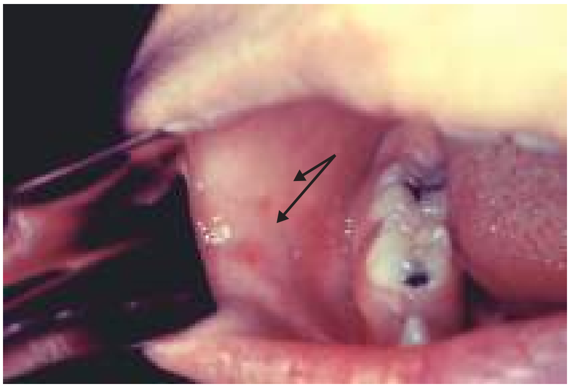

Figure 37–4. Very small, bright red spots on the buccal mucosa indicative of Koplik spots. (Public Health Image Library, CDC.)

supports the diagnosis. IgM assays can be falsely negative the first few days of infection and falsely positive in the presence of rheumatoid factor or with acute rubella, erythrovirus (formerly parvovirus B19), or HHV-6 infection.

Measles virus is technically difficult to culture. Real-time reverse transcriptase–PCR (RT-PCR), available from the CDC and some public health laboratories, can help establish a diagnosis promptly (nasopharyngeal and throat swabs preferred over serum or urine specimens).

Differential Diagnosis

Measles is usually diagnosed clinically but may be mistaken for Kawasaki disease and other exanthematous infections (Table 37–2). Frequent difficulty in establishing a diagnosis suggests that measles may be more prevalent than is recognized.

Complications

A. Respiratory Tract Disease

Early in the course of the disease, bronchopneumonia or bronchiolitis due to the measles virus may occur in up to 5% of patients and result in serious respiratory difficulties. Bronchiectasis may occur in up to a quarter of unvaccinated children. The incidence of severe respiratory disease may be increased among immunocompromised children and pregnant persons.

B. Central Nervous System

Postinfectious encephalomyelitis occurs in 0.05–0.1% of cases, with higher rates occurring in adolescents. It is an acute demyelinating disease that usually starts 3–7 days after the rash. Seizures, coma, and other neurologic symptoms and signs may develop. Treatment is symptomatic and supportive. Virus isolation from the CNS is uncommon. Mortality is 10–20%, and morbidity includes 33% of survivors left with neurologic deficits.

Measles inclusion body encephalitis is another form of neurologic complication that results in neurologic deterioration and death within months of the acute illness among patients with impaired cellular immunity. Treatment is supportive, including stopping immunosuppressants when feasible. Interferon and ribavirin are variably successful.

Subacute sclerosing panencephalitis is a very rare, fatal CNS complication that occurs 5–15 years after infection. It is characterized by progressive deterioration of motor and cognitive function leading to death. It is more common in those infected with measles before 2 years of age.

C. Other Complications

Immediately following measles, secondary bacterial infection, particularly otitis media (the most common complication), cervical adenitis, and pneumonia, occurs in about 15% of patients. Keratoconjunctivitis is a serious complication that caused blindness before the widespread use of measles vaccine and vitamin A supplementation. Diarrhea and protein-losing enteropathy (prodromal rectal Koplik spots may occur) are significant complications among malnourished children, although the mortality associated with diarrhea is primarily 1 week before and 4 weeks after the measles rash, with no longer-term mortality shown with measles-associated diarrhea.

Prevention

The measles vaccine is a *live* vaccine available worldwide as part of the trivalent MMR vaccine or the quadrivalent MMRV vaccine. Because measles is highly contagious, the vaccine coverage rates must exceed 95% to prevent outbreaks. Illness confers permanent immunity. One vaccine dose is about 93% effective, two doses 97% protective. The effect of the COVID outbreak was considerable in reducing the vaccination rates, with 83% of the world's children having received one dose of vaccine by their first birthday—the lowest rate since 2008. Geographic disparities and clustering of unvaccinated individuals increases the likelihood of an outbreak.

At 6 months of age, > 99% of infants of vaccinated women and 95% of infants of naturally immune women lose maternal antibodies. There are conflicting studies on the optimal timing of MMR vaccination—one suggested higher measles susceptibility in adults who received the vaccine before 15 months due to the impact of residual maternal antibodies. However, another study showed lower initial seroprotection rates after the first dose of MMR when given at 5–7 months, but no negative impact on the short-term responses to subsequent MMR vaccinations.

In the United States, children receive their first dose of MMR vaccine at 12–15 months of age (https://www.cdc.gov/vaccines/hcp/imz-schedules/child-adolescent-age.html). The second dose is given at age 4–6, before school entry. Studies from Guinea-Bissau, where routine administration occurs at 9 months of age, fail to show a statistically significant benefit from a second dose of measles vaccination at 18 months of age. Older children, teens, and adults without evidence of immunity should receive two MMR doses separated by 28 days. *For individuals born before 1957, herd immunity is assumed.* Persons at high risk for measles exposure (eg, teachers, health care workers, post–high school students, travelers to low- and middle-income countries) should also receive two vaccination doses at least 28 days apart. Immigrants and refugees should be screened and vaccinated if necessary. The MMRV vaccines may be used in place of the traditional MMR vaccine. Data on febrile convulsions after vaccination show a slightly increased risk associated with MMRV over MMR vaccination separate from vaccinia vaccination—but with the statistical weakness of the association, experts recommend that the two be separated only when there is an indication such as a family history of convulsions.

MMR and MMRV vaccine should *not* be administered to pregnant persons, patients with anaphylactic reactions to neomycin, and patients with known primary or acquired immunodeficiency. Asymptomatic patients living with HIV infection with CD4 cell counts higher than 200/mcL should receive the MMR vaccine but not the MMRV vaccine. Recent data also suggest that the MMR vaccine is both safe and effective in children post chemotherapy and hematopoietic stem cell transplant, as well as those post liver and kidney transplant (notably, mean time post transplant was 6.3 years and 73% were on low-level monotherapy for immunosuppression at time of vaccination).

There are new measles and rubella vaccines in development, utilizing microarray patches rather than injections. In a phase 1 clinical trial and another phase 1/2 clinical trial, this new method has shown promising results with seroconversion rates equivalent to MMR injections in adults, toddlers (age 15–18 months), and infants (age 9–10 months). Safety profile also is encouraging: the most common adverse reaction from the microarray patches are mild localized induration and discoloration at the patch site.

Repeated studies fail to show an association between vaccination and autism. MMR vaccine may cause fever and transient rash. Severe allergic reactions are rare. Quadrivalent MMRV vaccine is associated with an increased risk of febrile seizures that appear to be age-related; the risk is highest when MMRV is given to infants 12–23 months of age. Postimmunization seizures appear in whole genome studies to be associated with an IFN receptor and a measles receptor. Immune thrombocytopenia is a documented side effect. Rare cases of postimmunization encephalitis are reported.

In case of an outbreak, when susceptible individuals are exposed to measles, MMR vaccine can prevent disease if given within 3 days of exposure. Immunoglobulin should be administered within 6 days of exposure in any high-risk person exposed to measles, followed by active immunization 3 months later. All infants younger than 1 year of age should receive intramuscular immunoglobulin (0.5 mL/kg, maximum dose 15 mL). For infants aged 6–12 months, MMR vaccination with repeat at 15 months can be given in place of intramuscular immunoglobulin. Pregnant women and severely immunocompromised persons who are exposed to active measles cases should receive IVIG (400 mg/kg).

Patients with measles should be isolated for 4 days after the onset of rash. In the hospital setting, patients with measles should be placed under airborne precautions.

Treatment

Treatment is symptomatic, including antipyretics and fluids as needed. *Vitamin A supplementation for children reduces pediatric morbidity and measles-associated mortality*. Data are less substantial for adult supplementation, although many advocate megadose vitamin A given to the mother at delivery to boost infant vitamin levels.

Measles virus is susceptible to ribavirin and other antivirals in vitro. Ribavirin is used in selected severe cases of pneumonitis, but insufficient data prevent recommending antiviral use. Zinc has a role in maintaining normal immune functions, but routine zinc supplementation to children with measles is *not* recommended, again for lack of data.

Prognosis

In the United States, the case fatality rate is around 2 per 1000 reported cases, with deaths due principally to respiratory and neurologic complications. Deaths in the developing world are mainly related to acute diarrhea and protein-losing enteropathy. Pregnant persons with measles may be at increased risk for death. Historically famines are particularly associated with high measles mortality.

When to Refer

- Any suspect cases should be reported to public health authorities.
- HIV infection.
- Pregnancy.

When to Admit

- Meningitis, encephalitis, or myelitis.
- Severe pneumonia.
- Diarrhea that significantly compromises fluid or electrolyte status.

2. Mumps

ESSENTIALS OF DIAGNOSIS

- Exposure 12–25 days before onset.
- Painful, swollen salivary glands, usually parotid.
- Frequent involvement of testes, pancreas, and meninges in unvaccinated individuals.
- Mumps can occur in appropriately vaccinated persons in highly vaccinated communities.

General Considerations

Mumps is a paramyxoviral disease spread by respiratory droplets. Children are most commonly affected; however, in outbreaks, infection can affect patients in their second or third decades of life. Mumps can spread rapidly in congregate settings, such as colleges and schools. The incubation period is 12–25 days (average, 16–18 days). The mumps virus spreads through direct contact with respiratory secretions, saliva, or infected surfaces. Transmission can also be airborne or via droplets. Up to one-third of affected individuals have subclinical infection, which is still transmissible. Since the MMR vaccine was introduced in 1989 in the United States, the mumps case rate has decreased by > 99%, with only a few hundred cases reported most years. The CDC reported 694 cases of mumps in 2020, 154 in 2021, 399 in 2022, 436 in 2023, and 259 cases up to September 12, 2024. A combination of factors contributes to outbreaks, including efficacy of vaccines; waning individual immunity; and crowded conditions, which promote transmission.

The ubiquitous nature of mumps requires that travelers maintain vaccination coverage but not supplement coverage (see below). More than 500,000 cases occur globally per year. Outbreaks are commonly found in countries with low MMR vaccination rates (eg, India). However, as immunity wanes post MMR immunization, endemic transmission is still reported in countries where it is included in the routine vaccination schedule (eg, Canada and the United States).

Clinical Findings

A. Symptoms and Signs

Mumps is more serious in adults than children and appears to occur more commonly in male children, adolescents, and adults. *Parotid tenderness* and *overlying facial edema* (Figure 37–5) are the most common physical findings and typically develop within 48 hours of the prodromal symptoms. Usually, one parotid gland enlarges before the other, but unilateral parotitis occurs in 25% of patients. The parotid duct (orifice of Stensen) may be red and swollen. Trismus may result from parotitis. The parotid glands return to normal within 1 week. Involvement of other salivary glands (submaxillary and sublingual) occurs in 10% of cases. Fever and malaise are variable but often minimal in young children. The entire course of mumps rarely exceeds 2 weeks.

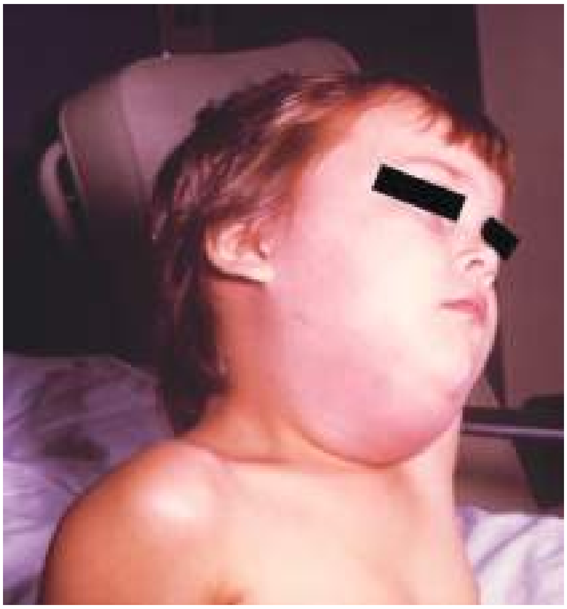

Figure 37–5. Mumps. (Public Health Image Library, CDC.)

The testes are the most common extra salivary disease site in adults. High fever, testicular swelling, and tenderness (unilateral in 75% of cases) denote *orchitis*, which usually develops 7–10 days after the onset of parotitis. In the mumps outbreaks that occurred between 2006 and 2010 in the United States, complications from mumps were rare; 3.3–10% of adolescents and men developed orchitis (which occurred less frequently in persons who have received two doses of vaccine). Lower abdominal pain and ovarian enlargement suggest oophoritis, which is usually unilateral and occurs in < 1% of postpubertal women.

Other rare complications, occurring in < 1% of cases, are meningitis, encephalitis, Guillain-Barré syndrome, hearing loss, priapism or testicular infarction from orchitis, pancreatitis, thyroiditis, keratitis, neuritis, hepatitis, myocarditis, thrombocytopenia, migratory arthralgias, and nephritis. No mumps-related deaths have occurred in the United States in recent outbreaks. A rare cause of mumps is iodine exposure in medical procedures (“iodide mumps”).

B. Laboratory Findings

Mild leukopenia with relative lymphocytosis may be present. Elevated serum amylase usually reflects salivary gland involvement rather than pancreatitis. Mild kidney injury is found in up to 60% of patients.

The characteristic clinical picture usually suffices for diagnosis. An elevated serum IgM is considered diagnostic. Repeat testing 2–3 weeks after the onset of symptoms is recommended if the first assay is negative because the rise in IgM may be delayed, especially in vaccinated persons. A fourfold rise in complement-fixing antibodies to mumps virus in paired serum IgG also confirms infection. Antimumps IgM and IgG in the CSF can confirm the diagnosis of mumps-associated meningitis. Nucleic acid amplification techniques, such as RT-PCR (of a buccal swab), are more sensitive than viral cultures and are available from some commercial laboratories, selected state laboratories, and the CDC. Diagnostic yield is highest if collected during the first 3 days of illness. Confirmatory diagnosis of mumps is also made by isolating the virus preferably from a swab of the duct of the parotid or other affected salivary gland. The virus can also be isolated from CSF early in aseptic meningitis. Vaccinated persons may shed virus for shorter periods than those who are unvaccinated.

Differential Diagnosis

Swelling of the parotid gland may be due to calculi in the parotid ducts, tumors, or cysts. Other causes include sarcoidosis, cirrhosis, diabetes, bulimia, pilocarpine usage, and Sjögren syndrome. Parotitis may be produced by pyogenic organisms (eg, *S aureus*, gram-negative organisms [particularly in debilitated individuals with poor oral intake]), drug reactions (phenothiazines, propylthiouracil), and other viruses (HIV, influenza A, parainfluenza, EBV infection, coxsackieviruses, adenoviruses, HHV-6). Swelling of the parotid gland must be differentiated from inflammation of the lymph nodes located more posteriorly and inferiorly than the parotid gland.

Prevention

Vaccination is the most effective way to prevent mumps, and the use of at least one dose of vaccine was reported from 122 countries in 2018.

The vaccination schedule, indications, and contraindications are described in the measles section. The mumps vaccine component of the MMR is less effective than the measles and rubella components. One dose is 78% (range: 49–92%) protective. Two vaccine doses are 88% (range: 66–95%) effective. Rare reported complications of mumps vaccination include immune thrombocytopenic purpura and aseptic meningitis. The CDC recommends a third dose of vaccine in case of an outbreak but does not recommend additional doses for travel to areas with a mumps outbreak.

A new live attenuated mumps vaccine is reported from China, and it appears to be safe and effective.

Suspected cases should be isolated. For outbreak control, the most important step is to vaccinate all susceptible individuals. The MMR vaccine is *not* effective in preventing the disease in unvaccinated patients who already have been exposed to the virus. In the health care setting, the following steps should be taken: implement droplet and standard precautions, isolate patients until swelling subsides (about 9 days from onset), and provide vaccination to health care workers with no evidence of immunity.

Treatment

Treatment is symptomatic. Topical compresses may relieve parotid discomfort. Some clinicians advocate IVIG for complicated disease (eg, thrombocytopenia), although its definitive role is unproven. No specific treatment exists for orchitis.

When to Refer

Any suspect cases should be reported to public health authorities.

When to Admit

- Trismus; meningitis; encephalitis; myocarditis; pancreatitis.
- Severe testicular pain; priapism.
- Severe thrombocytopenia.

3. Rubella

ESSENTIALS OF DIAGNOSIS

- Exposure 14–21 days before onset.
- No prodrome in children, mild prodrome in adults; mild symptoms (fever, malaise, coryza) coincide with, or precede by up to 5 days, the eruption of rash.
- Posterior cervical and postauricular lymphadenopathy 5–10 days before rash.
- Fine maculopapular rash of 3 days' duration; face to trunk to extremities.
- Leukopenia, thrombocytopenia.

General Considerations

Rubella is a systemic disease caused by a togavirus transmitted by inhalation of infective droplets. It is moderately communicable. Infection usually confers permanent immunity. The incubation period is 14–21 days. The disease is transmissible from 1 week before the rash appears until 15 days afterward.

The last cases of endemic rubella and **congenital rubella syndrome** were reported in 2009 from the Americas region. Each year in the United States, fewer than 10 cases of rubella are reported, all due to the arrival of infected persons from other countries. In 2015, the WHO declared the Americas the first region free of rubella and congenital rubella syndrome. Some European countries face a challenge with lower immunization coverage among refugees and migrants. Worldwide, cases are decreasing due to widespread implementation of rubella-containing vaccines (81% decline in rubella incidence: 93,816 cases in 2012 to 17,407 in 2022). As of 2022, the vaccine was added to the national vaccine schedule in 175 of 194 countries (90%), although it is important to note that extensive variation in the rate of national coverage exists. The countries that have not introduced rubella vaccination are mainly in Africa and the Eastern Mediterranean. Of note, the number of reported cases of congenital rubella syndrome is increasing, particularly in Africa and Southeast Asia. The increase in congenital rubella syndrome is likely secondary to increased surveillance and reporting of congenital rubella cases.

Clinical Findings

A. Postnatal Rubella

Rubella is a common childhood disease; most cases are asymptomatic. The clinical picture of rubella is difficult to distinguish from other viral illnesses, such as infectious mononucleosis, measles, echovirus infections, and coxsackievirus infections. Fever and malaise, usually mild, accompanied by tender suboccipital adenitis, may precede the eruption by 1 week. Early posterior cervical and postauricular lymphadenopathy is common. A fine, pink maculopapular rash appears and fades from the face, trunk, and extremities in rapid progression (2–3 days), usually lasting 1 day in each area (Table 37–2).

B. Congenital Rubella

The principal importance of rubella lies in its devastating effects on the fetus in utero causing fetal death, preterm delivery, and teratogenic effects. The severity of symptoms is directly related to the gestational age; fetal infection during the first trimester leads to congenital rubella in at least 80% of fetuses; however, an infection during the fourth month can lead to a 10% risk of a single congenital disability. In the second trimester of pregnancy, deafness is the primary complication.

C. Laboratory Findings

When rubella is suspected, the diagnosis requires serologic confirmation. Diagnosis of acute rubella infection is based on elevated IgM antibody, fourfold or greater rise in IgG antibody titers, or virus isolation. Serosensitivity to rubella is thought to change with subsequent pregnancies, although data from Hong Kong (lower immunity) and the United Kingdom (higher immunity) differed in their findings.

IgM is detectable in 50% of patients on day 1 of the rash but in most on day 5 after rash onset. Antibody testing can be performed on serum or saliva. An isolated IgM-positive test does not necessarily imply acute infection. IgM antibodies can persist after an infection or could be false-positive due to cross-reactivity with other antigens such as EBV, CMV, erythrovirus, and rheumatoid factor. *This distinction is very important to make when infection is suspected in pregnancy.* High-avidity anti-rubella IgG assays can distinguish between recent and remote infection. Low-avidity IgG is observed in acute rubella infections and lasts up to 3 months postinfection. After 3 months, low-avidity antibodies are replaced by high-avidity antibodies indicating remote infection.

The CDC can test for the virus by RT-PCR from throat swabs, oral fluids, or nasopharyngeal secretions. The timing of sample collection is important and is best if collected within the first 3 days of an acute illness and within 3 months in case of congenital rubella syndrome. After 3 months of age, up to 50% of infants with congenital rubella syndrome will not shed the virus.

Complications

Complications of rubella are rare aside from the congenital rubella syndrome. Polyarticular arthritis and arthralgia occur more commonly in adult women; involve the fingers, wrists, and knees; and usually subside within 7 days but may persist for weeks. Hemorrhagic manifestations due to thrombocytopenia and vascular damage occur more commonly in children, unlike other complications. Hepatitis has been reported. Encephalitis, another rare complication, occurs more commonly in adults and has a high mortality rate.

Prevention

Patients with rubella should be isolated for 7 days after rash onset.

In the United States, monovalent rubella vaccine is not produced. *Live attenuated* rubella virus vaccine is included in the MMR or MMRV vaccine. It is recommended that the first dose be given between 12 months and 15 months. The second dose is given between ages 4 and 6, before school entry. More details on scheduling, side effects, and contraindications are explained in the measles section. It is important that girls are immune to rubella before menarche. In the United States, about 80% of 20-year-old women are immune to rubella.

Rubella vaccine is safe and highly efficacious; a single dose of MMR vaccine is about 97% effective at preventing rubella. Vaccination outside the recommended age range (age > 7) is shown to be effective, and vaccine adherence is not affected by coadministration with yellow fever vaccine (in Argentina) or typhoid vaccine (in India and Malawi). Vaccination of health care workers is effective (Italy) in augmenting overall rates, and selective immunization of males has been effective in Japan where past policies included targeted vaccination of junior high school girls.

The immune status of pregnant persons should be evaluated because antibody titers fall in about 10% of vaccinated individuals within 12 years of vaccination. While no evidence exists for adverse outcomes with MMR immunization of pregnant persons, it is still recommended that women avoid pregnancy for at least 4 weeks after vaccination. *Opportunities should be made available to vaccinate all women of childbearing age.*

The administration of live vaccines to immunocompromised patients is controversial. In patients receiving immunosuppressive therapy and those who have undergone solid organ or bone marrow transplantation, seroconversion is higher in rubella compared with measles, mumps, and varicella. In addition, response to live attenuated vaccines may be lessened due to presence of antibodies from IVIG or other blood products.

Safety is another concern when administering live attenuated vaccines to immunocompromised patients. Because MMR vaccine has historically been considered contraindicated in solid organ transplant recipients, evidence recommends that seronegative patients receive one or two doses of the MMR vaccine at least 4 weeks before solid organ transplantation. Patients who have undergone bone marrow transplant lose antigen-specific antibodies and should be revaccinated regardless of their vaccination history. The guidelines recommend MMR and varicella vaccines be given to seronegative patients without graft-versus-host disease 2 years after hematopoietic stem cell transplantation. See the Prevention section under Measles, above, for more discussion of rubella vaccination in transplant patients.

Treatment

Rubella infection, including complications, is treated symptomatically.

Prognosis

Rubella typically is a mild illness and rarely lasts > 3–4 days. Congenital rubella has a high fetal mortality rate, and the associated congenital disabilities are largely permanent.

When to Refer

- Pregnancy.
- Meningitis/encephalitis.
- Significant vaccination reactions.
- Any suspected cases should be reported to public health authorities.

4. Poliomyelitis

ESSENTIALS OF DIAGNOSIS

- Incubation period 7–14 days after exposure.
- Headache, stiff neck, fever, vomiting, sore throat.
- Lower motor neuron lesion (flaccid myelitis) with decreased deep tendon reflexes and muscle wasting; sensation intact.

General Considerations

Poliomyelitis virus, an enterovirus, is highly contagious through the fecal-oral route, especially during the first week of infection. Three wild poliovirus serotypes exist; however, only wild poliovirus type 1 has remained endemic since 2012. Pakistan and Afghanistan are the only countries with endemic wild-type poliovirus transmission, with 7 and 6 cases respectively, although Mozambique also reported 1 case in 2022. Of concern is an increase in vaccine-derived polio outbreaks. Between January 2023 and June 2024, 672 circulating VDPV cases were reported from 39 countries worldwide. The WHO considers the following states to have ongoing polio outbreaks: wild polio virus type 1 in Afghanistan, Mozambique, and Pakistan; circulating vaccine-derived polio virus type 1 (VDPV1) in Madagascar, Mozambique, Malawi, the DRC, and Republic of the Congo. Additionally, the WHO recognizes 22 states (Israel plus 21 in Africa) infected with circulating VDPV2; a complete list can be found at polioeradication.org. In July 2022 a case of paralytic poliomyelitis due to VDPV2 was identified in the United States (in Rockland County, New York). Wastewater testing detected VDPV2 in Rockland County and neighboring counties from August 2022 to February 2023, but samples have been clear since then. Guatemala, Israel, and the United Kingdom have reported positive environmental samples. Specifically, although declared polio-free since 1999, VDPV2 was detected in the wastewater in Gaza amid a precipitous drop in vaccination rates during the ongoing armed conflict, and the first case in humans was detected in a 10-month-old infant in August of 2024.

Cases of acute flaccid myelitis (formerly acute flaccid paralysis) resembling polio but not due to poliomyelitis virus are being reported (see Acute Flaccid Myelitis, below).

Clinical Findings

A. Symptoms and Signs

At least 95% of infections are asymptomatic. Patients who become symptomatic can present with abortive poliomyelitis, nonparalytic poliomyelitis, or paralytic poliomyelitis. Post-poliomyelitis syndrome is the constellation of symptoms that affect polio survivors and is not infectious.

1. Abortive poliomyelitis—Nonspecific symptoms of this minor illness include fever, headache, vomiting, diarrhea, constipation, and sore throat lasting 2–3 days.

2. Nonparalytic poliomyelitis—In addition to the above symptoms, signs of meningeal irritation and muscle spasm occur in the absence of frank paralysis.

3. Paralytic poliomyelitis—Characterized as a flaccid asymmetric paralysis affecting mostly the proximal muscles of the lower extremities; the febrile period is present over 2–3 days. Sensory loss is very rare. Paralytic poliomyelitis is divided into two forms, which may coexist: (1) **spinal poliomyelitis** involving the muscles innervated by the spinal nerves, and (2) **bulbar poliomyelitis** involving the muscles supplied by the cranial nerves (especially nerves IX and X) and of the respiratory and vasomotor centers. The most life-threatening aspect of bulbar poliomyelitis is respiratory paralysis. The incidence of paralytic poliomyelitis is higher when infections are acquired later in life.

4. Post-poliomyelitis syndrome—The syndrome presents with signs of chronic and new denervation. The most frequent symptoms are progressive muscle limb paresis, muscle atrophy, fasciculations, and fibrillation during rest activity. Restless leg syndrome also is reported.

B. Laboratory Findings

The virus may be recovered from throat washings (early) and stools (early and late), and PCR of washings, stool, or CSF can also facilitate diagnosis. CSF findings include the following: (1) normal or slightly increased pressure and protein, (2) glucose is not decreased, and (3) WBC count usually < 500/mcL (0.5×10^9/L) and are principally lymphocytes after the first 24 hours. CSF findings are normal in 5% of patients. Neutralizing and complement-fixing antibodies appear during the first or second week of illness. Serologic testing cannot distinguish between wild-type and vaccine-related virus infections.

Differential Diagnosis

Acute inflammatory polyneuritis (Guillain-Barré syndrome), Japanese encephalitis virus infection, West Nile virus infection, and tick paralysis may resemble poliomyelitis. In Guillain-Barré syndrome (see Chapter 27), the weakness is more symmetric and ascending in most cases, but the Miller Fisher variant of Guillain-Barré is similar to bulbar poliomyelitis. Paresthesia is uncommon in poliomyelitis but common in Guillain-Barré syndrome. The CSF usually has high protein content but normal cell count in Guillain-Barré syndrome. While no evidence of poliomyelitis infection exists in acute flaccid myelitis that resembles polio, enteroviruses are isolated in some cases of acute flaccid myelitis.

Prevention

Given the epidemiologic distribution of poliomyelitis and the continued concern about vaccine-associated disease with the trivalent live OPV, the inactive (Salk) parenteral vaccine (IPV) is used in the United States for all four recommended doses (at ages 2 months, 4 months, 6–18 months, and 4–6 years).

Because most circulating vaccine-derived poliovirus and vaccine-associated poliomyelitis are live OPV type 2, the WHO replaced worldwide the trivalent live OPV (containing types 1, 2, and 3) with the bivalent live OPV (type 1 and 3) in 2016. *The goal is to replace all live OPV with inactive parenteral vaccination to eliminate poliovirus circulation.* The advantages of oral vaccination, however, are the ease of administration, low cost, effective local GI and circulating immunity, and herd immunity. Monovalent OPV type 2 (mOPV2) and trivalent OPV are used for control in countries with vaccine-derived type 2 outbreaks. A novel oral polio vaccine type 2 (nOPV2) has been developed in response to the ongoing circulating vaccine-derived type 2 poliovirus outbreaks and is safe and immunogenic in previously immunized adults. Studies so far have shown that nOPV2 is more genetically stable than the mOPV2 and therefore less prone to reverting to neurovirulence. The nOPV2 was recommended for initial use under the WHO's Emergency Use Listing Procedure in November 2020.

A variety of measures with inactivated vaccines lower costs and increase coverage, including newer adjuvants, new delivery systems with microneedle patches, and developing multimode and combination formats including fractional doses (Bangladesh).

Routine immunization of adults in most parts of the United States is *no longer recommended* because of the low incidence of the disease. Due to the growing concern for polio transmission in New York in 2022, the New York State Health Department recommended that previously unvaccinated adults receive the vaccine, and persons starting the vaccine series after age four should receive three doses. Vaccination should be considered for adults not vaccinated within the prior decade who are exposed to poliomyelitis or who plan to travel to endemic areas and adults engaged in high-risk activities (eg, laboratory workers handling stools).

Treatment

In the acute phase of paralytic poliomyelitis, patients should be hospitalized. In cases of respiratory weakness or paralysis, intensive care is needed. Intensive physiotherapy may help recover some motor function with paralysis. Attention to psychological disorders in longstanding disease is also important.

Immunodeficient individuals have prolonged excretion of poliovirus leading to virus circulation and threatening the polio eradication efforts.

Immune modulators, such as prednisone, IFN, and IVIG, do *not* show any clear benefit in the treatment of post-poliomyelitis syndrome.

Prognosis

The death-to-case ratio for paralytic polio ranges between 2% and 30%, depending on age. Bulbar poliomyelitis carries a mortality rate of up to 75%.

When to Refer

Any suspicious cases should be referred to public health authorities.

5. Acute Flaccid Myelitis

ESSENTIALS OF DIAGNOSIS

- Viral illness precedes neurologic signs.
- Flaccid paralysis usually affects upper limbs or all four limbs.
- Enterovirus is commonly isolated; poliomyelitis must be ruled out.

General Considerations

Before widespread polio vaccination in the 1950s, polio was the most common cause of acute flaccid myelitis (also known as acute flaccid paralysis). More recently, non-polio enteroviruses are most often the cause of acute flaccid myelitis. This disease has been reported throughout Africa (20 countries), the Eastern Mediterranean region (5 countries), intermittently in Europe (Germany and France), and the United States (50 states and the District of Colombia). The CDC began surveillance for acute flaccid myelitis in 2014. Since then, there have been three outbreaks in the United States. The largest to date occurred in 2018, with 238 confirmed cases; most had a preceding viral illness in the month before presentation of neurologic signs. The neurologic signs most commonly involved the upper limbs or all four limbs. The most commonly associated viruses were enterovirus A71 and enterovirus D68. In all instances, poliomyelitis was ruled out, but the exact cause of acute flaccid myelitis was not always determined. Updated US case counts can be found here: https://www.cdc.gov/acute-flaccid-myelitis/cases-in-us.html.

Clinical Findings

Acute flaccid myelitis is usually a childhood disease; the average age of presentation is 5 years. Cases usually present in late summer or early fall. The three clinical stages of acute flaccid myelitis are prodromal illness, acute neurologic injury, and convalescence.

A. Symptoms and Signs

The prodrome typically consists of fever, upper respiratory symptoms, and GI symptoms. One to four weeks later, neurologic symptoms begin and usually manifest as flaccid limb weakness with decreased reflexes. Fever may recur, and the patient experiences myalgia and flaccid weakness in one or more limbs. Upper extremities are affected more often than lower extremities. Once new neurologic symptoms have subsided, the convalescent phase can last months to years. During this time, patients may experience residual muscle weakness and atrophy.

B. Laboratory Findings

CSF analysis shows pleocytosis (WBC count > 5/mcL [0.005×10^9/L]) often paired with elevated protein level (and a normal glucose concentration).

All individuals with suspected acute flaccid myelitis should be tested for enteroviruses (including D68 and A71) and rhinovirus from relevant anatomic sites. Testing for arboviruses, adenovirus, and herpesviruses should also be considered. All suspected cases should be reported to the state health department, the CDC, or both.

C. Imaging

MRIs of the brain and spinal cord should be accompanied by lumbar puncture. MRI typically shows disease of the central gray matter within the spinal cord in the location of the anterior horn cells.

Prevention

Three effective enterovirus-A71 vaccines have been licensed in China for children.

Treatment

No specific treatment exists for acute flaccid myelitis. Management consists of supportive care. Many adjunctive therapies have been used, including IVIG, high-dose corticosteroids, and plasmapheresis, but none have shown efficacy. Neurologists specializing in the management of acute flaccid myelitis can be contacted through the AFM Physician Consult and Support Portal at https://bit.ly/2Y2U3VR.

Long-term therapy during the convalescent phase should include physical therapy and any other necessary forms of physical rehabilitation.

OTHER NEUROTROPIC VIRUSES

1. Rabies

ESSENTIALS OF DIAGNOSIS

- History of animal bite.
- Paresthesias, hydrophobia, rage alternating with calm.
- Convulsions, paralysis, thick tenacious saliva.

General Considerations

Rabies is a viral (rhabdovirus) encephalitis transmitted by infected saliva that enters the body by an animal bite or an open wound. Worldwide, > 17 million cases of animal bites are reported every year, and it is estimated that about 59,000 deaths annually are attributable to rabies. Rabies is endemic in > 150 countries; it is estimated that > 40% of the world's population lives in areas without rabies surveillance. About 95% of cases of rabies occur in Africa and Asia. In low- and middle-income countries, > 90% of human cases and 99% of human deaths from rabies are secondary to bites from infected dogs. Rabies among travelers to rabies-endemic areas is usually associated with animal injuries (including dogs in North Africa and India, cats in the Middle East, and nonhuman primates in sub-Saharan Africa and Asia), with most travel-associated cases occurring within 10 days of arrival. Rabies-free areas include much of Western Europe, Australia, New Zealand, Japan, and Hawaii in the United States. A map outlining these areas is available on Wikimedia Commons (https://commons.wikimedia.org/wiki/File:Rabies_Free_Countries_and_Territories.svg).

In the United States, domestically acquired rabies cases are rare (approximately 90.4% of cases are associated with wildlife) but probably underreported. Reports largely from the East Coast show an increase in rabies among cats, with about 1% of tested cats showing rabies seropositivity. The annual caseload in the United States is 0–3 cases (https://www.cdc.gov/rabies/php/protecting-public-health/). The most recent case (pending public health report) occurred in Fresno, California after an art teacher was bitten by a bat. Between 1960 and 2018, 125 human rabies cases were reported in the United States. These included 36 cases (28%) with a history of dog bites during international travel. The remaining 89 cases (72%) were acquired in the United States, most often from bats.

Surveillance for animal rabies in 2022 showed 3579 animal and zero human cases occurring in 54 US jurisdictions. *Wild animals accounted for 90.4% of cases, and among wild animals, bats were the most common animal (34%), followed by raccoons (28.3%), skunks (18.4%), and foxes (7.5%).* Wildlife reservoirs, with each species having its own rabies variant(s), follow a unique geographic distribution in the United States: raccoons on the East Coast; skunks in the Midwest, Southwest, and California; and foxes in the Southwest and in Alaska. However, some areas have all three wildlife reservoirs (eg, the hill country of Texas). Rodents and lagomorphs (eg, rabbits) are unlikely to spread rabies because they cannot survive the disease long enough to transmit it (woodchucks and groundhogs are exceptions). Wildlife epizootics present a constant public health threat in addition to the danger of reintroducing rabies to domestic animals. Vaccination is the key to controlling rabies in small animals and preventing rabies transmission to human beings. Due to successful animal vaccination efforts, animal rabies cases are rarely seen in domestic animals in the United States. Greater than 90% of domestic animal cases are due to cats, dogs, and cattle.

The virus enters dogs' salivary glands 5–7 days before their death from rabies, thus limiting their period of infectivity. Less common transmission routes include contamination of mucous membranes with saliva or brain tissue, aerosol transmission, and corneal transplantation. Recognized mutations in rabies virus proteins can subvert the host immune system. Transmission through solid organ and vascular segment transplantation from donors with unrecognized infection is also reported. Some transplantation-associated cases are reported, including two clusters in the United States. Postexposure prophylaxis can be administered in these patients and may prevent development of disease.

The incubation period may range from 10 days to many years but is usually 3–7 weeks depending in part on the distance of the wound from the CNS. The virus travels via the nerves to the brain, multiplies there, and then migrates along the efferent nerves to the salivary glands. Rabies virus infection forms cytoplasmic inclusion bodies similar to Negri bodies. These Negri bodies are thought to be the sites of viral transcription and replication.

▶ Clinical Findings

A. Symptoms and Signs

While patients usually report an animal bite, bat bites may not be recognized. Median incubation period ranges from 60 to 71 days with high variability amongst individuals. The prodromal syndrome consists of pain at the site of the bite in association with fever, malaise, headache, nausea, and vomiting. The skin is sensitive to changes of temperature, especially air currents (aerophobia). Percussion myoedema (a mounding of muscles after a light pressure stimulus) can be present and persist throughout the disease. Abnormal sexual behavior is also a recognized presenting symptom of rabies; such behavior includes priapism and frequent ejaculation in men and hypersexuality in women.

The CNS stage begins about 10 days after the prodrome and may be either encephalitic ("furious") or paralytic ("dumb"). The **encephalitic form** (about 80% of the cases) produces the classic rabies manifestations of delirium alternating with periods of calm, extremely painful laryngeal spasms on attempting drinking (hydrophobia), autonomic stimulation (hypersalivation), and seizures. In the less common **paralytic form**, an acute ascending paralysis resembling Guillain-Barré syndrome predominates with relative sparing of higher cortical functions initially. Both forms progress relentlessly to coma, autonomic nervous system dysfunction, and death.

B. Laboratory Findings

Biting animals that appear well should be quarantined and observed for 10 days. Sick or dead animals should be tested for rabies. A wild animal, if captured, should be sacrificed and the head shipped on ice to the nearest laboratory qualified to examine the brain for evidence of rabies virus. *When the animal cannot be examined, raccoons, skunks, bats, and foxes should be presumed to be rabid.*

Direct fluorescent antibody testing of skin biopsy material from the posterior neck of the potentially infected animal (where hair follicles are highly innervated) shows high sensitivity and specificity. The latest guidelines are available from the CDC (https://www.cdc.gov/rabies/hcp/prevention-recommendations/post-exposure-prophylaxis.html).

Quantitative RT-PCR, nucleic acid sequence-based amplification, direct rapid immunohistochemical test, and viral isolation from the patient's CSF or saliva are advocated as definitive diagnostic assays. Pathologic specimens often demonstrate round or oval eosinophilic inclusion bodies (Negri bodies) in the cytoplasm of neuronal cells, but the finding is neither sensitive nor specific. MRI signs are diffuse and nonspecific.

▶ Prevention

Immunization of household dogs and cats and active immunization of persons with significant animal exposure (eg, veterinarians) are important. The most important decisions, however, concern animal bites. Animals that are frequent sources of infection to travelers are dogs, cats, and nonhuman primates.

In the developing world, education, surveillance, and animal (particularly dog) vaccination programs (at recurrent intervals) are preferred over mass destruction of dogs, which is followed typically by invasion of susceptible feral animals into urban areas. In some Western European countries, oral vaccination campaigns of wild animals led to the elimination of rabies in wildlife.

A. Local Treatment of Animal Bites and Scratches

Thorough cleansing, debridement, and repeated flushing of wounds with soap and water are important. Rabies immune globulin (RIG) or antiserum should be given as stated below. Wounds caused by animal bites should not be sutured.

B. Postexposure Immunization

The decision to treat should be based on the circumstances of the bite, including the extent and location of the wound, the biting animal, the history of prior vaccination, and the local epidemiology of rabies. *Any contact or suspected contact with a bat, skunk, or raccoon is usually deemed a sufficient indication to warrant prophylaxis (eg, observing a bat in your room upon awakening).* Consultation with state and local health departments is recommended. Postexposure treatment including both immune globulin and vaccination should be administered as promptly as possible when indicated.

For patients who had not received rabies vaccination before possible exposure, the optimal form of **passive immunization** is human RIG (HRIG), 20 IU/kg, administered once, although 2020 data from Côte d'Ivoire make its utility unclear. As much as possible of the full dose should be infiltrated around the wound, with any remaining injected intramuscularly at a site distant from the wound. Finger spaces can be safely injected without development of a compartment syndrome. Topical 2% lidocaine is shown to reduce the pain of injection. If HRIG is unavailable and appropriate tests for horse serum sensitivity are done, equine rabies antiserum (40 IU/kg) can be used.

Two vaccines containing inactivated rabies viruses are licensed for **active immunization** and available for use in humans in the United States: a human diploid cell vaccine (HDCV, Imovax) and a purified chick embryo cell vaccine (PCECV, RabAvert). Several postexposure prophylaxis strategies are recommended. The most commonly used one is the "abbreviated Essen" strategy, where either of the current vaccines is given as four intramuscular injections of 1 mL in the deltoid or, in small children, into the anterolateral thigh muscles on days 0, 3, 7, and 14 after exposure (the fifth dose at 28 days after exposure is no longer recommended except among immunosuppressed patients). Although not currently routinely recommended, some centers suggest serologic testing for all over age 70, as inadequate titer levels have been seen in up to 6.5% of patients in this age group after the recommended four-dose vaccine schedule, with appropriate levels reached after a fifth booster dose. The vaccine should not be given in the gluteal area due to suboptimal response. An alternative intramuscular vaccination strategy that takes only 1 week, with injections on days 0, 3, and 7 after exposure with a purified Vero cell rabies vaccine (PVRV, Verorab), was reportedly successful in achieving adequate neutralizing titers at days 14 and 28 in a study from Thailand; this vaccine is not available in the United States. Several new rabies vaccines remain in clinical trials, including replication-defective chimpanzee adenovirus vaccines (ChAd155-RG and ChAdOx2 RabG), an mRNA vaccine (CureVac CV7202), and a reformulated serum-free, highly purified rabies vaccine (PRV-NG2).

An alternative to RIG, a monoclonal antibody cocktail called SYN023, developed by a Taiwanese company with Chinese and American support, completed phase 3 in December 2022. It reduces RIG efficacy if given simultaneously with vaccination, and may moderate long-term immune response to vaccination. Studies from China support using recombinant human rabies antibody (NM57) as equal in efficacy to human rabies immunoglobulin (HRIG). A new monoclonal antibody, also from China, ormutivimab, was shown to be safe with less interference when given with a rabies vaccine and with fewer adverse reactions than RIG. It was recently proven to be noninferior to HRIG in a phase 3 trial.

The WHO supports an intradermal vaccination strategy using Verorab and the inactivated rabies virus vaccine Rabipur (an alternative formulation of the purified chick embryo cell) (0.1 mL per intradermal injection) for regions of the world where vaccine is in short supply. Either vaccine can be given at two sites on days 0, 3, 7, and 28. A review from 2019 confirms the suitability of Verorab for rabies prophylaxis. Verorab-NG (next generation) also is safe in children. A study of three human rabies vaccines used internationally (HDCV, PVRV, and PCECV) all show similar immunogenicity, although the HDCV shows fewer side effects.

Rabies vaccines and HRIG should never be given in the same syringe or at the same site. Allergic reactions to the vaccine are rare and include a report of sudden unilateral sensorineural hearing loss and immune thrombocytopenic purpura, although local reactions (pruritus, erythema, tenderness) occur in about 25% and mild systemic reactions (headaches, myalgias, nausea) in about 20% of recipients. Rare cases of postimmunization encephalitis have been reported. Intradermal vaccines appear to be better tolerated than intramuscular vaccines, especially among young children (while titers achieved with intramuscular vaccinations are higher, the titers achieved with intradermal vaccination are deemed sufficient for protection against clinical rabies). The vaccines are commercially available or can be obtained through health departments. Adverse reactions to HRIG seem to be more frequent in women and rare in young children.

In patients with history of past vaccination, the need for HRIG is eliminated (HRIG is in short supply worldwide), but postexposure vaccination is still required. The vaccine should be given 1 mL in the deltoid twice (on days 0 and 3). Neither the passive nor the active form of postexposure prophylaxis is associated with fetal abnormalities and thus pregnancy is not considered a contraindication to vaccination. Peripartum rabies transmission occurs but is rare. Neonates may also receive both forms of postexposure prophylaxis at birth.

The WHO has a program to eliminate dog-transmitted human rabies by 2030.

C. Preexposure Immunization

Preexposure prophylaxis with two doses of rabies vaccine administered intramuscularly has been officially endorsed by the CDC in 2022 based on recommendations from the Advisory Committee on Immunization Practices Rabies Work Group. Before 2022 a three-dose series was recommended for preexposure prophylaxis. Injections of human diploid cell vaccine (Imovax) or purified chick embryo cell vaccine (RabAvert) intramuscularly (1 mL on days 0 and 7) are recommended for preexposure prophylaxis. The Work Group also redefined the risk categories. The highest risk categories (1 and 2) include exposures that might be unrecognized and apply to laboratory personnel working with rabies virus diagnostics, persons who frequently perform necropsies, or those who handle bats. The recommendation to check the rabies antibody titers periodically following vaccination in these categories was upheld. Veterinarians, veterinary technicians, animal control officers, their students or trainees, and long-term travelers to remote areas in endemic countries were classified as risk category 3. Short-term travelers with no expected high-risk travel past 3 years after vaccination constitute risk category 4. Both category 3 and 4 are associated with only recognized exposures; checking serial titers for these persons is unnecessary because recognized exposures should always prompt evaluation for postexposure prophylaxis. For risk category 3, a one-time titer check during years 1–3 after a two-dose primary series and a booster vaccine is recommended if titer is < 0.5 IU/mL. Alternatively, preemptive booster vaccine without checking titer levels between day 21 and year 3 after two-dose primary vaccination can be considered.

Immunosuppressive illnesses and agents including corticosteroids and antimalarials—particularly chloroquine—may diminish the antibody response.

Among persons with temporary immunocompromising conditions, it is recommended when possible to delay the vaccination until the immunocompromising condition resolves; if it cannot be resolved or temporarily reserved then rabies vaccination can be administered. The antibody titer should be checked after 2–4 weeks following the completion of the two-dose vaccination. If the titer is < 0.5 IU/mL, a booster dose should be administered, followed by a subsequent titer check. Local or state public health authorities should be consulted for guidance if two boosters fail to elicit response.

Treatment & Prognosis

Management requires intensive care with attention to the airway, maintenance of oxygenation, and control of seizures. Universal precautions are essential. Corticosteroids are of no use. Once symptoms appear, survival is rare, and data are insufficient to provide estimate of success.

If postexposure prophylaxis (discussed below) is given expediently, before clinical signs develop, it is nearly 100% successful in disease prevention. There is one documented case of death from rabies in a patient who received appropriate postexposure prophylaxis; they had inadequate neutralizing antibodies on later testing, with attributable risk factors of age, monoclonal gammopathy of unknown significance, and metastatic prostate cancer. Once symptoms have appeared, death almost inevitably occurs after 7 days, usually from respiratory failure. Most deaths occur in persons with unrecognized disease who do not seek medical care or in individuals who do not receive postexposure prophylaxis. The very rare cases in which patients recover without intensive care are referred to as "abortive rabies."

When to Refer

Suspicion of rabies requires contact with public health personnel to initiate appropriate passive and active prophylaxis and observation of suspect cases. A set of guidelines to determine need for treatment based on type of exposure is available at the WHO website: https://www.who.int/newsroom/fact-sheets/detail/rabies.

When to Admit

- Respiratory, neuromuscular, or CNS dysfunction consistent with rabies.
- Patients with suspect rabies require initiation of therapy until the disease is ruled out in suspected animals, and this requires coordination of care based on likelihood of patient compliance, availability of inpatient and outpatient facilities, and response of local public health teams.

2. Arbovirus Encephalitides

ESSENTIALS OF DIAGNOSIS

- Acute febrile illness; rash may be present; stiff neck progressing to stupor, coma, and convulsions.
- Upper motor neuron lesion signs: exaggerated deep tendon reflexes, absent superficial reflexes, and spastic paralysis.
- CSF opening pressure and protein are often increased with lymphocytic pleocytosis.

General Considerations

The arboviruses are arthropod-borne viral pathogens carried by mosquitoes or ticks that produce clinical manifestations in humans. The **mosquito-borne pathogens** include: togaviruses, most of which are of the genus *Alphavirus,* including Eastern, Venezuelan, and Western equine virus (EEEV, VEEV, WEEV) encephalitis, chikungunya, and Mayaro virus; flaviviruses (West Nile, St. Louis encephalitis [the epidemiology of which shows a westward migration in the United States], Japanese encephalitis, Murray Valley encephalitis, dengue, Zika, yellow fever, and Rocio viruses); and orthobunyaviruses, including the California serogroup viruses (Jamestown Canyon [seen largely in northeastern states], La Crosse [seen primarily in the upper Midwest and mid-Atlantic], and Keystone viruses). The **tick-borne** causes of encephalitis include the flaviviruses Powassan virus (North American Northeast and Great Lakes), tick-borne encephalitis virus (Europe and Asia), and the Colorado tick fever reovirus. Only those viruses causing primarily encephalitis in the United States are discussed here. The most commonly encountered arboviruses from 2022 in the United States are West Nile virus (1132 cases, 91% of arboviral disease), Powassan virus (47 cases, 4%), St. Louis encephalitis (33 cases, 3%), La Crosse virus (22 cases, 2%), Jamestown Canyon virus (12 cases, 1%), and Eastern Equine encephalitis (1 case, < 1%). Neuroinvasive disease was widely prevalent among all reported arboviruses: West Nile (73%), Powassan (91%), St. Louis (82%), La Crosse (86%), Jamestown Canyon (92%), and Eastern Equine encephalitis (100%, n = 1). Overall cases of arboviral disease decreased from 2021 to 2022 by 59%, mainly due to a decrease in West Nile virus cases. St. Louis encephalitis and Powassan viruses were notable exceptions, both with historically high numbers in 2022. **West Nile virus** is the leading cause of domestically acquired arboviral disease in the United States. West Nile virus disease is a nationally notifiable condition. The states reporting the most neuroinvasive disease cases are California (162 cases), Colorado (131 cases), and New York (75 cases): 44% of national cases. Asymptomatic seroconversion is frequent, perhaps the norm, and is not reported.

Outbreaks with West Nile infection tend to occur between mid-July and early September (85% of cases). Climatic factors, including elevated mean temperatures and rainfall, correlate with increased West Nile infection. In Africa as of December 2022, at least 28 countries report isolating the agent among humans, animals, and vectors. West Nile virus circulates between mosquitoes (mainly *Culex* species) and birds. In cases of West Nile virus outbreak, infected birds develop high-level viremia that leads to substantial avian mortality and a high incidence of mosquito infection. Infected mosquitoes bite and infect humans and other mammals. However, humans and other mammals are "dead-end" hosts since they do not transmit the virus on to other biting mosquitoes (although new data suggest that white-tailed deer may play a role in West Nile virus and other arboviral circulation); only dengue and VEEV produce viremias high enough to allow continued transmission to other mosquitoes and ticks between humans and vectors. Human-to-human transmission is usually related to blood transfusion and organ transplantation. Since 2003, all blood donations in the United States are screened with nucleic acid amplification assays for West Nile virus. In an international series of 74 transfusion-transmitted arboviruses, West Nile virus was responsible for 57% of such transmissions.

Clinical Findings

A. Symptoms and Signs

West Nile virus infection has an incubation period of 2–14 days. The infection is symptomatic in about 20% of the cases and < 1% progress to neuroinvasive disease, including meningitis, encephalitis, and flaccid paralysis. The case fatality rate is 3–15% in symptomatic patients.

Symptoms include acute febrile illness, and a nonpruritic maculopapular rash is variably present. Meningitis is indistinguishable from other viral meningitis. West Nile virus encephalitis presents with fever and altered mental status. Other signs include tremors, seizures, cranial nerve palsies, Bell palsy, and other pathologic reflexes. Acute flaccid (poliomyelitis-like) paralysis, which is asymmetric and can involve facial and respiratory muscles, is a well-known complication and is less commonly seen with other arboviruses infection. West Nile virus can also present as Guillain-Barré syndrome with radiculopathy. The disease manifestations associated with West Nile virus infection are strongly *age-dependent*: the acute febrile syndrome and mild neurologic symptoms are more common in the young, aseptic meningitis and poliomyelitis-like syndromes are seen in middle-aged persons, and frank encephalopathy is seen more often in older adults. All forms of disease tend to be severe in immunocompromised persons in whom neuroinvasive manifestations and associated high mortality are more apt to develop. Other risk factors for development of neuroinvasive disease and increased mortality include Black race, diabetes, CKD, and hepatitis C virus infection.

Host genetic variation in the IFN response pathway is associated with both risk for symptomatic West Nile virus infection and increased likelihood of West Nile virus disease progression. Quasispecies intrahost variation is also documented for eastern equine encephalitis.

B. Laboratory Findings

The peripheral WBC count is typically normal. Usually, CSF lymphocytic pleocytosis is present, and polymorphonuclear cells predominate early. The diagnosis of arboviral encephalitides depends on serologic tests. For West Nile virus, an IgM capture ELISA in serum or CSF is almost always positive by the time the disease is clinically evident, and the presence of IgM in CSF indicates neuroinvasive disease. Documentation of a fourfold increase in acute/convalescent IgG titers is confirmatory for all arboviruses. Antibodies to arboviruses persist for life, and the presence of IgG in the absence of a rising titer of IgM may indicate past exposure rather than acute infection. Serologic tests are available commercially and through local and state health departments. Cross-reactivity exists among the different flaviviruses, so a plaque reduction assay may be needed to definitively distinguish between West Nile fever, St. Louis encephalitis, and others. PCR assays (available through state laboratories and the CDC) can detect viral RNA in serum, CSF, or tissue early after illness onset and may be particularly useful in immunocompromised patients with abnormal antibody responses. Blood products are best screened using nucleic acid assays. Brain MRI may reveal increased T2-weighted sequences with leptomeningeal, basal ganglia, thalamic, periventricular enhancement, or a combination of these.

Differential Diagnosis

Mild forms of encephalitis must be differentiated from aseptic meningitis, lymphocytic choriomeningitis, and nonparalytic poliomyelitis. A concurrent outbreak of West Nile and St. Louis encephalitis in 2015 in Maricopa County, Arizona, showed that distinguishing the two clinically may be difficult.

Severe forms of arbovirus encephalitides are to be differentiated from other causes of viral encephalitis (HSV, mumps virus, poliovirus or other enteroviruses, HIV), encephalitis accompanying exanthematous diseases of childhood (measles, varicella, infectious mononucleosis, rubella), encephalitis following vaccination or infection (a demyelinating type seen after rabies, measles, pertussis vaccination), toxic encephalitis (from drugs, poisons, or bacterial toxins such as *Shigella dysenteriae* type 1), Reye syndrome, and severe forms of stroke, brain tumors, brain abscess, autoimmune processes such as lupus cerebritis, and intoxications. In the California Encephalitis Project, anti-*N*-methyl-D-aspartate receptor (anti-NMDAR) encephalitis is a more common cause of encephalitis than viral diseases, especially in the young, with 65% of cases of encephalitis due to anti-NMDAR occurring among patients 18 or younger.

Complications

Bronchial pneumonia, urinary retention and infection, prolonged weakness, and pressure injuries may occur. Retinopathy occurs in 24% of patients with a history of West Nile virus infection and is associated with increased risk in those with encephalitis. Individuals with chronic symptoms after West Nile virus infection may show persistent kidney infection for up to 6 years with West Nile virus RNA present in urine; kidney infection may lead to progressive renal pathology.

Prevention

Mosquito avoidance (eg, repellents, protective clothing, and insecticide spraying) is effective prevention. Laboratory precautions are indicated for handling all these pathogens. No human vaccine is available for the arboviruses prevalent in North America, although an NIH-sponsored, phase 1, randomized clinical trial of a trivalent virus-like particle vaccine against EEEV, WEEV, and VEEV is underway. A chimeric live attenuated West Nile virus vaccine is tested in phase 2 clinical trials and is shown to be safe and immunogenic in healthy adults. No licensed treatment protects against the other arboviral encephalitis. Transfusion products should be assayed for arboviruses, particularly the West Nile virus.

Treatment

Although specific antiviral therapy is not available for most causative entities, vigorous supportive measures can be helpful. Some studies suggest improved outcomes with the use of IVIG enriched with West Nile virus antibody; however, a randomized, controlled trial of IVIG did *not* show a benefit. A host of agents are under development for the encephalitic arboviruses EEEV, VEEEV, and WEEV, and their conserved mechanisms of pathogenesis offer potential for broadly acting medications, with one leading candidate being CID15997213, a quinazolinone compound effective in vitro against VEEV and WEEV, but not EEEV.

Prognosis

Although most infections are mild or asymptomatic, the prognosis is always guarded, especially at the extremes of age. WEEV can be severely pathogenic in younger patients where mortality in those under 1 year of age is 90%, and EEV shows a case fatality rate of 30%, with up to 70% in some outbreaks. Most fatalities occur with neuroinvasive disease.

Most patients with non-neuroinvasive West Nile virus disease or West Nile virus meningitis recover completely, but a syndrome of fatigue, malaise, and weakness can linger for weeks or months. Patients who recover from West Nile virus encephalitis or poliomyelitis often have residual neurologic deficits. The recovery of persons with severe neurologic compromise may take 6 months or longer. The sequelae of West Nile virus infection include a poliomyelitis-like syndrome, cognitive complaints, movement disorders, epilepsy, and depression; and they may become apparent late in the course of what appears to be a successful recovery.

Another entity (nonprimary infection), characterized by elevated serum IgG, absent serum IgM, and occasional detection of West Nile virus RNA in blood or CSF, is associated with underlying psychiatric disorders, hospitalization during times not associated with peak West Nile transmission, fever, and increased in-hospital mortality.

The long-term prognosis is generally better for Western equine than Eastern equine or St. Louis encephalitis.

3. Japanese Encephalitis

ESSENTIALS OF DIAGNOSIS

- Most important vaccine-preventable cause of encephalitis in the Asia-Pacific region.
- The virus is transmitted by mosquitoes, especially *Culex* species.
- Wide symptom spectrum; most infections are asymptomatic.

General Considerations

Japanese encephalitis virus (JEV) is a flavivirus akin to those causing West Nile infection and St. Louis encephalitis. It is the most common cause of encephalitis in East Asia, with > 100,000 estimated annual cases and 25,000 annual deaths. JEV has 5 genotypes and largely occurs in East Asia and the Western Pacific (genotype III), but it has been identified in Europe in 2010, Africa in 2016, and recently Australia in 2021–2023 (genotype IV). It primarily affects children in endemic countries, but there has been an increase in cases among adults. Climate change, terrain modification, and altered human–animal interfaces are deemed responsible for these changes, as they are for many expanding viral diseases.

Most cases occur in the summer and late fall, although in tropical and subtropical areas transmission occurs throughout the year. Major outbreaks every 2–15 years often correlate with patterns of agricultural development. The virus is transmitted by mosquitoes, especially *Culex* species. Wading birds (such as herons) and pigs more commonly sustain the infection as reservoirs in nature, since the viremia in humans is transient and not usually high enough to sustain transmission. Travelers to major urban areas for < 1 month are at minimal risk for Japanese encephalitis. Transmission by blood transfusion is documented.

Clinical Findings

A. Symptoms and Signs

The median incubation period is 5–15 days. Most patients asymptomatically seroconvert. The 1% of patients in whom disease develops report sudden-onset headaches, nausea, and vomiting, followed by mental status changes, parkinsonian movement disorders, and in a smaller percentage, seizures, typically in children.

Japanese encephalitis most closely resembles St. Louis encephalitis and West Nile encephalitis, although epidemiologic data readily distinguish these infections in most instances. The clinical course is less severe in patients with a history of dengue virus infection. Myelitis with flaccid paralysis has been reported, as has Guillain-Barré syndrome, and dystonia.

B. Laboratory Findings and Diagnosis

The disease should be suspected in patients with symptoms of CNS infection who recently visited or reside in an endemic area.

Common laboratory abnormalities include leukocytosis, mild anemia, and hyponatremia. CSF typically has a mild to moderate pleocytosis with a lymphocytic predominance, slightly elevated protein, and normal glucose. MRI findings include T2/FLAIR and diffusion restriction in the thalamus, substantia nigra, and basal ganglia.

Diagnosis is confirmed by finding anti-JEV IgM in CSF or serum using ELISA. Definitive diagnosis requires a fourfold increase in virus-specific IgG confirmed by plaque reduction neutralization assay. Because of low levels of viremia in humans, RT-PCR is not recommended. A point-of-care simple diagnostic assay is needed. Serologic cross-reactivity is common with other flaviviruses (the viruses causing dengue, West Nile, and Zika infections).

In severe disease, brain imaging reveals thalamic lesions, with the hippocampus, midbrain, basal ganglia, and cerebral cortex affected to varying degrees.

Prevention

Using mosquito repellents; wearing long sleeves, long pants, and socks; and using air-conditioned facilities and bed nets are essential means of protection.

In the United States, formalin inactivated Vero cell culture-derived Japanese encephalitis vaccine (IXIARO) is licensed to prevent Japanese encephalitis in nonpregnant persons 2 months or older. Travelers who plan to spend > 1 month in endemic areas should receive the vaccine. Vaccine should also be considered for travelers who plan to spend < 1 month in endemic areas but are at increased risk for Japanese encephalitis (based on season, location, activities). Primary vaccination requires two doses administered 28 days apart, to be completed > 1 week before travel. A Japanese study shows efficacy of a microneedle patch vaccination with two doses 3 weeks apart. For adults, a booster dose is recommended in case of potential re-exposure or continued risk for infection if the primary series of the vaccine was administered > 7 years earlier.

At least eight effective types of vaccine against Japanese encephalitis are available worldwide, including inactivated mouse brain-derived vaccines, inactivated Vero cell-derived vaccines, live attenuated vaccines, and live recombinant (chimeric) vaccines. The live attenuated SA14-14-2 vaccine from China is becoming the vaccine most often used in endemic countries.

Antibodies persist for up to 7 years. The benefits of a third dose of the vaccine are established among Korean children. The risk of serious reactions, including potential encephalitis with live vaccines, is low and decreases with age. Rare reported neurologic reactions are not definitively associated with vaccination. The CV (ChimeriVax-JE, marketed as IMOJEV) vaccine is shown to be particularly safe in different studies. No studies exist detailing the safety of IXIARO in pregnant persons. Therefore, administering this vaccine to pregnant persons should be deferred, unless the risk of infection outweighs the risk of vaccine complications.

Treatment

Treatment is supportive, including antipyretics, analgesics, bed rest, and fluids. Corticosteroids may result in clinical improvement of opsoclonus-myoclonus syndrome. The extensive list of agents under study in clinical trials includes several traditional antiviral agents as well as other repurposed antimicrobials (IFN, ribavirin, minocycline, curcumin, pentoxifylline, amphotericin, ivermectin, and mycophenolate). The key role of the endoplasmic reticulum in Japanese encephalitis pathogenesis may direct future trials.

Prognosis & Complications

The case fatality rates have decreased from 26% in the 1960–1970s to < 20% since 2000. Just under half (46%) of survivors live normally, but 49% (with a wide range based on the studies, 3–86%) show neurologic sequelae. The sequelae include a variety of cognitive, neurologic, and psychiatric complications, including memory impairment and intellectual impairment in adults and children. Sequelae can persist at least 1–2 years after the acute infection. Opsoclonus myoclonus syndrome is rarely reported.

Severe complications appear to be associated with upregulation of certain inflammasome genes.

4. Tick-Borne Encephalitis

ESSENTIALS OF DIAGNOSIS

- Flaviviral encephalitis found in Eastern, Central, and occasionally Northern Europe and Asia.
- Transmitted via ticks or rarely ingestion of unpasteurized dairy products.
- Long-term neurologic sequelae in 2–25% of cases.
- Therapy is largely supportive.
- Prevention: vaccinate and avoid tick exposure and unpasteurized milk

General Considerations

Tick-borne encephalitis (TBE) is a flaviviral infection caused by TBE virus with three subtypes: **European**, **Siberian**, and **Far Eastern.** The principal reservoirs and vectors for TBE virus are ticks with small rodents as the amplifying host; humans are an accidental host. The vectors for most cases are *Ixodes ricinus* (European subtype) and *Ixodes persulcatus* (Siberian and Far Eastern subtype), but *Dermacentor reticularis* also is a vector. Infection results from tick bites during outdoor activities in forested areas (it is known to predominate in a “beech climate”), predominantly in the late spring through fall. Ingestion of unpasteurized milk from viremic livestock (goats, sheep, and cattle) is also a recognized mode of transmission. Transmission by transplantation of solid organs is reported, leading to fatal outcomes. TBE is endemic in certain parts of Europe (where its prevalence has been expanding in recent years), Asia (principally China but a few cases from Japan as well), and where a variety of subtypes extend beyond the original three (Western, Siberian, and Far Eastern). The WHO reports 10,000–12,000 cases per year, which is considered a gross underestimate, with the actual number of reported cases annually fluctuating significantly depending on surveillance, human activities, socioeconomic factors, ecology, and climate. The incubation period is 7–14 days for tick-borne exposures but only 3–4 days for milk ingestion.

Powassan virus is the only North American member of the tick-borne encephalitides. Its vector is several *Ixodes* ticks. Most cases occur in older men (majority over age 60; death occurred in 12% of cases), primarily from Northeast and North Central states (especially Minnesota, New York, and Wisconsin). It is also reported from Canada and Russia. Most reported cases are neuroinvasive with presentations including acute encephalitis and aseptic meningitis. The incubation period can range from 1 to 5 weeks, although pinpointing the date of actual exposure is often difficult. It is reportedly transmitted by renal transplantation.

Alkhurma hemorrhagic fever is also caused by a flavivirus first uncovered in Jeddah, Saudi Arabia, in 1995 and is re-emerging in the Middle East with occurrences in tourists to Egypt, Djibouti, and possibly India. Its extent of geographic distribution is unknown.

Clinical Findings

A. Symptoms and Signs

Most cases are subclinical, and many resemble an influenza-like syndrome with 7–10 (reported extreme range, 4–28) days of fever (usually with malaise, headache, and myalgias). In some cases, the disease is biphasic where the initial flu-like period is followed by a 1- to 21-day symptom-free interval followed by a second phase with fevers and neurologic symptoms (cases from Asia appear not to show this biphasic pattern). The neurologic manifestations range from febrile headache to aseptic meningitis and encephalitis with or without myelitis (preferentially of the cervical anterior horn) and spinal paralysis (usually flaccid). A myeloradiculitic form can also develop but is less common. Peripheral facial palsies, sometimes bilateral, tend to occur infrequently late in the course of infection, usually after encephalitis and generally are associated with a favorable outcome within 30–90 days. Acute myositis is rare but can be associated with severe disease. The main sequela of disease is paresis. Other causes of long-term morbidity include protracted cognitive dysfunction and persistent spinal nerve paralysis. Alimentary infection occurs within 3–4 days of ingesting unpasteurized milk and dairy products, is reported throughout Central Europe, occurs in family or small outbreaks, is commonly (38.9% incidence) biphasic with frequent nonsevere meningoencephalitis, and has a very high probability of recovery.

The **post-encephalitic syndrome** is characterized by headache, difficulties concentrating, balance disorders, dysphasia, hearing defects, and chronic fatigue. A progressive motor neuron disease and partial continuous epilepsy are complications. Longstanding psychiatric complications are reported and include attention deficits, slowness of thought and learning impairment, depression, lability, and mutism.

Mortality in TBE is usually a consequence of brain edema or bulbar involvement.

B. Laboratory Findings and Diagnosis

Leukopenia alternating with leukocytosis can be seen. Abnormal CSF findings include an inconsistent pleocytosis that may persist for up to 4 months. Hyponatremia is more commonly seen than with other viral encephalitides. Neuroimaging might show cerebral atrophy and hyperintense lesions in the thalamus, brainstem, and basal ganglia. In research studies, viral load correlates with disease severity in cases where the CNS is not involved.

The European Centre for Disease Prevention and Control has a case definition for diagnosis, split into possible, probable (clinical + probable laboratory criteria, *or* clinical criteria + epidemiologic link), and confirmed (clinical + confirmed laboratory criteria). Clinical criteria are any symptoms of CNS inflammation. Laboratory criteria for confirmation are any of the following five:

- Serum TBE IgM AND IgG
- CSF TBE IgM
- Fourfold increase or seroconversion of TBE antibodies in convalescent samples
- Viral nucleic acid detection in a clinical specimen
- Isolation of TBE virus from a clinical specimen

Laboratory criteria for a probable diagnosis is detection of serum TBE IgM antibodies only. Epidemiological criterion is exposure to a common source such as unpasteurized milk or ticks.

Note, when neurologic symptoms develop, the TBE virus is typically no longer detectable in blood and CSF samples. Cross-reactivity with other flaviviruses or a vaccinated state may require confirmation by detecting TBE virus-specific antibodies by plaque reduction neutralization tests.

Differential Diagnosis

The differential diagnosis includes other causes of aseptic meningitis, such as enteroviral infections; poliomyelitis (no longer reported from Eastern Europe); herpes simplex encephalitis; and a variety of tick-borne pathogens, including tularemia, the rickettsial diseases, babesiosis, Lyme disease, and other flaviviral infections. Coinfections are documented with *Anaplasma, Babesia*, and *Borrelia* infections.

Prevention

An inactivated, whole-virus vaccine (TicoVac; known as FSME-Immun in Europe) was approved for use in the United States in 2021 for adults and children. The vaccine is safe and effective and should provide cross-protection against all three TBE virus subtypes. The initial vaccination schedule requires three doses given over 6 or more months with booster 3 years after initial vaccination. Five other TBE vaccines licensed internationally are not available in the United States. Breakthrough TBE in vaccinated individuals is reported, especially among recipients > 50 years of age and those who are immunosuppressed, such as those receiving anti-TNF therapy or methotrexate, indicating the need for a modified immunization strategy in such patients. Data, based on an impaired immune response in older adults, support adding an extra booster vaccine dose for individuals age 50 years and older (with a schedule of 0–7–21–360 days). Neuritis and neuropathies of peripheral nerves (plexus neuropathy—paresis of lower limb muscles, polyradiculopathy) are recognized complications of TBE vaccination. The vaccine is indicated for those residing and traveling to endemic areas (and the disease is now extending to higher altitudes with climate change).

The low popularity of the vaccine in endemic countries is responsible for the limited ability to control the disease. When utilized, it is quite effective: a systematic review of 25 European countries from 2003–2023 (primarily looking at the FSME-IMMUN and Encepur vaccines) reported vaccine efficacy > 92%, with thousands of deaths prevented by vaccination. Other prevention recommendations include avoiding tick exposure and pasteurizing cow and goat milk.

Treatment

No specific antiviral treatment is available, and therapy is largely supportive. Recombinant antibody therapy is under development. Minocycline has reduced TBE viral levels in vitro, but clinical data are lacking.

Prognosis

The three subtypes of TBE have different prognoses. The European subtype is usually milder with up to 2% mortality and 30% neuroinvasive disease. The Siberian subtype is associated with 3% mortality and chronic, progressive disease. The Far Eastern subtype is usually more severe with up to 40% mortality and higher likelihood of neurologic involvement. All three subtypes are more severe among older adults compared with children. Coinfection with *Borrelia burgdorferi* (the agent of Lyme disease; transmitted by the same tick vector) may result in more severe disease. A European cohort showed increased odds of severe disease in patients with autoantibodies to type 1 IFNs, although only present in 10% of severe TBE cases. In cases without CNS involvement, the mean duration of illness is 7 days.

5. Lymphocytic Choriomeningitis

ESSENTIALS OF DIAGNOSIS

- "Influenza-like" prodrome of fever, chills, and cough, followed by a meningeal phase.
- Aseptic meningitis: stiff neck, headache, vomiting, lethargy.
- CSF: slight increase of protein, lymphocytic pleocytosis (500–3000/mcL [0.5–3.0 × 10^9/L]).
- Complement-fixing antibodies within 2 weeks.

General Considerations

The lymphocytic choriomeningitis virus is an arenavirus (related to the pathogen causing Lassa fever, discussed below) that primarily infects the CNS. Its main reservoir is the house mouse (*Mus musculus*), and the prevalence of LCM correlates with the expansion of rodents. Other rodents (such as rats, guinea pigs, porcupines, and pet hamsters), monkeys, shrews, dogs, and swine also are potential reservoirs. The infected animal sheds lymphocytic choriomeningitis virus in nasal secretions, urine, and feces; transmission to humans probably occurs through aerosolized particles and mucosal exposure, percutaneous inoculation, direct contact, or animal bites.

The disease in humans is underdiagnosed and occurs most often in autumn and early winter. The lymphocytic choriomeningitis virus is typically not spread person to person, although vertical transmission is reported, and it is considered to be an *underrecognized teratogen*. Rare cases related to solid organ transplantation and autopsies of infected individuals are also reported. All reported cases were donor-derived. Outbreaks are uncommon and usually occur in laboratory settings among those workers with significant rodent exposure.

The ubiquitous nature of its reservoir and the large distribution of the reported cases suggest a widespread geographic risk of lymphocytic choriomeningitis virus infection. Serologic surveys in the United States show significant variability in prior infection, from < 1% in New York to 3–5% in southern and eastern United States.

Clinical Findings

A. Symptoms and Signs

The incubation period is 8–13 days to the appearance of systemic manifestations and 15–21 days to the appearance of meningeal symptoms. Symptoms are biphasic, with a prodromal illness characterized by fever, chills, headache, myalgia, cough, and vomiting, occasionally with lymphadenopathy and maculopapular rash. After 3–5 days, the fever subsides only to return after 2–4 days along with the meningeal phase, characterized by headache, nausea and vomiting, lethargy, and variably present meningeal signs. Arthralgias can develop late in the course. Transverse myelitis, deafness, Guillain-Barré syndrome, and transient and permanent hydrocephalus are reported. Lymphocytic choriomeningitis virus is an increasingly recognized cause of congenital infection frequently complicated with obstructive hydrocephalus, periventricular calcifications, chorioretinitis, ventriculomegaly, and microcephaly. In fetuses and newborns with ventriculomegaly or other abnormal neuroimaging findings, screening for congenital lymphocytic choriomeningitis may be considered; mothers are asymptomatic half the time. In over one-third of cases, rodent exposure is reported retrospectively. Occasionally, a syndrome resembling viral hemorrhagic fevers is described in transplant recipients of infected organs and patients with lymphoma.

B. Laboratory Findings

Leukocytosis or leukopenia and thrombocytopenia may be initially present. During the meningeal phase, CSF analysis frequently shows lymphocytic pleocytosis (total count is often 500–3000/mcL [0.5–3.0 × 10^9/L]) with a slight increase in protein, while a low to normal glucose is seen in at least 25%. The virus may be recovered from the blood and CSF by mouse inoculation. Complement-fixing antibodies appear during or after the second week. Detection of specific IgM by ELISA is widely used. Detection of lymphocytic choriomeningitis virus by PCR is available in research settings.

Differential Diagnosis

The influenza-like prodrome and latent period may distinguish this from other aseptic meningitides, and bacterial and granulomatous meningitis. A history of exposure to mice or other potential vectors is an important diagnostic clue.

Prevention

Pregnant persons should be advised of the dangers to their unborn children inherent in exposure to rodents. Infection risk can be reduced by limiting contact with pet rodents and rodent trappings.

Treatment

Treatment is supportive. In several survivors of transplant-associated outbreaks, ribavirin (effective against other arenaviruses) has been used successfully along with decreasing immunosuppression. Ongoing studies are evaluating favipiravir and umifenovir, both anti-influenza agents. Favipiravir has been tried unsuccessfully in early COVID-19 infection, and umifenovir (unavailable in the United States) is used for influenza in Russia and China and has activity against several arenavirus infections. Its use in pregnancy also needs study.

Prognosis

Complications and fatalities are rare in the general population. The illness usually lasts 1–2 weeks, though convalescence may be prolonged. Congenital infection is more severe, with a ~30% mortality rate among infected infants, and > 90% of survivors suffer long-term neurologic abnormalities. Lymphocytic choriomeningitis in solid organ transplant recipients is associated with a poor prognosis; the mortality rate may exceed 80%.

6. Prion Diseases

ESSENTIALS OF DIAGNOSIS

- Rare in humans.
- Cognitive decline.
- Myoclonic fasciculations, ataxia, visual disturbances, pyramidal and extrapyramidal symptoms.
- Variant form presents in younger persons with prominent psychiatric or sensory symptoms.
- Specific EEG patterns.

General Considerations

The **transmissible spongiform encephalopathies** are a group of fatal neurodegenerative diseases affecting humans and animals. They are caused by proteinaceous infectious particles called **prions**. These agents show slow replicative capacity and long latent intervals in the host. They induce the conformational change ("misfolding") of a normal brain protein (prion protein; PrP[C]) into an abnormal isoform (PrP[Sc]) that accumulates and causes neuronal vacuolation (spongiosis), reactive proliferation of astrocytes and microglia, and, in some cases, the deposition of β-amyloid oligomeric plaques.

Prion disease can be hereditary, sporadic, or transmissible in humans. **Hereditary** disorders are caused by germ line mutations in the PrP[C] gene causing familial Creutzfeldt-Jakob disease (fCJD), Gerstmann-Sträussler-Scheinker syndrome, and fatal familial insomnia. Another uncommon hereditary disorder is PrP systemic amyloidosis.

Sporadic Creutzfeldt-Jakob disease (sCJD) is the most common of the human prion diseases, accounting for approximately 85% of cases; it has no known cause. Transmissible prion disease is described only for kuru and Creutzfeldt-Jakob disease in its **iatrogenic (iCJD)** and **variant (vCJD)** form. Iatrogenic transmission of CJD is associated with prion contaminated human corneas, dura mater grafts, pituitary-derived growth hormone, gonadotropins, stereotactic electroencephalography, electrodes, and neurosurgical instruments. A subset of cases with a history of neurosurgical intervention shows hyperintense thalamic lesions but no periodic sharp wave complexes on EEG (which may be a presymptomatic sign for most cases of sCJD). Abnormal prion proteins have been detected in the nasal mucosa and urine of patients with Creutzfeldt-Jakob disease, raising health concerns about the possibility of transmission.

Kuru, once prevalent in central New Guinea, is now rare, a decline in prevalence that started after the abandonment of cannibalism in the late 1950s.

More than 200 cases of vCJD (**bovine spongiform encephalopathy** [BSE] or "mad cow disease") were reported in the United Kingdom since the first documented cases there in the mid-1990s. It is far less common in North America, with only four cases reported in the United States (the last one in 2015) and two deaths in Canada from definite or probable vCJD. Of the US-reported cases, none are confirmed to have acquired the disease locally (two of them acquired the infection in the United Kingdom, one in Saudi Arabia, one possibly in a Middle Eastern or Eastern European country). The overall annual incidence of prion disease worldwide is approximately 1–2 persons per million and decreasing. Per European Union surveillance data, only 1 human case of BSE was observed in 2022 among 36 reporting countries. BSE is characterized by its bovine-to-human transmission through ingestion of meat from cattle infected with BSE. BSE does not spread from animal to animal, and milk and its derived products are not considered infectious. Reports of secondary transmission of vCJD due to blood transfusions from asymptomatic donors are reported in the United Kingdom.

A **chronic wasting disease** also due to a transmissible spongiform encephalopathic agent is increasing; occurs among deer, elk, and moose; and is reported from 26 states including most of Wyoming and parts of Colorado but present in the East and South as well. Although no cases of transmission to humans are documented, transmission in the laboratory to squirrel monkeys has occurred, and the CDC recommends refraining from killing bizarrely acting animals, not handling or eating roadkill, and wearing gloves when dressing wild game. Testing for the virus in game animals may be useful, but its efficacy is not established.

Clinical Findings

A. Symptoms and Signs

Both sCJD and fCJD usually present in the sixth or seventh decade of life, whereas the iCJD form tends to occur in a much younger population. Clinical features of these three forms of disease usually involve mental deterioration (dementia, behavioral changes, loss of cortical function) that is progressive over several months, as well as myoclonus and extrapyramidal (hypokinesia) and cerebellar manifestations (ataxia, dysarthria). Finally, coma ensues, usually associated with an akinetic state and less commonly decerebrate/decorticate posturing. Like iCJD, vCJD usually affects younger patients (averaging ~28 years), but the duration of disease is longer (about 1 year). The degree of organ involvement is often extensive, and the clinical symptoms are unique, mainly characterized by prominent psychiatric and sensory symptoms.

B. Laboratory Findings

CJD should be diagnosed in the proper clinical scenario, in the absence of alternative diagnoses after routine investigations. Abnormalities in CSF are subtle and rarely helpful. The detection of 14-3-3 protein in the CSF is helpful for the diagnosis of sCJD but not in vCJD and fCJD. Its sensitivity and specificity are widely variable among different studies and may be increased with use of tau protein assays. CSF detection of total PrP can differentiate CJD from atypical Alzheimer disease with 82% sensitivity and 91% specificity.

A blood-based assay and PCR in CSF may help diagnose vCJD with high specificity but 71% sensitivity. The assay as well as 14-3-3 protein assay and a "quaking induced conversion" assay are all available through referral laboratories. It is also recognized that the presence of a variant with low titers ("very low peripheral prion colonization") in peripheral tissue, including frequently biopsied tonsillar tissue, may be responsible for the underrecognition of vCJD. A skin biopsy, CSF sample, or nasal brushings using a prion "real-time quaking induced conversion" (RT-QuIC) is commercially available in some countries and may be the most sensitive diagnostic tool for sCJD, showing 89–92.9% sensitivity and 100% specificity.

The currently recommended diagnostic criteria for sporadic CJD include neuropsychiatric symptoms plus (1) RT-QuIC as described above, (2) detecting small amounts of CJVD-specific prion protein, and (3) clinically correlated diffusion-weighted images on MRI. The applicability of these assays beyond CJD is unknown and challenging to ascertain due to low case numbers.

CDC has guidelines for sCJD diagnosis (https://www.cdc.gov/creutzfeldt-jakob/hcp/clinical-overview/diagnosis.html). Definite sCJD requires neuropathologic diagnosis. A probable diagnosis can be assigned with a neuropsychiatric disorder plus positive RT-QuIC in the CSF or other tissues. A probable diagnosis can also be made in the presence of rapidly progressive dementia *and* two of four clinical features (myoclonus, visual or cerebellar signs, pyramidal/extrapyramidal signs, and akinetic mutism) *and* a positive laboratory assay (typical EEG, positive 14-3-3 CSF assay with duration < 2 years) *and* MRI hyperintensity in the caudate nucleus/putamen and/or at least two cortical regions (occipital, parietal, and temporal) on diffusion-weighted imaging or fluid-attenuated inversion recovery (FLAIR) imaging. In sCJD, the EEG typically shows a pattern of paroxysms with high voltages and slow waves, while the MRI is characteristic for bilateral areas of increased signal intensity, predominantly in the caudate and putamen. MRI findings of cortical and subcortical atrophy occur in both fast and slow progressors; the modality is more sensitive in patients < 80 years old (91.4% vs 67.8%). An MRI can improve early diagnosis of sCJD because clinical findings are often missed. When an experienced neuroradiologist or a prion disease expert reviews the MRI, diagnostic sensitivity of MRI for sCJD increases to 91%.

▶ Differential Diagnosis

Autoimmune encephalitis can have a similar clinical picture. High-titer autoantibodies (eg, to the NMDA receptor) in the CSF is consistent with autoimmune encephalitis. A presentation suggesting cerebrovascular accident can also be seen with sCJD, complicating the diagnostic profile.

▶ Treatment & Prevention

CJD does not have a specific treatment. Once symptoms appear, the infection invariably leads to death. Flupirtine (an analgesic medication) is sometimes useful in slowing the associated cognitive decline but does not affect survival. Antibodies against PrP are also proposed as a therapeutic strategy. Studies continue to identify epitopes for vaccine development, but no promising candidates currently exist.

Iatrogenic CJD can be prevented by limiting patient exposure to potentially infectious sources as mentioned above. Prevention of vCJD relies on monitoring livestock for possible infection. The American Red Cross does not accept blood donations from persons with a family history of CJD or with a history of dural grafts or pituitary-derived growth hormone injections.

The United States no longer defers blood donors with a history of transfusion in the United Kingdom—and Europe imports US plasms, exposing the inconsistency of some EU guidelines.

7. Progressive Multifocal Leukoencephalopathy (PML)

PML is a rare demyelinating CNS disorder caused by the reactivation of two polyoma viruses, the **JC virus** (John Cunningham virus or JCV) and, less commonly, the **BK virus** (associated with nephropathy). The JC virus usually causes its primary infection during childhood with about 80% of adults typically being seropositive. The virus remains latent in the kidneys, lymphoid tissues, epithelial cells, peripheral blood leukocytes, bone marrow, and possibly brain until *reactivation* occurs and symptoms become evident. This reactivation is usually seen in adults with impaired cell-mediated immunity, especially patients with AIDS (5–10% of whom develop PML), as well as those with idiopathic CD4 lymphopenia syndrome. Although the prevalence of PML is only ~0.56% in people living with HIV (PLWH) in general, they constitute anywhere from 43.7% to 84.8% of PML cases. It is also reported among those with lymphoproliferative and myeloproliferative disorders; in those with granulomatous, inflammatory, and rheumatic diseases (SLE and rheumatoid arthritis in particular); in those who have undergone solid and hematopoietic cell transplantation; and occasionally in those who have other medical states, including cirrhosis and kidney disease. Diagnostic criteria that use clinical, imaging, pathologic, and virologic manifestations of JCV are available from the American Academy of Neurology.

Medication-associated PML is described with the use of natalizumab, rituximab, infliximab, alemtuzumab, fingolimod, azathioprine with corticosteroids, cyclophosphamide, mycophenolate mofetil, dimethyl fumarate, and sphingosine 1–phosphate receptor modulators—as well as possibly the newer disease-modifying agents siponimod (for multiple sclerosis), ofatumumab (for leukemia), and a few other drugs. Natalizumab, a monoclonal antibody used in the treatment of multiple sclerosis, is associated with the risk of PML developing in 3–4 per 1000 treated patients, with the rate increasing with duration of therapy. The risk of clinical PML appears to increase up to 36 months of therapy and levels off thereafter. The mean interval between the use of a medication to the diagnosis of PML is 5.5 months. JCV is detected in the CSF of up to one-half of all patients treated with natalizumab. An immune reconstitution inflammatory state (IRIS) may follow cessation of natalizumab or other monoclonal antibody therapy, although the JCV presence and the residual neurologic deficits may not clear for years after therapy is stopped. The risk of developing PML associated with rituximab is at least 1 in 10,000 exposed patients with cases reported in various autoimmune conditions treated with rituximab (SLE, rheumatoid arthritis, multiple sclerosis). Although the exact relationship between latent JCV and frank PML remains unclear, higher JC viral loads are detected among immunosuppressed patients and among those who have HIV infection with lower CD4 cell counts.

PML is reported in patients without immunosuppression and the average age for the progressive neurodegeneration in such patients is 57.5, with a male predominance.

Clinical Findings

A. Symptoms and Signs

JCV causes lytic infection of oligodendrocytes in the white matter and symptoms presenting subacutely reflect the diverse areas of CNS involvement. Symptoms include altered mental status, aphasia, ataxia, hemiparesis or hemiplegia, and visual field disturbances. Seizures occur in about 18% and status epilepticus is seen with a particular PnP variant (E200K). Involvement of cranial nerves and the cervical spine is rare.

B. Laboratory Findings

Quantitative PCR for JCV in CSF is used to diagnose patients with compatible clinical and radiologic findings. Serum and urinary JCV PCR are not predictive of PML, and utilization is not recommended in routine clinical practice. An anti-JCV IgG was higher 6 months before diagnosis but was not predictive of PML in a cohort of patients living with HIV infection. Serum neurofilament levels are increased in natalizumab-treated patients with multiple sclerosis who develop PML compared with those who do not and may provide prognostic utility (specificity 67%, specificity 80%).

C. Imaging

MRI of the brain shows multifocal areas of white matter demyelination without mass effect or, usually, contrast enhancement. Lesions are more often bilateral than unilateral and subcortical U fibers are often reported. The findings may not be distinguishable from IRIS. Increased uptake of methionine with concomitant decreased uptake of fluorodeoxyglucose in PET may be helpful for diagnosis. In patients with HIV, a syndrome of cerebellar degeneration is described. Case reports attest to the variability of MRI findings and should not be relied upon solely for diagnosis.

Treatment & Prevention

There are no effective antiviral drugs against the JC virus. *Limiting the immunosuppressed state without inducing IRIS represents the mainstay of therapy for HIV-associated PML.* Treatment of HIV with ART reduces the incidence of PML, improves the clinical symptoms, reverses some of the radiographic abnormalities, and improves the 1-year mortality rate, regardless of baseline CD4 cell count. ART with enhanced CNS penetration has not seemed to have any benefit over other ART regimens in controlling PML. Immune recovery can induce worsening of the clinical picture in a few cases. Immune reconstitution syndromes do not alter mortality but are associated with a form of PML called **non-determined leukoencephalopathy** associated with a chemokine polymorphism. Significant neurologic sequelae to PML infections are the rule and deficits may persist for years. In the modern ART era, 1-year mortality has decreased to 22–38.2% and is even lower in those with CD4 > 50 cells/mcL at time of diagnosis (11%) and those with CD4 > 50 cells/mcL *and* no opportunistic infections at the time of diagnosis (4.5%).

Decreasing immunosuppression in patients without HIV but with PML (eg, patients with multiple sclerosis or those who have undergone transplant) is important. Cidofovir may be beneficial in non-HIV-related cases, while corticosteroids may be useful with immune reconstitution. Because the JCV infects cells through serotonin receptors, some clinicians recommend using risperidone and mirtazapine. Anecdotal reports show that premature stopping of natalizumab in multiple sclerosis may itself lead to IRIS states and that the combination of teriflunomide with IFN may hold PML symptoms in abeyance while allowing for control of underlying multiple sclerosis. Plasma exchange, which theoretically reduces the plasma level of agents associated with PML, may be useful in natalizumab-associated PML but is associated with a high risk of IRIS. In patients post-kidney transplantation, a preinduction regimen with IVIG and rituximab and transplantation with lymphocyte-depleted cells appears to reduce the risk of PML. Titers of JC antibody are not shown to significantly increase before clinical onset of PML in patients who have undergone solid organ transplantation.

Among patients with PML without any obvious immune impairment, treatment responses are reported with mirtazapine and IV pulse methylprednisolone, but in one series the mortality within months of initiating such therapy was 50%.

Programmed cell death protein (PD-1) inhibitor therapy (also known as "immune checkpoint inhibitor") were evaluated but in a meta-analysis of 35 articles, patients with PML associated with immunosuppressive therapy are less likely to respond to checkpoint inhibitors even though the PD-1 inhibitor pembrolizumab reduced JC viral load and increases CD4+ and CD8+ activity against the virus in a preliminary set of eight patients with PML with different predisposing conditions. In addition, allogeneic BK virus-specific T cells are useful in lowering JC viral load.

8. Human T-Cell Lymphotropic Virus (HTLV)

HTLV-1 and -2 are retroviruses that infect CD4 and CD8 T cells, respectively, where they persist as a lifelong latent infection. HTLV-1 infects an estimated 5–10 million individuals worldwide. It is endemic to many regions, including southern Japan, the Caribbean, much of sub-Saharan Africa, South America, Eastern Europe, and Oceania. The Caribbean basin and southwestern Japan historically show the highest prevalence of infection (4–37%, 13% of Caribbean pregnant women). Conversely, HTLV-2 is mainly found in native populations of South (1–58%), Central (8–10%), and North America (2–13%) as well as African Pygmy tribes. In some areas of Africa (eg, Malawi), HTLV-2 seroprevalence is higher than HTLV-1 seroprevalence.

In the United States, studies done on blood donors show a seroprevalence of HTLV-1 of 0.005% and HTLV-2 of 0.014%, a decline since the early 1990s. The virus is transmitted horizontally (sex), vertically (intrauterine, peripartum, and prolonged breastfeeding), and parenterally (injection drug use and blood transfusion). Hence, a higher prevalence is seen among persons who inject drugs. Coinfection with HIV-1 occurs (in < 5% in a series from Spain) but is likely underrecognized. Transmission via organ transplant has been reported. Disease may flare when biologic agents are used for rheumatoid conditions. HTLV-1 infection is associated with **HTLV-1 adult T-cell lymphoma/leukemia** (**ATL**) and **HTLV-1–associated myelopathy/tropical spastic paraparesis (HAM/TSP).** In contrast, HTLV-2 is significantly less pathogenic, with few reported cases of HAM/TSP and or other neurologic manifestations. The causative association of HTLV-1 with ATL, attributed to the virally encoded oncoprotein *tax*, is well established.

▶ Clinical Findings

A. Symptoms and Signs

The lifetime risk of developing ATL among HTLV-1 seropositive persons is estimated to be 3% in women and 7% in men, with an incubation period of at least 15 years. The mean age at diagnosis of ATL is 40–50 years in Central and South America and 60 years in Japan.

ATL clinical syndromes may be classified as chronic, acute (leukemic), smoldering, or lymphomatous. A primary cutaneous tumor is also described (with appearance ranging from papular lesions to exfoliative erythroderma) and shows a worse prognosis compared with the smoldering type. Clinical features of ATL include diffuse lymphadenopathy, maculopapular skin lesions that may evolve into erythroderma, periodontitis, a bronchoalveolar disorder, organomegaly, lytic bone lesions, and hypercalcemia. Opportunistic infections, such as *P jirovecii* pneumonia and cryptococcal meningitis, are common. Chronic infectious eczema is often associated with HTLV infection and in a review of chronic crusted scabies, 8.5% of cases were associated with HTL-1 infections.

HAM/TSP, associated with HTLV-1 and HTLV-2, develops in 0.3–4% of seropositive individuals and is more common in women and older individuals. Chronic inflammation of the CNS and spinal cord leads to intense and progressive motor weakness and symmetric spastic paraparesis, bilateral facial palsies, cognitive impairment, falls, nociceptive low back pain, and paraplegia with hyperreflexia. Bladder and sexual disorders (eg, dyspareunia, erectile dysfunction), sensory disturbances, and constipation are also common. Both viruses can also induce motor abnormalities, such as leg weakness, impaired tandem walk, and vibratory sensory findings, without overt HTLV-associated myelopathy.

Studies from Brazil show that a subset of chronically inflamed patients with HTLV-1 infections may be asymptomatic and are recognized as having an "intermediate syndrome" that may progress to full-blown myelopathy.

HTLV-1 seropositivity is associated with an increased risk of tuberculosis, *Strongyloides stercoralis* hyperinfection, crusted scabies, and infective dermatitis. Inflammatory states associated with HTLV-1 infection include arthropathy, recurrent facial palsies, polymyositis, uveitis, and sicca, but inconsistently Sjögren syndrome, vasculitis, cryoglobulinemia, infiltrative pneumonitis, and ichthyosis. Bronchioloalveolar carcinoma is more frequent in the presence of HTLV-1 infection. HTLV-1 is also associated with a bronchioloalveolar disorder with non-necrotizing granulomata.

HTLV-2 appears to cause a myelopathy that is milder and slower to progress than HAM. All-cause and cancer-associated mortality are higher among HTLV-2 seropositive patients.

HTLV-1/HIV coinfection is associated with higher CD4 cell counts and a higher risk of HAM.

B. Laboratory Findings

The peripheral smear can show atypical lymphoid cells with basophilic cytoplasm and convoluted nuclei (flower cells). The diagnostic standard is evidence of clonal integration of the proviral DNA genome into tumor cells. The identification of HTLV-1 antibodies supports the diagnosis. Serum neopterin levels may indicate disease activity. An HTLV-1 provirus load in peripheral blood mononuclear cells and CSF cells and an HTLV-1 proviral load are proposed as markers of HAM risk and progression. HTLV positivity is associated with erythrocytosis, lymphocytosis (HTLV-2), and thrombocytosis (HTLV-1). Viral load positivity is also a recognized pre-disease marker.

▶ Treatment, Prevention, & Prognosis

No vaccine or antiviral therapy exists to prevent and treat HTLV infections.

Management of ATL consists mainly of chemotherapy (such as CHOP and EPOCH regimens), followed by allogeneic stem cell transplantation. Immunotherapies are increasingly used, including monoclonal antibodies (eg, the anti-CCR4 inhibitor mogamulizumab, anti-CD25 agents), spleen tyrosine kinase and Janus kinase (JAK) inhibitors (eg, cerdulatinib and ruxolitinib), and PD-1/immune checkpoint inhibitors (eg, nivolumab). A chemotherapy regimen in Japan using eight different agents shows a higher response rate than traditional biweekly CHOP (40% versus 25%). A clinical trial is underway evaluating lenalidomide plus EPOCH (NCT04301076). Combination therapy with zidovudine and IFN-α may be helpful. Prophylaxis against infections is needed in ATL because patients show a profound immunodeficiency.

HAM is treated with a variety of immune-modulating agents (including corticosteroids) without consistent results. Modalities of therapy, none of which are uniformly accepted as a mainstay, include combination therapy with the antiretroviral raltegravir alone or in combination with zidovudine; IFN-α; and a combination of prednisolone, pegylated IFN, and sodium valproate; pentoxifylline, cyclosporine, and the retinoid tamibarotene. Small, uncontrolled studies suggest plasmapheresis improves gait and sensory disturbance among some patients and improves muscle pain with pulsed methylprednisolone. A Japanese trial showed that I-arginine may improve motor function.

Screening of the blood supply for HTLV-1 is required in many countries including the United States. HTLV-1 and HTLV-2 have significant serologic cross-reactivity, but PCR can distinguish the two. Improved assays to screen organ donors for HTLV-1 and -2 infections are needed. Antenatal screening and avoiding breastfeeding (where the virus can be transmitted) also are important preventive measures.

VIRAL HEMORRHAGIC FEVERS

1. Ebola Viral Disease (EVD)

ESSENTIALS OF DIAGNOSIS

- ▶ Early-stage EVD: a nonspecific febrile illness.
- ▶ Later stage EVD: severe GI symptoms, then neurologic symptoms and hypovolemic shock.
- ▶ Hemorrhagic manifestations are late-stage manifestations.
- ▶ Uveitis is prominent.
- ▶ Travel and contact history from an Ebola-affected country raise suspicion.
- ▶ Virus is detected via RT-PCR.

▶ General Considerations

Genus *Ebolavirus* is a single-stranded RNA virus in the Filoviridae family. Four different species of *Ebolavirus* have been identified to cause human disease. Fruit bats are possible reservoirs for *Ebolavirus*. Zoonotic transmission to humans occurs via contact with the reservoir or an infected primate. *Ebolavirus can continue to be transmitted among humans who have direct contact with infected body fluids.* To acquire EVD, the virus must enter the body via mucous membranes, nonintact skin, sexual intercourse, breastfeeding, or needlesticks. Traditional burial practices in some African communities (which entail considerable contact with the corpse) and unprotected direct care of persons with EVD are associated with highest transmission risk. *Ebolavirus* has been detected in semen up to 9 months after recovery from infection.

EVD has a 2–21-day incubation period. Prior to manifestation of symptoms, *Ebolavirus* is not transmissible. Even at symptom onset, the risk of transmission is low but increases over time.

Since the first simultaneous epidemic outbreak in 1976 in the Democratic Republic of Congo and South Sudan, > 20 outbreaks have occurred across West, Central, and East Africa. The estimated average case fatality rate is 60%. The outbreak between 2014 and 2016 was associated mostly with the Zaire Ebola virus, but a recent outbreak in South Sudan in 2022–2023 involved the re-emergence of the Sudan Ebola virus. Many cases and deaths in these countries occurred among healthcare workers. In the United States, 11 persons were treated for Ebola; most were healthcare workers who were evacuated to the United States, and 4 cases were diagnosed in the United States.

Clinical Findings

A. Symptoms and Signs

At symptom onset, **early-stage EVD** most typically presents as a nonspecific febrile illness. Along with fever, patients experience headaches, weakness, dizziness, malaise, fatigue, myalgia, and arthralgia. After 3–5 days, patients with **later stage EVD** may develop abdominal pain, severe nausea, vomiting, and diarrhea accompanying the febrile illness. This stage of the illness may continue for a week, during which time neurologic symptoms gain prominence. Encephalitis is commonly observed and manifested as confusion, slowed cognition, agitation, and occasional seizures. Hypovolemic shock develops in most patients, but hemorrhagic manifestations (GI bleeding, diffuse mucosal bleeding, conjunctival bleeding) develop in only 1–5% of patients. Respiratory symptoms are not typical for EVD, although interstitial pneumonia and respiratory failure are reported.

B. Laboratory Findings

During the first few days of symptoms, diagnosis may be made via several modalities, including antigen-capture ELISA, IgM ELISA, RT-PCR, or virus isolation. Blood samples obtained within the first 3 days of illness and tested by a molecular method should be repeated if results are negative and clinical symptoms and signs persist. RNA levels peak at a median of 7 days after illness onset. Later in the disease course or after recovery, IgM and IgG serologic tests may be sent. After about 10 days, IgM antibodies begin to develop, and, after approximately 2 weeks, an IgG antibody response develops. Postmortem diagnosis may be made using immunohistochemistry, RT-PCR, or virus isolation. The WHO recommends automated or semi-automated nucleic acid tests (NATs) of EDTA-anticoagulated whole blood from symptomatic patients for routine diagnostic management, and rapid antigen detection tests in areas where NATs are unavailable. Oral fluid can be used for diagnostics when blood collection is not possible. **Importantly, patient samples are extreme biohazard risks and should be handled accordingly using appropriate personal protective equipment.**

Given that filoviruses infect dendritic cells and then hepatocytes and renal cortical cells, laboratory findings typically include a low platelet count (and a thrombotic thrombocytopenic purpura syndrome has been postulated with the probable cause multifactorial), leukopenia, and transaminitis (AST > ALT). As nonspecific symptoms progress to a severe systemic inflammatory response, coagulopathy with evidence of platelet dysfunction and disseminated intravascular coagulopathy (DIC) often develops. Whether DIC is a common cause of bleeding has not yet been firmly established because clinical measurements of fibrinogen, prothrombin time, fibrin-split products, and platelets are not routinely taken in the communities where most outbreaks have occurred. Additional observed laboratory abnormalities include hypoalbuminemia, electrolyte imbalance, and increased serum creatinine level. Elevated BUN, AST, and creatinine upon presentation are associated with higher mortality.

Differential Diagnosis

The differential diagnosis varies with the stage of illness. Early-stage EVD is commonly mistaken for malaria, typhoid, and other viral illnesses. As GI symptoms develop, health providers should also consider viral hepatitis, toxins, leptospirosis, and rickettsial diseases. In later stage EVD, bacterial, viral, and parasitic illnesses, including cholera and, in children, rotavirus infection, can present with severe gastroenteritis and shock. Encephalitis must be differentiated from the confusion associated with uremia. Hemorrhagic manifestations raise suspicion for EVD but could be due to leukemia, thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, or DIC. Travel and contact history are crucial when considering the differential diagnosis in areas where Ebola is not endemic.

Complications

Hypovolemic shock and multiorgan failure are the most common complications of EVD. Hemorrhage can occur in late stages. Rhabdomyolysis is reported frequently and may explain many of the associated laboratory abnormalities. Coinfections with malaria or bacteria (or both) are important considerations and can occur before presentation and during treatment of EVD. The virus is known to persist in immunologically privileged sites, such as the CNS, eye, and testes; however, viral relapse is uncommon. Post-EVD musculoskeletal pain, headache, auditory symptoms including hearing loss, and ocular symptoms (uveitis being the most common ocular finding) may develop. EVD survivors exhibit high rates of neuropsychological long-term sequelae including depression, anxiety, insomnia, and PTSD.

Prevention

Risk reduction should focus on preventing wildlife-to-human transmission and reducing human-to-human transmission by surveillance, early detection and isolation of cases, contact tracing, containment measures (disinfection, hygiene, and sanitation), strict droplet and contact precautions in health care settings, and reduction of sexual transmission in Ebola survivors. The WHO recommends that *men avoid sexual activity or use barrier protection* during intercourse for 12 months from onset of symptoms or until their semen tests negative twice for Ebola virus.

The recombinant vesicular stomatitis virus (rVSV)-based vaccine expressing Z ebolavirus (ZEBOV) glycoprotein (rVSV-ZEBOV, marketed as Ervebo by Merck) is a live attenuated single-dose vaccine, effective in disease prevention as soon as 10 days from vaccine administration, and seems to generate a long-lived immune response. Side effects, such as fever, myalgia, chills, fatigue, headaches, and oligoarthritis, develop in most patients who received the vaccine. rVSV-ZEBOV was approved by the European Medicines Agency (EMA) the US FDA in 2019. A second vaccine, an adenovirus/vaccinia virus vector vaccine (marketed as Zabdeno-and-Mvabea), approved by the EMA in 2020, is a two-dose series of two different vaccines, Ad26.ZEBOV (replication-incompetent recombinant adenovirus 26 expressing the ZEBOV [Mayinga strain] glycoprotein) and MVA-BN-Filo (a nonreplicating modified vaccinia Ankara-Bavarian Nordic virus vector expressing the glycoproteins of Zaire and Sudan ebolaviruses, Marburg virus, and the nucleoprotein of Tai Forest virus), given about 8 weeks apart. This vaccine is undergoing clinical trials (eg, NCT02876328) and not considered appropriate for use in situations where immediate protection is needed, such as during an outbreak. Thus, in an outbreak setting, rVSV-ZEBOV is preferred.

The other two vaccines—Ad5EBOV (recombinant adenovirus type 5 vector-based vaccine, licensed by the Chinese National Medical Products Administration and currently undergoing a phase 2 clinical trial) and GamEvac-Combi (heterologous VSV and Ad-5-vectored vaccine, licensed for emergency use in Russia)—have completed phase 4 clinical trials. Data are yet to be published.

Risk stratification may be useful in deciding when and to whom to administer antiviral postexposure prophylaxis. A high-risk exposure is defined as penetrating sharps injury from used device or through contaminated gloves or clothing or direct contact with an infected patient (alive or deceased) or their bodily fluids with broken skin or mucous membranes such as eyes, nose, or mouth. The rVSV-ZEBOV vaccine was used in the setting of postexposure prophylaxis among healthcare workers and found to be effective. The vaccine-mediated immunity requires an average of 10 days to develop and might not be fast enough in certain cases to prevent infection.

The use of antiviral agents in postexposure prophylaxis is another alternative that, to date, also shows no clear survival benefit.

Treatment

Treatment is primarily supportive. Several studies have shown that *intravenous fluids can reduce the mortality rates to < 50%*. Despite the wide availability of oral rehydration salts, mortality is high, ranging from 25% to 90%. Almost all patients treated in the United States or Europe received intravenous fluids, electrolyte supplementation, and empiric antibiotic therapy. Invasive or noninvasive mechanical ventilation and continuous renal replacement therapy are necessary in many cases. This increased level of intervention likely contributed to the decreased mortality (19%) among these patients. Individual air-conditioned biosecure cubicles are preferred to the burdensome protective equipment used during the 2014 West African outbreaks, allowing more time spent with patients.

Two monoclonal antibody cocktails (Inmazeb [known as REGTN-EB3] and Ebanga [known as mAb114]) were approved for the treatment of infection with the *Zaire ebolavirus* species in adults and children by the United States in 2020. In 2022, the WHO published the first guidelines for treatment of EVD, making a strong recommendation for treatment with mAb114 or REGN-EB3 for patients with PCR confirmed EVD caused by *Zaire ebolavirus* species and neonates 7 days or younger born to mother with confirmed EVD caused by *Zaire ebolavirus*. The guidelines make a conditional recommendation *against* remdesivir or ZMapp use in those cases.

Aside from supportive treatment and experimental therapeutics, patients typically receive empiric antimalarial agents in endemic areas and broad-spectrum antibiotics.

Prognosis

Children under 5 years of age and adults older than 40 have a high risk of death from EVD. Pregnancy is a risk factor for severe illness and death. In the 2014–2016 outbreak, the average maternal mortality was 86%. Immunosuppressed patients had shorter incubation time, rapid progression of disease, and poor outcomes. A higher baseline viral load was a strong predictor of mortality. In general, poor overall medical care confers a poor prognosis. Among survivors, protective antibodies persist for at least 10 years.

When to Admit

Persons living in or returning from a country with high rates of Ebola transmission should be monitored for 21 days and admitted to a health care facility when symptoms meeting the WHO case definition of a suspected EVD case develop, in accordance with the screening protocol designated by the respective country's governmental health decision-making body.

2. Other Hemorrhagic Fevers

This diverse group of illnesses results from infection with one of several single-stranded RNA viruses (members of the families Arenaviridae, Bunyaviridae, Filoviridae, Flaviviridae, and Nairoviridae). Flaviviruses, such as the pathogens causing dengue and yellow fever, and Filoviridae, causing EVD, are discussed in separate sections.

Lassa fever is a rodent-associated disease caused by an Old World *arenavirus*. Rodents shed the virus in urine and droppings and transmit the virus to humans either by direct contact with these materials, ingestion, or inhalation of aerosolized particles. Lassa fever is mostly endemic in West Africa, where 100,000 to 300,000 cases and 5000 deaths are seen annually. Case fatality rates in hospitalized patients in West Africa are up to 50%. Other arenaviruses include the **Junín virus** (cause of Argentine hemorrhagic fever), the **Machupo virus** (cause of Bolivian hemorrhagic fever), the **Chapare virus** (cause of Chapare hemorrhagic fever, which also occurs in Bolivia), the **Guanarito mammarenavirus** (GTOV; cause of Venezuelan hemorrhagic fever), the **Brazilian mammarenavirus** (cause of Brazilian hemorrhagic fever), and the **Lujo virus**.

The **bunyavirus hemorrhagic fevers** include hantaviruses (discussed separately), Crimean-Congo hemorrhagic fever, Rift Valley fever, and several newly emerging viruses such as one that causes severe fever with thrombocytopenia syndrome.

Crimean-Congo hemorrhagic fever (CCHF) is transmitted from ticks and livestock. Human-to-human transmission can occur in the community or hospital setting by contact with infected body secretions. The geographic distribution is widespread with cases reported from Africa, Asia, the Middle East, Eastern Europe, particularly the East Mediterranean region.

Rift Valley fever is transmitted from livestock animals, infected mosquitoes, and flies. No human-to-human transmission is reported. Risk factors for acquiring Rift Valley fever include working with abortive animal tissue; slaughtering, skinning, or sheltering animals; and drinking unpasteurized milk. Rift Valley fever causes outbreaks in Africa and, more recently, the Arabian Peninsula.

A new bunyavirus was identified in 2009 in central and northeastern China and was named for its symptoms: **severe fever with thrombocytopenia syndrome (SFTS)** virus. SFTS is transmitted by tick bite (Ixodidae family, including the tick *Haemaphysalis longicornis,* which is found in Asia and among animals [rarely humans] in the eastern United States). It may also be transmitted between humans through direct contact with infected blood or secretions. Another virus (**Heartland virus**), identified in the United States, is similar to the SFTS virus. Transmission occurs via the Lone Star tick (*Amblyomma americanum*). The virus appears to be amplified in deer and raccoons. In the United States, most cases are reported from the Midwest and southern states. More recently a novel *orthonairovirus*, named **Songling virus** (SGLV), was identified in northeastern China. SGLV causes a febrile illness often associated with headache and is likely transmitted by ticks.

Oropouche virus, belonging to *Orthobunyavirus,* was first detected in 1955 in a village called Vega de Oropouche in Trinidad and Tobago. It is spread primarily by the bite of infected midges and some mosquitos. One case report from Italy describing a traveler from Cuba discussed higher levels of Oropouche viral RNA in semen, raising concern for human-to-human transmission via sexual encounters. Most outbreaks have been identified in areas within the Amazon Basin and recently in 2024 have affected new regions in South America including Cuba, the Dominican Republic, and Guyana.

Clinical Findings

A. Symptoms and Signs

The incubation period varies between species, ranging from 2 to 21 days. The clinical symptoms in the early phase of a viral hemorrhagic fever are indistinguishable from other viral illnesses. Due to lack of specific symptoms on presentation, viral hemorrhagic fevers are an important cause to consider in fever of unknown origin in children in endemic areas. The late phase is more specific and is characterized by organ failure, altered mental status, and hemorrhage. Exanthems and mucosal lesions can occur.

In advanced stages, significant edema, pleural effusion, and fewer hemorrhagic manifestations compared with EVD can develop in patients with Lassa fever and Lujo virus infection. Hearing loss in various degrees is the most common complication of Lassa fever infection. Mortality in pregnant patients during the third trimester and fetal mortality are very high.

CCHF has more prominent hemorrhagic manifestations. Patients have red eyes, flushed face, red throat, and petechiae that progress to severe uncontrollable bleeding. Severe headaches are common in CCHF and correlate with the severity of vascular damage, vasodilatation, and cytokine release.

Rift Valley fever disease can present with three distinct syndromes: (1) ocular disease; retinitis is the most common complication and permanent vision loss develops in 1–10% of patients; (2) meningoencephalitis occurs in < 1% of cases; these patients have headache, coma, or seizures 1–4 weeks after initial symptoms and a low mortality but a high morbidity with neurologic deficits that can be severe; and (3) hemorrhagic fever; patients present 2–4 days after illness and show evidence of severe liver impairment and later hemorrhages; the hemorrhagic state occurs in < 1% of patients, but the case fatality ratio of such patients reaches about 50%.

The Oropouche virus disease typically presents with abrupt onset of fever, severe headaches, chills, myalgia, and arthralgia and less commonly has hemorrhagic symptoms with epistaxis, gingival bleeding, melena, menorrhagia, and petechiae. About 4% of patients can develop neurologic symptoms with meningitis and encephalitis. The Pan American Health Organization (PAHO) issued an alert on July 17, 2024, about vertical transmission of the Oropouche virus with adverse pregnancy outcomes in Brazil.

B. Laboratory Findings

Laboratory features usually include thrombocytopenia, leukopenia (although with Lassa fever leukocytosis is noted), anemia, elevated liver biochemical tests, and abnormalities consistent with DIC.

Special care should be taken when handling clinical specimens of suspected cases. Laboratory personnel should be warned about the diagnostic suspicion, and, in the United States, the CDC should be contacted for guidance. The diagnosis may be made by PCR, antigen detection (by ELISA), or demonstration of a fourfold rise in antibody titer. Lassa virus can be cultured from blood, urine, or throat swabs; however, isolation of the virus in culture requires a biosafety level 4 laboratory. CCHF is best diagnosed with RT-PCR, but ELISA or antigen detection test also can be used. Serologic assays may produce early false-negative and late false-positive results.

Differential Diagnosis

The differential diagnosis for hemorrhagic fever includes meningococcemia or other septicemias, rickettsial infection, dengue, typhoid fever, and malaria. SFTS differential diagnosis includes anaplasmosis, hemorrhagic fever with renal syndrome, or leptospirosis. The likelihood of acquiring hemorrhagic fevers among travelers is low.

Treatment & Prevention

Patients should be placed in private rooms with standard contact and droplet precautions. Barrier precautions to prevent contamination of skin or mucous membranes should also be adopted by health care providers. Airborne precautions should be considered in patients with significant pulmonary involvement or undergoing procedures that stimulate cough.

Supportive care is the mainstay of therapy. No antiviral medication is approved for use against Lassa virus, but ribavirin may reduce mortality if administered early in the course. An RCT comparing ribavirin and favipiravir has been completed in West Africa; data will be published soon. A small-molecule antiviral called LHF-535 is being developed to treat Lassa fever and other arenaviruses.

Convalescent plasma is routinely used to treat patients with Argentine hemorrhagic fever.

Postexposure prophylaxis with ribavirin in the management CCHF appears to be effective; however, little data exist to support its efficacy for Lassa fever and other arenaviruses. The antitrypanosomal agent suramin may be effective against the Rift Valley fever virus. Sorafenib, a tyrosine kinase inhibitor approved for treatment of renal cell and HCC, has antiviral activity against Rift Valley fever virus. A combination of monoclonal antibodies that cross-react with the glycoproteins of Lassa virus has been tested in macaques with promising results.

An inactivated vaccine has been developed for Rift Valley fever but is not licensed or commercially available. No vaccines are approved for other viruses causing viral hemorrhagic fever. Several vaccines have been developed for Lassa virus but only three have entered clinical trials. A one-dose Lassa virus vaccine consisting of a measles vector simultaneously expressing LASV glycoprotein and nucleoprotein and a DNA-based vaccine (MV-LASV) completed a phase 1 clinical trial. A third vaccine (rVSVΔG-LASV-GPC) has shown promising protective efficacy in primates, and phase 2 trials in humans in West Africa are underway (NCT05868733).

The main method of preventing Rift Valley fever is vaccinating susceptible livestock before outbreaks occur. Several vaccines have been developed for Rift Valley fever control in livestock, but only one, the Smithburn vaccine (a live attenuated virus), is produced commercially and used in East Africa. An inactivated vaccine has been developed for humans but is neither licensed nor commercially available. A newer vaccine, ChAdOx1, completed a phase 1 clinical trial in healthy adults conducted in the United Kingdom (NCT04754776) and now is being investigated for phase 1b trial in Uganda.

When to Admit

- Persons with symptoms of any hemorrhagic fever and who have been in possible endemic areas should be isolated for diagnosis and symptomatic treatment.
- Isolation is particularly important because diseases due to some of these agents, such as the Lassa virus, are highly transmissible to healthcare workers.

Raabe V et al. Lassa virus infection: a summary for clinicians. Int J Infect Dis. 2022;119:187. [PMID: 35395384]

3. Dengue

ESSENTIALS OF DIAGNOSIS

- Incubation period 7–10 days.
- Sudden onset of high fever, chills, severe myalgias and arthralgias, headache, and retroorbital pain.
- Severe dengue is defined by the presence of plasma leakage, hemorrhage, or organ involvement.
- Signs of hemorrhage such as ecchymoses, GI bleeding, and epistaxis appear later in the disease.

General Considerations

Dengue virus belongs to the genus *Flavivirus* and has four distinct serotypes (considered distinct viruses by some virologists) that can cause infection. Infection with one serotype does not confer immunity to the other serotypes. Dengue is transmitted primarily from human to human by the bite of the *Aedes* mosquito. Healthcare-associated transmission (needlestick or mucocutaneous exposure) and vertical transmission occur rarely. Transmission via bone marrow and solid organ transplant is also known to occur. The WHO reports that dengue is endemic in 128 countries, mostly in tropical and subtropical regions with > 3 billion persons at risk for infection. *An estimated 100–400 million cases of dengue fever occur annually.* Case numbers have increased over the last two decades; this surge of cases is associated with climatic factors, travel, and urbanization. Thus, along with malaria, *dengue is one of the two most common vector-borne diseases of humans.* Dengue is also the *second overall cause of a febrile illness (after malaria and excluding common upper respiratory viral infections) in travelers returning from low- and middle-income countries.*

Most dengue cases occur in Asia (about 70% of cases) and Latin America. As of November 2024, > 14 million cases have been reported globally. The most reported cases in 2024 are from the Americas, particularly Brazil (9.8 million), followed by Argentina, Mexico, Colombia, and Paraguay. Dengue cases were also reported from Asia (India, Bangladesh, Afghanistan, Cambodia, China, Iran, Laos, Malaysia, Nepal, Pakistan, the Philippines, Saudi Arabia, Singapore, Sri Lanka, Thailand, and Vietnam) and Africa (Burkina Faso, Cameroon, Cabo Verde, Central African Republic, Chad, Cote d Ivoire, Ethiopia, Ghana, Guinea, Kenya, Mali, Mauritius, Niger, Nigeria, Sao Tome and Principe, Senegal, Sudan, and Togo) in 2024. For Europe in 2024, cases were reported in Italy (213), France (83), and Spain (8).

Dengue has been a nationally notifiable condition in the United States since 2010. Even though dengue is endemic in Northern Mexico and the *Aedes* mosquito is common in the southern states, outbreaks are uncommon in the continental United States. Locally acquired dengue cases have been reported in Florida, California, Texas, and Arizona. Most cases occur in travelers, immigrants, or inhabitants of US territories that are endemic to the dengue virus. Puerto Rico experiences periodic large outbreaks, as did Hawaii in 2015 and 2016. As of November 27, 2024, 5151 dengue cases were reported in the United States and territories (4957 reported from Puerto Rico and 764 reported from Florida).

The incubation period is usually 7–10 days. When the virus is introduced into susceptible populations, usually by viremic travelers from endemic countries, epidemic attack rates range from 50% to 70%.

Clinical Findings

A. Symptoms and Signs

A history of travel to a dengue-endemic area within 14 days of symptom onset helps establish a diagnosis. Most infected patients are asymptomatic. Only 20% develop symptoms ranging from mild disease (**dengue fever**) to severe hemorrhagic fever to fatal shock (**dengue shock syndrome**). In 1997 the WHO classified symptomatic dengue into dengue fever, dengue hemorrhagic fever, and dengue shock syndrome. The 2009 WHO classification of dengue is the following: dengue without warning signs; dengue with warning signs; and severe dengue. This classification was criticized for lacking clarity and mixing distinct disease phenotypes within each category and was not adopted by all countries.

After the incubation period, the febrile phase can begin abruptly with nonspecific symptoms, high fever, chills, facial flushing, malaise, retroorbital eye pain, generalized body pain, and arthralgia. Some patients might have maculopapular rash, sore throat, and conjunctival injection. Not all patients have all symptoms or fever. Mild hemorrhagic manifestations can be seen. Most patients will recover, and fever is usually cleared by day 8.

A subset of patients, especially those with suboptimally controlled type 2 diabetes and/or obesity, and more commonly with serotype 2, may progress to severe dengue, which is defined by the presence of plasma leakage, hemorrhage, or organ involvement. Hematocrit increase may be the earliest sign and an indicator of the severity of plasma leakage. Pleural effusion and ascites can develop and may be detected by lateral decubitus CXR or ultrasound before clinical detection. Increasing liver size, persistent vomiting, and severe abdominal pain are indications of plasma leakage. Signs of hemorrhage such as ecchymoses, GI bleeding, and epistaxis appear. Severe organ involvement may develop, such as hepatitis, encephalitis, and myocarditis.

Shock develops in patients when a critical volume of plasma is lost through leakage. Decrease in the level of consciousness, hypothermia, hypoperfusion resulting in metabolic acidosis, progressive organ impairment, and DIC leading to severe hemorrhage should raise concern for shock. AKI in dengue largely occurs with shock syndrome and shows a high mortality.

B. Laboratory Findings

Leukopenia is characteristic, and elevated transaminases are found frequently in dengue fever. Thrombocytopenia, fibrinolysis, and hemoconcentration occur more often in the hemorrhagic form of the disease. In other forms of disease, especially in children, anemia is more common. The ESR is normal in most cases.

The nonspecific nature of the illness mandates laboratory verification for diagnosis, usually with IgM and IgG ELISAs after the febrile phase. Virus is recovered from the blood by PCR or detection of the specific viral protein NS1 by ELISA or rapid test during the first few days of infection. Immunohistochemistry for antigen detection in tissue samples and dried blood spots can also be used. Thrombocytopenia and blood vessel fragility in remote settings can be assessed with a tourniquet test. General evaluation recommendations include testing for infecting serotype and monitoring platelet count and serum albumin, AST, and ALT during the febrile phase of illness to monitor for development of severe disease.

Differential Diagnosis

Distinguishing between dengue and other causes of febrile illness in endemic areas is difficult. Fevers due to dengue are more often associated with neutropenia and thrombocytopenia and with myalgias, arthralgias/arthritis, and lethargy among adults. Rickettsial diseases may have a similar presentation but can often be distinguished by differences in epidemiology and cutaneous manifestations. Chikungunya is distinct in that it is more apt to cause chronic arthritis. The arboviral encephalitides require additional epidemiologic information and serologic data to make the diagnosis. Influenza and malaria are easily confused early in disease, although rhinitis and malaise should help distinguish influenza, and the cyclicity of fevers and presence of splenomegaly should suggest malaria.

Complications

Usual complications include pneumonia, bone marrow failure, hepatitis, iritis, retinal hemorrhages, and maculopathy, orchitis, and oophoritis. Neurologic complications (such as encephalitis, Guillain-Barré syndrome, phrenic neuropathy, subdural hematoma, cerebral vasculitis, and transverse myelitis) are less common. Acute disseminated encephalomyelitis has been linked with infection and the live dengue vaccine. Bacterial superinfection can occur. Oral complications include acute gingivitis, palatal bleeding, tongue plaques, xerostomia, and rarely osteonecrosis of the jaw.

Maternal infection poses a risk of hemorrhage in both the mother and the infant if infection occurs near term. Severe dengue is a risk factor for obstetric complications, cesarean delivery, fetal distress, and maternal morbidity.

Prevention

Preventive measures should be encouraged, such as control of mosquitoes by screening and insect repellents including long-lasting insecticides, particularly during early morning and late afternoon exposures. Screening blood transfusions for dengue is important, especially in endemic areas.

Dengvaxia (CYD-TDV), a recombinant, live, attenuated, tetravalent dengue vaccine, is FDA-approved for children 9–16 years old with previous history of dengue infection and who live in endemic areas. Dengvaxia trials reported overall 56% efficacy; however, efficacy was lower in younger age groups, and those infected with dengue serotype 2. The vaccine is given as a 0-, 6-, and 12-month series, although a two-dose schedule is likely efficacious. Serious side effects were no more common than in placebo recipients. Vaccination is indicated for those between ages 9 and 45 years. However, Dengvaxia carries an increased risk of severe dengue in those who experience their first natural dengue infection after vaccination (those who were seronegative at the time of vaccination). Thus, the WHO recommends limiting the vaccine to those who have had at least one dengue infection prior to vaccination and, for countries considering using Dengvaxia as part of their dengue control program, recommends pre-vaccination screening using dengue serology. Pregnant persons and immunosuppressed persons should *not* be vaccinated.

Another live tetravalent dengue vaccine, Takeda's two-dose TAK-003, completed phase 3 clinical trials with 3 years of follow-up and showed cumulative efficacy of 62.0% against symptomatic dengue cases and 83.6% efficacy against hospitalized dengue cases, without significant safety concerns. Importantly, TAK-003 has efficacy against all four dengue serotypes in children 4–16 years old living in endemic countries who are seropositive at baseline and against serotypes 1 and 2 in children who are seronegative at baseline.

Treatment

No specific therapeutic options are available for the clinical management of dengue besides supportive care. Treatment entails the appropriate use of volume replacement, blood products, and vasopressors. Acetaminophen is recommended for analgesic and antipyretic treatment. NSAID usage should be minimized and preferably avoided to decrease the risk of gastritis and bleeding, particularly in patients with a predilection for hemorrhage or with abnormalities in platelets, liver function, or clotting factors.

Platelet counts do not usefully predict clinically significant bleeding. Platelet transfusions may be considered for severe thrombocytopenia (< 10,000/mcL [10.0×10^9/L]) or for patients who are bleeding. Benefit in the absence of bleeding, however, may not be observed, and harm may be caused by delay in count recovery. Monitoring vital signs and blood volume may help anticipate the complications of dengue hemorrhagic fever or shock syndrome.

Repurposed medications, such as chloroquine, statins, and balapiravir, have *not* shown clear therapeutic benefit. Research is focusing on monoclonal antibodies as a therapeutic option as well as medications, including peptide agents that target structural and nonstructural proteins of dengue virus essential to its replication.

Prognosis

Although fatalities occur with severe disease, the estimated mortality (2.5% of severe cases) appears to be diminishing, likely due to improved recognition of the disease and wider availability of supportive treatment. Causes of death include hemorrhagic fever (seen with recurrent disease) and occasionally fulminant hepatitis. Thrombocytopenia and acute hepatitis are predictors of severe dengue and higher mortality. AKI in dengue shock syndrome portends poor prognosis. In general, the more severe forms of disease (hemorrhagic fever and shock) occur more often in Asia than in the Americas. Comorbidities of CVD, diabetes, stroke, pulmonary disease, kidney disease, and older age are associated with more severe dengue.

4. Hantaviruses

ESSENTIALS OF DIAGNOSIS

- Transmitted by rodents and cause two clinical syndromes.
- **Hemorrhagic fever with renal syndrome (HFRS):** mild to severe illness.
- **Hantavirus pulmonary syndrome (HPS):** 40% mortality rate.

General Considerations

Hantaviruses are enveloped RNA bunyaviruses naturally hosted in rodents, moles, and shrews. Globally, hantaviruses infect > 200,000 persons annually, and their collective mortality rate is about 35–40%. Hantavirus infection in humans can cause several disease syndromes. HFRS is primarily caused by Old World hantaviruses, namely Dobrava-Belgrade virus, Puumala virus, Seoul virus, and Hantaan virus in Asia and Europe. *Nephropathia epidemica* is a milder form of HFRS. Puumala virus is the most prevalent pathogen and is present throughout Europe. The HPS, also known as hantavirus cardiopulmonary syndrome, is caused mainly by Sin Nombre virus and Andes virus, the New World Hantaviruses in the Americas. While they share many clinical features, a specific strain is not associated with a specific syndrome and overlap is seen between the syndromes. The primary reservoirs include the field mouse for Hantaan virus HFRS, the bank vole for Puumala virus, and the deer mouse for SNV-HPS.

Aerosols of virus-contaminated rodent urine and feces are thought to be the main vehicle for transmission to humans. Person-to-person transmission was reported only with the Andes virus, however, the data are limited. *Occupation is the main risk factor for transmission of all hantaviruses*: animal trappers, forestry workers, laboratory personnel, farmers, and military personnel are at highest risk. *Climate change* appears to be impacting the incidence of hantavirus infection mainly through effects on reservoir ecology.

Clinical Findings

A. Symptoms and Signs

Vascular leakage is the hallmark of the disease for both syndromes, with kidneys being the main target with variants associated with HFRS and the lungs with variants associated with HPS.

1. HFRS—HFRS manifests as mild, moderate, or severe illness depending on the causative strain. A 2- to 3-week incubation period is followed by a protracted clinical course, typically consisting of five distinct phases: febrile period, hypotension, oliguria, diuresis, and convalescence phase. Various degrees of kidney involvement are usually seen. Puumala virus infection is often referred to as nephropathia epidemica. Thromboembolic phenomena are also recognized complications. A secondary hemophagocytic lymphohistiocytosis can be seen with HFRS. Pulmonary edema is not typically seen but when present usually occurs in the final stages of disease (oliguric and diuretic phase). Encephalitis and pituitary involvement are rare findings with Hantavirus infection, although a few cases are reported with Puumala virus infection. Patients may have persistent hematuria, proteinuria, or hypertension up to 35 months after infection. Smoking appears to exacerbate the viremia with the Puumala virus infection, and bradycardia can also be prominent.

2. HPS—The clinical course of HPS is divided into a febrile prodrome, a cardiopulmonary stage, oliguric and diuretic phase, followed by convalescence. A 14- to 17-day incubation period is followed by a prodromal phase, typically lasting 3–6 days, associated with myalgia; malaise; abdominal pain, nausea, vomiting, and diarrhea; headache; chills; and fever of abrupt onset. An ensuing cardiopulmonary phase is characterized by the acute onset of pulmonary edema. In this stage, cough is generally present, abdominal pain and symptoms as above may dominate the clinical presentation, and in severe cases, significant myocardial depression occurs. AKI and myositis may occur. Sequelae include neuropsychological impairments in some HPS survivors.

B. Laboratory Findings

Laboratory features include hemoconcentration and elevation in LD, serum lactate, and hepatocellular enzymes. Early thrombocytopenia and leukocytosis (as high as 90,000 cells/mcL [90.0 × 10^9/L] in HPS) are seen in both HFRS and HPS. In HPS, immunoblasts (activated lymphocytes with plasmacytoid features) can be seen in blood, lungs, kidneys, bone marrow, liver, and spleen.

An indirect fluorescent assay and enzyme immunoassay are available to detect specific IgM or low-avidity IgG virus-specific antibodies that remain detectable for 6–8 months. A quantitative RT-PCR is available; however, the viremia of human hantavirus infections is short-term, and therefore, viral RNA cannot be readily detected in the blood or urine of patients unless for the more readily detected early viremia of the Andes variant.

A plaque reduction neutralization test remains a gold standard serologic assay and distinguishes between the different hantavirus species, although cross-reaction between Old and New World viruses exists. This test must be performed in a laboratory with appropriate biosafety (level 3).

Differential Diagnosis

The differential diagnosis of the acute febrile syndrome seen with HFRS or early HPS includes scrub typhus, leptospirosis, and dengue. HPS requires differentiation from other respiratory infections caused by such pathogens as SARS-CoV-2, *Legionella, Chlamydia*, and *Mycoplasma*. Coxsackievirus infection should also be considered in the differential diagnosis.

Prevention

Because infection is thought to occur by inhalation of rodent waste, prevention is aimed at eradication of rodents in houses and avoidance of exposure to rodent excreta, including forest service facilities. Climatic changes often require particular attention to rodent populations in parks. Inactivated vaccines are used in several Asian countries where patients are at risk for HFRS. Hantaan/Puumala virus DNA vaccine (delivered via a TriGrid device) completed its phase 2 clinical trials (NCT02116205). Similarly, the ANDV DNA vaccine completed its phase 1 in human trials in 2023 (NCT03682107).

Treatment

Treatment is mainly supportive. Cardiorespiratory support with vasopressors is frequently needed; extracorporeal membrane oxygenation may be required in severe cases of HPS. Intravenous ribavirin is used in HFRS (Hantaan virus) with some success in decreasing the severity of the kidney injury. Its effectiveness in HPS, however, is not established.

Prognosis

The outcome is highly variable depending on severity of disease. HPS is a more severe disease than HFRS, with a mortality rate of about 40%. In Sin Nombre virus infections, the persistence of elevated IgG titers correlates with a favorable outcome.

5. Yellow Fever

ESSENTIALS OF DIAGNOSIS

- Endemic area exposure: tropical and subtropical South America and Africa.
- Sudden onset of severe headache, aching in legs, and tachycardia.
- Brief (1 day) remission, followed by bradycardia, hypotension, jaundice, hemorrhagic tendency.
- Albuminuria, leukopenia, bilirubinemia.

General Considerations

Yellow fever is a zoonotic flavivirus infection transmitted by *Aedes* mosquito bites. The three types of transmission cycles include **sylvatic** (or jungle; humans working or traveling in the forest are bitten by infected mosquitoes), **intermediate** (most common type of outbreak in Africa; mosquitoes infect both monkeys and humans leading to outbreaks in separate villages), and **urban** (seen in large epidemics; infected mosquitoes transmit the virus from person to person). Elevated temperatures and increased rainfall are major determinants of transmission.

Yellow fever occurs in 47 endemic countries in Africa and in Central and South America. Around 90% of cases reported every year occur in sub-Saharan Africa. Adults and children are equally susceptible, though attack rates are highest among adult men because of their work habits. Modeling data from Africa in 2013 estimates the annual caseload is 84,000 to 170,000 annual cases with 29,000 to 60,000 deaths. The number of persons at risk for infection with yellow fever virus worldwide is estimated to be between 394 million and 473 million.

The last decade has seen a resurgence of yellow fever, likely due to suboptimal vaccination coverage and waning population-level immunity.

Clinical Findings

A. Symptoms and Signs

Most patients have no illness or only mild illness. The incubation period is 3–6 days in persons in whom symptoms develop.

1. Mild form—Symptoms are malaise, headache, fever, retroorbital pain, nausea, vomiting, and photophobia. Relative bradycardia (a lower-than-expected heart rate for the degree of body temperature elevation), conjunctival injection, and facial flushing may be present.

2. Severe form—Severe illness develops in about 15%. Initial symptoms are similar to the mild form, but brief fever remission lasting hours to a few days is followed by a "period of intoxication" manifested by fever and relative bradycardia, hypotension, jaundice, hemorrhage (GI, nasal, oral), and delirium that may progress to coma.

B. Laboratory Findings

Leukopenia, elevated liver enzymes, and bilirubin can occur. Proteinuria is present and usually disappears completely with recovery. Bleeding dyscrasias with elevated prothrombin and partial thromboplastin times, decreased platelet count, and presence of fibrin-split products can also occur.

In the early stages of the disease (up to 10 days), diagnosis is confirmed if yellow fever virus RNA is detected by RT-PCR in blood from a person with no history of recent yellow fever vaccination. PCR determinants can distinguish between wild type virus and vaccine-associated strains.

In later stages, serologic diagnosis can be made by using ELISA to measure IgM 3 days after the onset of symptoms; however, yellow fever vaccination and infection with other flaviviruses, including dengue, West Nile, and Zika viruses, may give a false-positive ELISA test result. Thus, the presence of yellow fever virus–specific IgM antibody and negative ELISA panel for other relevant flaviviruses confirm the diagnosis. If ELISA is positive for other flaviviruses, the more specific plaque reduction neutralization assay should be done in reference laboratories, which measures the titer of the neutralizing antibodies in the serum toward the infecting virus.

Differential Diagnosis

It may be difficult to distinguish yellow fever from other viral hepatitides, malaria, leptospirosis, louse-borne relapsing fever, dengue, and other hemorrhagic fevers on clinical evidence alone. *Albuminuria* is a constant feature in yellow fever patients, and its presence helps differentiate yellow fever from other viral hepatitides. Serologic confirmation is often needed.

Prevention

Four live attenuated yellow fever virus vaccines (all derived from the 17D strain) are prequalified by the WHO. All are given as a single dose (10-year booster doses are recommended for some groups) and are safe and effective. A single dose of vaccine in the past was considered to provide lifelong immunity. While the 10-year booster dose is no longer recommended for most patients, persistent seropositivity at 8 years postvaccination is only 85% (and below 60% in children vaccinated at 9–12 months of age). Thus, at-risk groups with waning immunity and high probability of exposure may consider receiving a second dose of vaccine after 10 years (these groups are listed at https://www.cdc.gov/yellowfever/healthcareproviders/vaccine-info.html).

Yellow fever vaccine is recommended for persons age > 9 months who are traveling to or living in areas at risk for yellow fever virus transmission. *This vaccine should never be given to children under 6 months old* due to their higher risk of developing encephalitis related to the vaccine. *The WHO recommends that all endemic countries include yellow fever vaccine in their national immunization programs and provides a list of countries requiring yellow fever vaccination for entry.* The vaccine is contraindicated in persons with severe egg allergies or who are severely immunocompromised, including patients with primary immunodeficiencies, HIV infection with CD4+ cell count below 200/mcL, thymus disorder with abnormal immune function, malignant neoplasms, transplantation, or immunosuppressive and immunomodulatory therapies. The vaccine should not be given to breastfeeding women or patients > 60 years of age because this age group is at higher risk for viscerotropic and neurologic disease. It should be administered at least 24 hours apart from the measles vaccine. Pregnant persons should receive the vaccine only if they cannot defer travel to endemic areas (Chapter 35). Clinicians should be aware of rare but frequently fatal vaccine-induced reactions, including anaphylaxis, yellow fever vaccine–associated viscerotropic disease, and yellow fever vaccine–associated neurologic disease.

A 2017 initiative, the Eliminate Yellow Fever Epidemics (EYE) program, is composed of > 50 organizations and designed to increase surveillance and control in 40 countries of Africa and the Americas in an attempt to reach 1 billion at-risk individuals with seroprotection by 2026.

The best personal protective measures are to avoid mosquito bites. If not in an endemic area, the patient should be isolated from mosquitoes to prevent transmission, since blood in the acute phase is potentially infectious.

Treatment

No specific antiviral therapy is available. Treatment is directed toward symptomatic relief and management of complications. A randomized clinical trial of sofosbuvir for treatment of yellow fever is underway in Brazil.

Prognosis

The mortality rate of the severe form is 20–50%, with death occurring most commonly between the sixth and the tenth days. Convalescence is prolonged, including 1–2 weeks of asthenia. Infection confers lifelong immunity to those who recover.

OTHER SYSTEMIC VIRAL DISEASES

1. Zika Virus

ESSENTIALS OF DIAGNOSIS

- Most infected persons asymptomatically seroconvert.
- Clinical symptoms are akin to chikungunya virus infection but with less arthritis.
- Complications include microcephaly and ocular abnormalities in infants born to mothers infected during pregnancy, as well as Guillain-Barré.
- No effective antiviral or vaccine is available.

General Considerations

Zika is a flavivirus, akin to the viruses that cause dengue fever, Japanese encephalitis, and West Nile infection.

The virus was noted in Africa and Asia during the 1950s–1980s but first spread beyond those two continents in 2007 when an outbreak occurred in Yap State, Federated States of Micronesia. A large outbreak occurred in French Polynesia in 2013. The virus then spread to the Western hemisphere and was first noted in northeastern Brazil in 2015, and 239,742 cases were subsequently reported between 2015 and 2018. Zika virus spread rapidly throughout the Americas, including the United States and worldwide. Despite distinct lineages, Zika virus exists as only one serotype.

Aedes species mosquitoes, particularly *Aedes aegypti*, are primarily responsible for Zika virus transmission. The biodistribution of the species largely determines the area of prevalence for Zika virus. Rarely, a few other mosquito species including *Anopheles* and *Culex* may be competent for the Zika virus. The virus can also be transmitted via blood transfusion, vertical transmission and sexual transmission (vaginal, anal, or oral sex). As of the most recent WHO update, in February 2022, 89 countries/territories reported local Zika virus transmission cases, including all WHO regions except the Eastern Mediterranean region. Zika virus incidence has been declining in most WHO regions since mid-2019.

Since the onset of the first reported cases in the United States in 2015, most transmissions were reported in Puerto Rico, with limited local transmission reported in Florida and Texas. No confirmed Zika cases in US territories have been reported since 2019.

Clinical Findings

A. Symptoms and Signs

The incubation period is 3–14 days. Most (50–80%) of Zika virus infections are asymptomatic. Symptoms include acute-onset fever, maculopapular rash that is usually pruritic, nonpurulent conjunctivitis, and arthralgias, the latter mimicking the symptoms of the chikungunya virus. Rash may outlast the fever but is not always present. Symptoms last up to 7 days. Most infections are asymptomatic. Viral infections most often confused with Zika include dengue and chikungunya virus infections.

B. Laboratory Findings and Diagnostic Studies

Diagnosis is made by detecting viral RNA (nucleic acid testing) in patients presenting with onset of symptoms < 7 days. Nucleic acid testing can be performed within 14 days of illness onset. People tested 14 days or more after symptom onset should be tested using IgM serology. Commercial RT-PCR assays and IgM ELISAs (usually present up to 12 weeks after illness onset) are available. Matched serum and urine specimens should be tested simultaneously. Although not routinely recommended, RT-PCR can be performed on amniotic fluid, CSF, and placental tissue. A positive RT-PCR test definitively diagnoses Zika virus infection and does not require additional confirmatory testing. A negative test does *not* exclude the presence of the virus in other tissues and does not rule out infection. Persons with negative

NATs and symptoms of Zika infection should undergo further testing for Zika virus IgM antibody and other arboviral infections. Serologic testing for Zika virus should only be conducted by laboratories with experience in performing flavivirus serology.

Recommended serologic assays include enzyme immunoassays and immunofluorescence assays (which detect IgM antibodies using viral lysate, cell culture supernatant, or recombinant proteins) and neutralization assays (such as plaque reduction neutralization tests). The Zika MAC-ELISA can be performed on serum or CSF. Anti-Zika IgM antibodies are observed in CSF of children with congenital infection. Neutralizing antibodies can cross-react with dengue and other flaviviruses, so samples testing positive should be sent to public health laboratories for confirmation.

In the United States, testing for asymptomatic pregnant persons is not recommended by the CDC even after travel to an area with Zika activity. The WHO, however, still recommends testing via IgM antibody for asymptomatic pregnant persons who could have had contact with vector-borne or sexually transmitted Zika virus. In areas with active Zika transmission, asymptomatic pregnant persons should be tested for IgM antibodies as part of routine obstetric care. Persistent Zika virus RNA in serum has been reported in pregnancy. Pregnant persons with confirmed or suspected Zika virus infection may be monitored by serial ultrasounds at 3- to 4-week intervals, assessing fetal anatomy and growth. With a declining prevalence of Zika virus infection, positive antibody tests run the risk of more likely being false-positives and thus the need for the outlined assessments exists.

Complications

Two neurologic complications are of particular concern: (1) **congenital microcephaly,** often associated with brain calcifications and other abnormalities, first noted during the outbreak in Brazil; and (2) **Guillain-Barré syndrome,** first noted during the outbreak in French Polynesia. The incidence of Guillain-Barré syndrome is estimated at 2–3 cases per 10,000 Zika virus infections. In addition to microcephaly, Zika causes a spectrum of congenital disabilities of the CNS that collectively are termed **congenital Zika syndrome.** These include fetal brain disruption sequence, subcortical calcifications, pyramidal and extrapyramidal signs, ocular lesions of chorioretinal atrophy, focal pigmented mottling of the retina, and congenital contractures. Newborns of women infected with Zika virus during pregnancy have a 5–14% risk of congenital Zika syndrome and a 4–6% risk of Zika virus–associated microcephaly. Spontaneous abortions and rare deaths related to Zika virus infection are reported.

As with Ebola virus, the Zika virus can persist in semen for months; in the male reproductive tract the prostate gland and the testes are the presumed reservoirs. Persistence of the virus in the female reproductive tract is possible.

Prevention

The most effective means is environmental control of mosquitoes and removing areas where water is stagnant or builds up. Such measures include screens on houses; removal of old tires and debris from endemic areas of infection; and movement toward better living conditions, including air conditioning in impoverished areas. Because of the association between microcephaly and Zika virus infection during pregnancy, *pregnant persons should avoid travel to areas where Zika virus is circulating*. Guidelines for testing pregnant persons potentially exposed are available through the CDC. The CDC recommends that pregnant couples use condoms or abstain from sex for the entire pregnancy if the pregnant person's partner had a possible Zika virus exposure. Infected individuals should refrain from sexual intercourse (https://www.cdc.gov/zika/hc-providers/clinical-guidance/sexualtransmission.html) and blood donations for several months.

No approved vaccine against the Zika virus exists; however, several inactivated vaccine candidates have shown the ability to induce neutralizing antibodies based on phase 1 trials, including an inactivated whole-Zika virus vaccine (Takeda's TAK-426; NCT03343626) and several mRNA vaccine candidates (mRNA-1325 trial NCT03014089 and mRNA-1893 trial NCT04064905). A phase 2 multicenter randomized trial evaluating Zika virus wild type DNA vaccine is undergoing data analysis. Vaccine candidate evaluation has been hampered by the declining incidence of Zika virus.

Treatment

No antivirals are approved for treatment of Zika virus; thus, management should focus on supportive care. Aspirin and NSAIDs are avoided during illness caused by the flavivirus dengue because of its propensity to cause hemorrhage. Zika virus infections, however, do not appear to be associated with major hemorrhagic complications.

World Health Organization. Zika epidemiology update – February 2022. https://www.who.int/publications/m/item/zika-epidemiology-update—february-2022

2. Chikungunya Fever

Chikungunya ("that which bends up" in the Bantu language Kimakonde) fever is an alphavirus infection transmitted to humans by *A aegypti* and *A albopictus* and is considered a classic "arthritogenic" virus. The virus originated with two strains, one in West Africa and the other in East/Central/Southern Africa. The first documented clinical cases in India were derivative of the E/C/S African strains with later reports of outbreaks in Kenya in 2004. Subsequently, there were reports from areas that adjoin the Indian Ocean, Southeast Asia and its neighboring islands (2005–2007), South India (2005), and the island of La Réunion (2005–2006), with further spread including autochthonous cases in Italy and France (2007). In 2013, the first autochthonous case of chikungunya reported in the western hemisphere occurred on Saint Martin in the Caribbean, with isolates derivative of the East/Central/South Africa strains. Despite these differences, only one serotype exists.

Chikungunya virus is ubiquitous in endemic countries in Africa, the Americas, Asia, and Europe. The CDC reported 0 locally acquired cases and 141 travel-associated US cases in 2024. The last reported cases of local chikungunya transmission in the United States occurred in 2015. However, as of November 2024, 480,000 cases and 281 deaths have been reported worldwide.

Among naïve populations, attack rates are often as high as 50%. On Saint Martin, 39% of infections were asymptomatic. Vertical transmission is documented if the mother is viremic during parturition, and transmission does not appear to occur throughout pregnancy as it does with Zika virus. Infectious virus was isolated from saliva, although transmission from oral secretions is not observed among humans. Endemicity of *A aegypti* in the Americas and the introduction of *A albopictus* into Europe and the New World raise concern for further extension of the epidemic. Case reports show that chikungunya virus may coinfect patients with yellow fever virus, plasmodia, Zika virus, and dengue virus.

Clinical Findings

A. Symptoms and Signs

After an incubation period of 1–12 days (estimated median 3), acute presentation is characterized by viremic phase (5–10 days with abrupt fever; headache; polyarthralgia affecting small, large, and axial joints; myalgia; and cutaneous rash) followed by postviremic phase (6–21 days) with sustained polyarthralgia/arthritis, fatigue, and myalgia. The simultaneous involvement of > 10 joints and tenosynovitis (especially in the wrist) are characteristic. The *stooped posture* of patients gives the disease its name. Joint symptoms persist for 4 months in 33% and linger for years in about 10%. A centrally distributed pigmented or pruritic maculopapular rash is reported in 10–40% of patients; it can be bullous with sloughing in children. Mucosal disease occurs in about 15%. Facial edema and localized petechiae are reported. Neurologic complications, including encephalitis, myelopathy, peripheral neuropathy, Guillain-Barré syndrome, myeloneuropathy, and myopathy, are usually found in persons younger than 5 years or older than 49 years. Encephalitis occurred in 8.6 per 100,000 persons infected in La Réunion during 2005–2006 with 17% mortality and increased risk of encephalitis among those older than 65 years. Hemorrhagic fever–like presentations are unusual. Coinfection with other respiratory viruses and with dengue is common. Some of the neuropathology may be immune-mediated, and these cases are usually in those over age 20 and associated with longer latencies and better outcomes. Death is rare and usually related to underlying comorbidities. The differential diagnosis includes other tropical febrile diseases, such as malaria, leishmaniasis, or dengue.

B. Laboratory Findings

Diagnosis is made epidemiologically and clinically. Mild leukopenia occurs as does thrombocytopenia, which is seldom severe. Elevated inflammatory markers do not correlate well with the severity of arthritis. Radiographs of affected joints are normal during the acute phase. Bone lesions are visible in some patients with chronic symptoms.

Serologic confirmation requires elevated IgM titers or fourfold increase in convalescent IgG levels using an ELISA. RT-PCR and ELISA are commercially available; no ELISA kit is FDA-cleared. Culture techniques (viral isolation in insect or mammalian cell lines or by inoculation of mosquitoes or mice) require BSL 3 (biosafety level 3) containment. Directions on submitting specimens for testing may be obtained from the CDC Arboviral Diseases Branch, 970-221-6400. Suspected cases in the United States should be promptly reported to public health authorities.

Complications & Prognosis

Common complications of chikungunya fever are long-term weakness, asthenia, myalgia, arthralgia, and arthritis, noted to be present in 25–66.5% of cases at 1 year. Risk factors for long-term arthralgias include the existence of such symptoms at 4 months after onset of disease and age > 35 years. Persons with preexisting arthritis are also at increased risk for prolonged symptoms after chikungunya infection with polyarthralgias occasionally lasting for years. Nasal skin necrosis is rarely reported. The Guillain-Barré syndrome is also reported. Comorbid conditions, including hypertension, diabetes, and cardiac diseases, may contribute to severe outcomes; although in some series, patients with significant neurologic complications do not show comorbidities. Severe outcomes and higher mortality are reported among more recent Brazilian cases.

Treatment & Prevention

Treatment is supportive with NSAIDs and corticosteroids. Chloroquine and methotrexate may be useful for managing refractory arthritis. Chronic disease may require disease-modifying antirheumatic medications, such as the reports from La Réunion where methotrexate was associated with a positive response. The first Chikungunya vaccine (Ixchiq-VLA1553) was approved in the United States in November 2023. It is recommended for adults ≥ 18 years traveling to endemic areas with outbreaks or evidence of chikungunya virus human transmission within the last 5 years. The vaccine is contraindicated in immunocompromised patients, including those on immunosuppressive and immunomodulatory therapies or with history of allergic reaction to a vaccine component. Detailed recommendations can be accessed at https://www.cdc.gov/chikungunya/hcp/vaccine/. Vimkunya, a recombinant chikungunya vaccine, was given accelerated approval in February 2025 for prevention of disease in individuals > 12 years.

There are ongoing trials for inactivated BBV87 vaccine (NCT04566484) and mRNA vaccines (mRNA-1388; NCT03325075). A measles-vectored chikungunya virus vaccine (MV-CHIK) demonstrated good immunogenicity and was shown to be safe and effective in a phase 2 clinical trial (NCT03635086). An aluminum hydroxide-adjuvanted chikungunya virus-like particle vaccine, PXVX0317, induced robust immune responses in a phase 2 clinical trial and has completed phase 3 trials. Prevention relies on avoidance of mosquito vectors. Transplantation of tissue from immigrants or from travelers to known endemic areas should be discouraged. Prophylaxis with specific chikungunya immunoglobulins may be useful for immunosuppressed persons.

Ng WH et al. Chronic chikungunya disease (CCD): clinical insights, immunopathogenesis and therapeutic perspectives. QJM. 2024;117:489. [PMID: 38377410]

3. Colorado Tick Fever

ESSENTIALS OF DIAGNOSIS

- Onset 1–19 days (average, 4 days) following tick bite.
- Fever, chills, myalgia, headache, prostration.
- Leukopenia, thrombocytopenia.
- Second attack of fever after remission lasting 2–3 days.

General Considerations

Colorado tick fever is a reportable biphasic, febrile illness caused by a reovirus infection transmitted by *Dermacentor andersoni* tick bite. About five cases occur annually, largely among men age > 40. The disease is limited to the western United States and Canada and is most prevalent during the tick season (March to November), typically at 4,000–10,000 feet above sea level in grassy areas. Most cases (90%) report a discrete tick bite or exposure history. Fewer cases of Colorado tick fever are reported each year, with only 59 cases reported to the CDC between 2010 and 2019. Most recent cases are reported from Wyoming, Montana, and Utah. The virus infects the marrow erythrocyte precursors. Blood transfusions can be a vehicle of transmission.

Clinical Findings

A. Symptoms and Signs

The incubation period is 3–6 days, rarely as long as 19 days. The onset is usually abrupt with a high fever. Severe myalgia, headache, photophobia, anorexia, nausea and vomiting, and generalized weakness are prominent. Physical findings are limited to an occasional faint rash. The acute symptoms resolve within a week. Remission is followed in 50% of cases by recurrent fever and a full recrudescence lasting 2–4 days.

The differential diagnosis includes influenza, Rocky Mountain spotted fever, numerous other viral infections, and, in the right setting, relapsing fevers.

B. Laboratory Findings

Leukopenia with a shift to the left and atypical lymphocytes occurs, reaching a nadir 5–6 days after the onset of illness. Thrombocytopenia may occur. An RT-PCR assay may be used to detect early viremia. Detection of IgM by capture ELISA or plaque reduction neutralization is possible after 2 weeks from symptom onset and is the most frequently used diagnostic tool.

Complications

Aseptic meningitis (particularly in children), encephalitis, and hemorrhagic fever occur rarely. Malaise may last weeks to months. Fatalities are very uncommon. Rarely, spontaneous abortion or multiple congenital anomalies may complicate Colorado tick fever infection acquired during pregnancy.

Prevention

Tick avoidance is the best prevention. The tick season is primarily from March to November, and the ticks mostly live at high altitudes (> 7000 feet) in sagebrush.

Treatment

No specific treatment is available. Ribavirin has shown efficacy in an animal model. Antipyretics are used, although salicylates should be avoided due to potential bleeding with the thrombocytopenia seen in patients with Colorado tick fever.

Prognosis

The disease is usually self-limited and benign. Fatalities are rare.

COMMON VIRAL RESPIRATORY INFECTIONS

1. Severe Acute Respiratory Syndrome—Coronavirus 2019 (SARS-CoV-2)

ESSENTIALS OF DIAGNOSIS

- When symptomatic, adults often have respiratory tract illness with fever and cough; upper tract symptoms are more prominent with more recently circulating variants.
- Advanced pulmonary complications (pneumonia, acute respiratory distress syndrome [ARDS]) occur with fulminant disease.
- High predilection for older adults and patients who are immunocompromised, have chronic diseases, and live in crowded conditions.
- Now in endemic phase, with World Health Organization declaring the end of the pandemic phase on May 5, 2023 (with ongoing management with yearly booster vaccinations recommended for older persons and treatment when indicated).

General Considerations

Coronaviruses are a large family of viruses commonly found in humans and other species of animals, including bats, camels, cattle, cats, white-tailed deer, and hamsters. There are four genera of coronaviruses, of which only the alphacoronaviruses (coronavirus NL63 and 229E) and the betacoronaviruses affect humans. Like SARS-CoV-1, MERS-CoV, and the human common cold coronaviruses HC43 and HKU1, the SARS-CoV-2 virus is a betacoronavirus. All coronaviruses likely originated in bats.

A. Transmission

R_0 is the basic reproductive number signifying the number of contacts infected by one individual. Calculations of R_0 for SARS-CoV-2 have varied, but the true R_0 likely lies somewhere between 2 and 3, although transmission rates vary by SARS-CoV-2 strain. While the case fatality rate was far higher with the 2003 SARS-CoV-1 virus and with the MERS virus, the rate of person-to-person spread and the number of infected cases is much higher with SARS-CoV-2 than with either the SARS-CoV-1 or MERS viruses. Transmission is particularly efficient within higher-density living facilities and employment settings and is increased among newer variants such as Omicron (see below). Presymptomatic spread accounts for many cases, and the viral load for SARS-CoV-2 was highest the day before symptoms developed prior to widespread population immunity. After population immunity from vaccines and natural infection, the highest viral load for SARS-CoV-2 was on day four of symptoms, with most of the current spread occurring during active symptoms.

The incubation period for SARS-CoV-2 ranges from 2 to 24 days with an average of about 5 days. The principal mode of transmission is respiratory droplets (such as saliva) rather than by air (aerosolization), though aerosolization can occur during activities such as heavy exercise and singing. Simply talking (or singing) in close quarters may efficiently spread the virus. In a medical setting, the WHO and the CDC recommend that healthcare providers use both *droplet* and *contact* precautions for all patients in whom COVID-19 is suspected or diagnosed. Additionally, these organizations recommend that healthcare providers use *airborne* precautions when performing aerosol-generating medical procedures (such as collecting induced sputum or intubating the patient).

In utero transmission of SARS-CoV-2 is reported but appears to be rare. In general, the virus does *not* seem to be transmitted in breast milk.

Superspreading events (ie, when a person infected with SARS-CoV-2 is at the most infectious stage [usually around day 4 of infection] and infects a disproportionate number of susceptible persons) can play an important role in SARS-CoV-2 transmission. The importance of venues outside the home for spreading infection is evident from a Japanese review in which 61% of all national cases were traceable to clusters outside the home, including restaurants, bars, event venues, and workplaces. In a study from the University of Colorado at Boulder, the role of "supercarriers" also was identified, with just 2% of infected individuals carrying 90% of the virions circulating within the community. These persons may be superspreaders.

B. Risk Factors

Data from the United States early in the COVID-19 epidemic showed that the rate of infection was highest among young and middle-aged adults, with nearly 25% of confirmed cases occurring in persons age 20–29 and about 20% of cases in those age 50–64. Data from the southern United States showed increases in incidence among persons age 20–39 precede the increases among those age > 60 by 4–15 days. *COVID-19 mortality rates are distinctly higher over the age of 50* and among persons with comorbid medical conditions *such as diabetes, obesity, hypertension, chronic heart, lung, or kidney disease, and prior stroke.* In one large multiethnic cohort study of adults hospitalized with COVID-19, obesity was associated with a 113% increased risk of hospitalization and a 43% increased risk of death.

Children are just as susceptible to SARS-CoV-2 acquisition as adults, although they are much *less* likely to manifest symptoms. Younger individuals, including children, are more likely to have been previously exposed to benign cold-causing coronaviruses that may provide relative protection from severe SARS-CoV-2 infection. Additionally, children have lower concentrations of ACE-2 receptors—the receptor used by SARS-CoV-2 to infect host cells—in lung tissue, which may explain their lower propensity toward severe infection.

1. COVID-19 in immunosuppressed patients—Immunocompromised persons (ie, persons with malignancy, solid organ and hematopoietic stem cell transplant recipients, persons living with HIV, and individuals receiving biologic treatments for autoimmune or other conditions, among others) are at increased risk of severe illness due to COVID19, though risks vary by patient population in this heterogeneous category. Patients with cancer, especially those with metastatic tumors or lymphomas, or who have recently received chemotherapy, show higher risks of adverse outcomes when infected with SARS-CoV-2. In one review, the subgroups of cancer patients who had disproportionately high COVID-19 mortality included those with lung cancer (case fatality rate [CFR] 18–55%) and those with hematologic malignancy (CFR 33–41%). Immunocompromised individuals may demonstrate prolonged viral shedding and can show a reduced response to vaccination, particularly persons who have received B cell–depleting agents such as rituximab.

2. COVID-19 in pregnancy—See also Chapter 22. While pregnancy is not clearly associated with an increased risk of *acquisition* of SARS-CoV-2, complications develop in pregnant patients at a higher rate than in nonpregnant patients. In a large multinational cohort study of pregnant patients, COVID-19 is shown to be associated consistently with higher maternal morbidity and mortality including increased rates of preeclampsia and eclampsia, severe maternal infections, and maternal ICU admissions. While miscarriage rates are not increased, SARS-CoV-2 can rarely cause placentitis which may lead to stillbirth. In addition, SARS-CoV-2 infection during pregnancy has been associated with preterm birth in some but not all studies.

C. SARS-CoV-2 Variants

Multiple SARS-CoV-2 genetic variants have been identified to date; detailed information on current variants can be found on the WHO (https://www.who.int/en/activities/tracking-SARS-CoV-2-variants/) and CDC websites (https://covid.cdc.gov/covid-data-tracker/#variants-genomic-surveillance).

Most reported mutations are within the spike ("S") protein and can be associated with reduced neutralization by antispike antibodies. Indeed, the evolution of the S protein in the current-era variants have rendered all former monoclonal antibody treatments ineffective.

Clinical Findings

A. Symptoms and Signs

Most infected individuals are asymptomatic, although the ratio of asymptomatic to symptomatic infection changes as more individuals are tested and has evolved with increasing vaccination and infection-inducted immunity. Adults can manifest a wide range of symptoms from mild to severe illness that typically begin 2–14 days after exposure to SARS-CoV-2. Symptomatic patients may have cough, fever, chills/rigors, myalgias, or pharyngitis. The presence of dyspnea is variable, but it is common in severe infection. No one symptom should be used as a discriminant for disease. Less frequent early symptoms include rhinitis, pharyngitis, abdominal symptoms such as nausea and diarrhea, headaches, anosmia, and ageusia (absence of taste). At the pandemic's beginning, 15–20% of adults with SARS-CoV-2 infection required hospitalization and 3–5% required critical care. These rates evolved substantially throughout the pandemic with the development of inpatient treatment (eg, remdesivir, dexamethasone) and, later, administration of the COVID-19 vaccines.

B. Laboratory Findings

Hematologic findings include neutrophilia, absolute lymphopenia, and an increased neutrophil-to-lymphocyte ratio. As disease advances, blood chemistry findings often include elevated liver biochemical tests and total bilirubin. Serum markers of systemic inflammation increase in most patients with severe COVID-19, including LD, ferritin, CRP, procalcitonin, and interleukin 6 (IL-6). A coagulopathy is often seen in severe COVID-19, identified by elevated von Willebrand factor (VWF) antigen, elevated D-dimer, and fibrin/fibrinogen degradation products; the prothrombin time, partial thromboplastin time, and platelet counts are usually unaffected initially (see Chapter 14).

C. Diagnostic Studies

The three commonly used types of diagnostic tests are *molecular* tests (most sensitive and specific) and *rapid antigen detection* tests (inexpensive and fast but not as sensitive). *Antibody (serologic)* tests are infrequently used as they are not generally able to distinguish vaccination from infection (depending on assay). Viral culture can be done in research settings but is not used in clinical practice given slower turnaround and lab biosafety requirements.

1. Molecular tests—Reverse transcriptase polymerase chain reaction (RT-PCR) assays have remained a mainstay of COVID-19 diagnosis. These tests detect genetic material and do not directly assess the presence of replicating virus. Isolation of the virus by nucleic acid assays > 10 days after the onset of symptomatic infection (or 15 days after exposure, on average) is usually not associated with replicative infectious particles. Prolonged viral shedding of viral RNA is common (particularly among immunocompromised persons) and underpins guidelines to avoid retesting for SARS-CoV2 within 90 days of prior infection in most instances. RT-PCR testing is generally done on upper respiratory swabs such as nasopharyngeal swabs. Patients may have positive tests from lower respiratory samples (eg, bronchoalveolar lavage fluid) despite negative samples from the upper respiratory tract.

2. Rapid antigen detection tests—Rapid antigen detection tests are available both in healthcare settings and as home tests. These tests generally are performed on specimens from the upper respiratory tract. Sensitivity of antigen-based testing is lower than that of nucleic acid–based testing, particularly among asymptomatic persons, but performance improves substantially among symptomatic persons (85% compared with culture-based standard in one CDC study). Antigen-based testing may therefore have a role in triaging a case's potential infectiousness.

3. Antibody (serologic) tests—A number of antibody assays are available; they are not useful in diagnosing SARS-CoV-2 infection but can be used to determine immune status. In setting of widespread population immunity, serologic testing is generally not clinically useful for immunocompetent persons. These tests generally are performed on blood (specifically, serum) specimens.

D. Imaging

Early in the disease course, neither CXRs nor chest CT scans provide diagnostic utility, since both may be normal, and the nonspecific findings overlap with those of many respiratory viral infections. Later in the disease course, nonspecific diffuse ground-glass opacities (which may be peripherally-based) and/or multilobar infiltrates become more common. Chest ultrasonography, MRI, and PET/CT findings tend to confirm the CT findings of an evolving organizing pneumonia.

Differential Diagnosis

The clinical presentation of COVID-19 overlaps considerably with other respiratory viruses (including influenza, RSV, and others), necessitating specific testing. The rates of COVID-19 in the community (based on clinical testing or wastewater surveillance data) inform the likelihood of a positive COVID-19 diagnosis. Seasonal influenza infection can usually be ruled out by a nasal PCR. Concomitant infection with influenza or other respiratory pathogens is reported. A useful table comparing symptoms of an upper respiratory infection, influenza, and COVID-19 is available at https://www.medicalnewstoday.com/articles/coronavirus-vs-flu#symptoms.

Complications

Many extrapulmonary complications are reported, and most of these are likely related to SARS-CoV-2–induced inflammatory reactions.

1. SARS-CoV-2–related immune activation—Individuals with more severe COVID-19 disease show pronounced systemic inflammation at presentation, often called a "cytokine storm" in the later phase of illness. Persistent immune activation in predisposed patients can lead to uncontrolled amplification of cytokine production (including IL-6), leading to multiorgan failure and death. An increased incidence of autoimmune disease is reported, from Guillain-Barré to autoimmune thyroiditis and autoimmune encephalitis.

2. Pulmonary complications—The most common system involved with complications of severe COVID-19 is pulmonary. Some patients progress to ARDS akin to the coronavirus infections that cause SARS and MERS. In a large Veterans Affairs database early in the pandemic, the risk for such progression was 19-fold greater among COVID-19 patients than among influenza patients. Determination of need for noninvasive ventilation versus intubation versus extracorporeal membrane oxygenation (ECMO) is based on disease severity and likelihood of progressive ARDS.

3. Coagulation complications—See also Chapter 14. **COVID-19-related coagulopathy** is well described and associated with a predisposition to pulmonary embolism and deep venous thrombosis. In general, *outpatients* with COVID-19 should not receive anticoagulant or antiplatelet therapy to prevent venous or arterial thrombosis unless other strong indications are present. Therapeutic anticoagulation with heparin has been recommended for *hospitalized* patients requiring supplemental oxygen (but **not** high-flow nasal cannula oxygen or noninvasive or mechanical ventilation) with elevated d-dimer and without increased bleeding risk. Prophylactic-dose heparin is recommended for other persons hospitalized with COVID-19 who do not have another indication for therapeutic anticoagulation, including critically ill patients requiring high-flow nasal canula oxygen or noninvasive or mechanical ventilation. The reader is directed toward online guidance for the most current recommendations relating to anticoagulant management.

Vaccine-induced thrombosis and thrombocytopenia are discussed below (see Vaccine-associated reactions and complications, below).

4. Cardiac complications—In a multicenter US cohort study, MI occurred in 14% of patients with COVID-19; survival was infrequent (2.9%) in those with infarction who were older than 80 years. A fulminant myocarditis occurs in about 15% of ICU patients, which can be further complicated by HF, cardiac arrhythmias, ACS, stress cardiomyopathy, cardiac aneurysms, vasculitis, and sudden death. The rates of myocarditis and pericarditis following infection are considerably higher than the rates following vaccination.

5. Renal complications—AKI occurred in approximately 12% of patients hospitalized with COVID-19 early in the pandemic. Of these, > 20% required renal replacement therapy. Overactive bladders and increased incidences of UTIs are seen with long COVID (see below).

6. Rheumatologic complications—Examples include inflammatory arthritis, SLE, and less often rhabdomyolysis and myositis. An IgA vasculitis has been reported in patients with long COVID.

7. GI complications—SARS-CoV-2 is shed in the stool in up to 80% of patients and, in a small subset (3.8%), is shed for up to 7 months. Such patients are more likely to report GI symptoms, particularly abdominal pain, nausea, and vomiting (but not diarrhea, which is infrequent). A particularly strong association existed between acute pancreatitis and SARS-CoV-2 infection.

8. Neurologic complications—Commonly reported neurologic complications are headaches; seizures; strokes; and more often, a loss of taste and smell (ageusia and anosmia). The loss of smell without significant rhinorrhea or nasal congestion suggests a neurotropism by this coronavirus. SARS-CoV-2–related meningitis as well as other neurologic complications, including impairment of consciousness to a comatose state, Guillain-Barré syndrome, paresthesia, and acute hemorrhagic necrotizing encephalopathy, have been reported. Such neurologic manifestations were associated with higher in-hospital mortality.

9. Psychiatric complications—Acute psychiatric diagnoses occurring at increased frequency include anxiety, depression, substance use disorder, and PTSD. Increased social isolation resulting from lockdowns was one of several factors contributing to worsened mental health during the early years of the pandemic. Opioid use disorders increased and were attendant with a decrease in outpatient visits for management and a possible decrease in access to naloxone.

10. Dermatologic complications—Skin manifestations are diverse and, on occasion, the presenting sign. Approximately 5–20% of patients with COVID-19 are found to have dermatologic symptoms. One review of patients with COVID-19 identified acral lesions as the most common rash type, followed by erythematous maculopapular rashes, vesicular rashes, urticarial rashes, and many others. COVID-19 has also been associated with increased risk of herpes zoster virus (VZV) reactivation (shingles) in adults 50 years and older.

11. Infectious complications—One systematic review found that approximately 8% of patients hospitalized with COVID-19 have bacterial coinfection or secondary infection. Invasive pulmonary aspergillosis and mucormycosis have been recognized in some cases.

12. Endocrine complications—A host of endocrine abnormalities are reported including diabetic ketoacidosis, subacute thyroiditis with clinical thyrotoxicosis, new-onset Graves disease, autoimmune (Hashimoto) thyroiditis, and new-onset adrenal insufficiency.

13. Multisystem inflammatory syndrome—A hyperinflammatory syndrome akin to atypical Kawasaki disease (KD) is called **multisystem inflammatory syndrome in**

children (MIS-C) and rarely **in adults (MIS-A)** in the United States. The leading systems involved are GI (the nonspecific symptoms have been diagnosed as appendicitis), cardiovascular, hematologic, mucocutaneous, and pulmonary. MIS-A presents with inflammatory complications weeks after mild or asymptomatic SARS-CoV-2 infection.

14. Long COVID—*While it is common for symptoms such as mild fatigue to slowly resolve after COVID-19, some individuals report persistent symptoms and deficits for 3 months or more following infection ("long COVID"). The prevalence of long COVID appeared to be between 4% and 7% of those who had acute COVID-19 infection early in the pandemic. With more population immunity and a less severe variant (ie, Omicron), the rate of postinfectious complications is now much lower at 0.2%.* A compilation of nine studies of **post-acute COVID-19 syndrome** demonstrates that the most common complications are fatigue (32%), smell or taste disorder (22%), dyspnea (16%), headache (12%), memory impairment (11%), hair loss (10%), and sleep disorder (10%). Vaccination appears to reduce the incidence of long COVID substantially, and the RECOVER cohort from the NIH has launched to examine a variety of holistic and pharmaceutical therapies for this condition.

Prevention

A. Personal and Public Health Measures

Recommended or required population-level and individual public health precautions have varied over the course of the pandemic and by locale. Precautions remain important in communities where SARS-CoV-2 continues to circulate, or most community members are unvaccinated, or both. COVID-19 rates have been more challenging to estimate in recent years due to reduced testing (among other factors), prompting interest in metrics such as wastewater testing to estimate disease activity.

1. Masks—Well-fitted and filtering masks can reduce transmission of respiratory viruses. For healthcare personnel, correctly sized but expired N95 masks with intact elastic bands and masks subjected to sterilization procedures had unchanged fitted filtration efficiencies (FFEs) of > 95%. Portable high-efficiency particulate air (HEPA) cleaners reduce aerosol exposure up to 90% when combined with universal masking. Data have been mixed regarding the real-world effectiveness of masks at reducing the risk of transmission of respiratory viral infections including COVID-19, but masking remains an important intervention to consider for the most medically vulnerable populations including elderly and immunocompromised.

2. Other nonpharmaceutical interventions—Current CDC guidelines recommend that persons with COVID-19 isolate at home until they have been fever-free for at least 24 hours (without fever-suppressive medications such as acetaminophen or NSAIDs) and show symptomatic improvement. These guidelines are distinct from those in healthcare settings where time-based criteria (that can be shortened in some cases by follow-up negative testing) remain in use.

Prior to the availability of vaccines and treatments, the nonpharmaceutical interventions used for COVID-19 were physical distancing, face masks, ventilation, avoidance of indoor gatherings, testing, and contact tracing. Widespread asymptomatic testing did not seem to decrease transmission over other infection-prevention controls in healthcare settings, and the Society of Healthcare Epidemiology of America (SHEA) recommended against preadmission and preprocedure testing in 2022. After the availability and uptake of vaccines in high-income countries, and after the milder Omicron variant emerged, most countries stopped using lockdowns to curb viral transmission, given the negative impacts on overall public health.

3. Vaccines—Current vaccines targeting SARS-CoV2 stimulate the production of neutralizing antibodies against the viral spike protein. In the United States, these vaccines include mRNA-based vaccines (manufactured by both Pfizer and Moderna) and less commonly a protein-based vaccine (Novavax). An adenovirus-vector based vaccine from Janssen/Johnson and Johnson is no longer available. All persons 6 months and older without contraindications are eligible for COVID vaccination in the United States. As vaccination guidance has been evolving, the reader is directed to online resources for the most current guidance.

While current COVID-19 vaccines provide modest efficacy against viral infection, they remain highly protective against severe illness. The continued evolution of SARS-CoV-2 has led to successive vaccine updates to better match circulating viral variants. Immunocompromised individuals are less likely to develop protective immunity following vaccination, prompting interest in passive immunotherapy with monoclonal antibodies, though providing durable protection in face of new viral variants remains a challenge.

4. Vaccine-associated reactions and complications—The COVID-19 vaccines are generally safe and well tolerated. CDC data show that non–COVID-19–associated death rates among those vaccinated show lower mortality than the rates among the nonvaccinated, with appropriate cofactor adjustments (sex, age, race, ethnicity, location), thus confirming the safety profile of COVID-19 vaccines. Commonly reported side effects post–mRNA vaccine administration include nausea, low-grade fevers, injection-site soreness, headaches, and fatigue. Surveillance data show that myocarditis/pericarditis occurs disproportionately in young adults age 12–39 years at an excess rate of 6.3 per million doses during the week following vaccination. Rates are slightly higher after the second dose and for younger males.

5. Vaccination in pregnant and lactating patients—Vaccine registry data indicate that mRNA vaccines are safe in pregnant patients; thus pregnant patients and those planning pregnancy should be targeted for vaccination with the mRNA vaccines. Among vaccinated patients, SARS-CoV-2 vaccine antibodies appear in breastmilk by 2 weeks after vaccination and persist for 7 weeks; thus lactating patients and their breastfeeding children likely benefit from vaccination.

Treatment

The WHO (https://www.who.int/teams/health-care-readiness/covid-19), and the Infectious Diseases Society of

America (IDSA) (https://www.idsociety.org/practice-guideline/covid-19-guideline-treatment-and-management/) provide guidance for the management of COVID-19 patients from screening to discharge.

While previously vaccinated and otherwise healthy persons with COVID-19 may require only supportive care, additional treatments (discussed below) should be offered to persons with increased risk for complications including unvaccinated, elderly, and immunocompromised individuals. Because of the biphasic nature of *advanced* cases, antiviral therapies may be most efficacious early on in the illness, with a greater role for anti-inflammatory agents at later stages.

A. Viral Protease Inhibitors

The oral boosted protease inhibitor nirmatrelvir/ritonavir (**Paxlovid**) is FDA-approved for the treatment of mild to moderate COVID-19 in outpatients age 12 years or older weighing ≥ 40 kg who are at high risk for progression to severe COVID-19. Treatment should be initiated within 5 days of symptom onset. Akin to protease inhibitors used in the treatment of HIV, nirmatrelvir is boosted with ritonavir, a potent CYP3A4 inhibitor. In phase 2/3 trials, nirmatrelvir/ritonavir showed a relative risk reduction of about 85% for hospitalization or death for patients at high risk of severe disease. The dose is 300 mg nirmatrelvir/100 mg ritonavir orally every 12 hours for 5 days (nirmatrelvir dose adjusted to 150 mg for GFR 30–60 mL/min/1.73 m^2 and contraindicated with GFR < 30 mL/min/1.73 m^2). The benefit of nirmatrelvir/ritonavir among otherwise healthy vaccinated persons is less clear, but treatment is still recommended for persons at increased risk of severe disease based on age or medical comorbidities (particularly in setting of immunocompromise).

Recurrent symptomatic viremia (“rebound”) has been reported in up to 6.6% of patients after nirmatrelvir/ritonavir is stopped, but this phenomenon has also been noted with molnupiravir therapy and in the absence of antiviral therapy. Recurrent symptoms tend to be mild. The use of nirmatrelvir/ritonavir requires screening for potentially serious drug interactions (see https://www.covid19-druginteractions.org/checker), including with several anticonvulsants and antidepressants. Suspension of certain medications during nirmatrelvir/ritonavir treatment may be considered, but when CYP3A4 enzyme inducers are being used (eg, phenytoin, rifampin), alternative anti-COVID therapy is needed. For patients with a creatinine clearance < 30 mL/min, nirmatrelvir/ritonavir should *not* be given.

Ensitrelvir, an oral SARS-CoV-2 3C-like protease inhibitor currently available in Japan, was found to reduce symptom duration by about 1 day compared to placebo among patients treated within < 72 hours of disease onset in the SCORPIO-SR trial.

B. RNA Polymerase Inhibitors

Remdesivir (Veklury) is a viral RNA-dependent RNA polymerase (RdRp) inhibitor approved by the FDA for the treatment of COVID-19 patients requiring hospitalization. Although trials have not demonstrated a mortality benefit from remdesivir, existing data suggest it improves time to clinical recovery. Remdesivir is recommended for hospitalized patients requiring supplemental oxygen therapy, but its benefit among patients receiving mechanical ventilation or ECMO is uncertain. Among hospitalized patients, 5 days of remdesivir was found to be noninferior to 10 days of remdesivir. In some cases, treatment beyond 5 days may be considered depending on the patient’s clinical trajectory. Remdesivir also has a role in treatment of outpatients with mild to moderate COVID-19 who are at increased risk for severe disease based on age ≥ 60 or comorbidities and are seen within 7 days of symptom onset. Treatment duration is 3 days in these cases, and was associated with an 87% reduction in risk of death or hospitalization in a study done before COVID19 vaccinations were widely available. Remdesivir is available only for intravenous use. Liver function test monitoring is recommended during treatment.

Molnupiravir is an oral antiviral that targets the SARS-CoV-2 RdRp and induces mutations that prohibit coronaviral propagation. While molnupiravir has been associated with reduced mortality compared to placebo, its overall role at a time when COVID-19 related mortality is low remains to be defined. Concern has also been raised about its mutagenic potential. Thus, molnupiravir should not be used in pregnant or breastfeeding women or those under 18 years of age (in whom it may affect bone and cartilage growth). Persons who are of childbearing potential or who have sexual partners of childbearing potential should use effective contraception while taking molnupiravir and subsequent to completing molnupiravir therapy (4 days for females, 3 months for males). In the United States, an FDA EUA has been granted for molnupiravir (800 mg every 12 hours for 5 days) *for the treatment of mild to moderate COVID-19* in adults with positive SARS-CoV-2 tests provided they are: (1) evaluated within 5 days of symptom onset; (2) at high risk for progression to severe disease, hospitalization, or death; and (3) not able to receive other FDA-approved COVID-19 antiviral therapies (ie, nirmatrelvir/ritonavir [Paxlovid] or remdesivir).

C. Corticosteroids

Dexamethasone has been shown to reduce the risk of death among hospitalized patients with severe respiratory complications of COVID-19. *Dexamethasone is recommended only for treatment of patients with severe disease* (ie, those who require supplemental oxygen and those who are mechanically ventilated or need ECMO). A 10-day course of therapy is standard but can abbreviated in cases with quick clinical improvement. Very lengthy steroid courses should be avoided due to potential for multiple adverse effects including superinfection, bleeding, hyperglycemia, hypertension, and neuropsychiatric complications among others. Patients without hypoxia and who do not require mechanical ventilation or ECMO should *not* be given corticosteroids. If dexamethasone is unavailable, the NIH COVID-19 treatment guidelines recommend using alternative glucocorticoids, including prednisone, methylprednisolone, or hydrocortisone.

D. IL-6 Receptor Inhibitors

The IL-6 receptor inhibitors tocilizumab and sarilumab were developed and FDA-approved for treatment of a variety of autoimmune/inflammatory conditions including rheumatoid arthritis and were subsequently evaluated as adjunctive therapeutics for severe COVID-19 based on the recognition that high levels of IL-6 are a key component of the "cytokine storm" associated with severe SARS-CoV-2 infection. Of the two agents, there is greater clinical experience with tocilizumab. IL-6 inhibitors can be considered for patients with rapidly increasing respiratory needs and evidence of systemic inflammation, as well as those within 24 hours of admission to the ICU. They are not recommended in the setting of an underlying immunocompromising condition or concurrent (non–COVID-19) infection. IL-6 inhibitors can be used concurrently with corticosteroids, but JAK inhibitors such as baricitinib or tofacitinib (discussed below) should not be given with tocilizumab or sarilumab.

E. Janus Kinase Inhibitors

The Janus kinase (JAK) inhibitors baricitinib and tofacitinib also have attracted interest as adjunctive anti-inflammatory therapies in COVID-19. Like the IL-6 antagonists, these agents are also FDA-approved for treatment of autoimmune/inflammatory conditions including rheumatoid arthritis. In the context of COVID-19, JAK inhibitors have been associated with reduced disease progression and may be associated with reduced mortality. They may be most beneficial for persons receiving high-flow supplemental oxygen or noninvasive ventilation. Baricitinib has been studied in combination with remdesivir and may be considered as an alternative to corticosteroids among persons unable to tolerate corticosteroids. Due to venous thromboembolism risk, persons receiving JAK inhibitors should receive at least prophylactic-dose anticoagulation.

Prognosis

In the earlier COVID-19 surges, the infection fatality rate was < 1% for persons age < 65 years but increased to 15% for persons age ≥ 85 years. The severity of the infection has evolved as variants have appeared and population immunity has increased from infection, vaccination, or both. In a large CDC analysis conducted from December 2020 to October 2021 among > 1.2 million adults who completed primary vaccination, the rate of COVID-19 severe breakthroughs was 0.015% and the rate of COVID-19 death after a vaccine breakthrough was 0.0033%. A large analysis of severe breakthrough infections after 2 vaccine doses across 30 million individuals in the United Kingdom showed that age ≥ 80 years, chronic kidney disease, being on immunosuppressants, or having ≥ 5 comorbidities were continued risk factors for severe diseases. These kinds of population-level studies allow the public health community to target those at risk of severe breakthroughs (older patients and those on immunosuppressants) for booster vaccination and antiviral treatment.

When to Admit

The principal complications requiring admission for adults with COVID-19 are respiratory. Progression to respiratory failure and ARDS can be rapid, and any patient in a high-risk category for complications (eg, those with advanced age, immunosuppression, or chronic diseases, such as hypertension, obesity, and diabetes) or any patient with evident thrombotic, neurologic, or multiple organ system disease should be admitted for observation and placed under intensive care based on respiratory parameters.

2. Respiratory Syncytial Virus (RSV) & Other Paramyxoviruses

ESSENTIALS OF DIAGNOSIS

- RSV is a major cause of morbidity and mortality at the extremes of age (< 5 years and > 65 years).
- Treatment is largely supportive.
- No active vaccination for RSV is available.

General Considerations

RSV is a paramyxovirus that causes annual outbreaks during the wintertime with usual onset of pulmonary symptoms between mid-October and early January in the continental United States, although RSV incidence first decreased then increased at unseasonable times in 2022 after the peak of the COVID-19 pandemic. Outside the United States, RSV usually peaks during wet months in areas with high annual precipitation and during cooler months in hot and dry areas. Infections occur earlier in urban areas. RSV is also shown to be increased among refugees and asylum seekers. Each year RSV causes > 3.6 million hospitalizations and ~100,000 deaths in children < 5 years of age.

There are two major subtypes of RSV: A and B. The A subtype may be associated with severe disease. RSV is a frequent cause of hospitalization in US children, with annual hospitalization rates of 6 per 1000 children younger than 5 years. RSV is the most common cause of bronchiolitis and pneumonia in children younger than 1 year in the United States. Prematurity and bronchopulmonary dysplasia are major risk factors for severe disease. Early RSV bronchiolitis in children, along with a family history of asthma, are associated with persistence of airway reactivity later in life.

RSV also causes upper and lower respiratory tract infection in adults, with the virus entering through contact with mucous membranes. RSV occurs with increasing severity in those with comorbid conditions, older adults (accounting for a rate of 4 per 1000 hospitalizations and 14,000 deaths annually), persons with severe combined immunodeficiency, and patients after lung or bone marrow transplantation (because CD8 T cells are not available for viral clearance). An IL-1 receptor polymorphism is associated with more severe bronchiolitis. Recurrences occur throughout life. In 2023, major advances in combatting RSV occurred, with two RSV vaccines being approved for individuals 60 years and older and for pregnant women between 32 and 36 weeks' gestation to protect the neonate. A monoclonal antibody for RSV (nirsevimab) was approved for infants and young children for severe disease. The average incubation period is 5 days. Up to 10% of disease classified as invasive pneumococcal disease is thought to be RSV or influenza.

In immunocompromised patients, such as bone marrow transplant recipients, serious pneumonia can occur, and outbreaks with a high mortality rate (> 70%) are reported.

Other paramyxoviruses important in human disease include human metapneumovirus, parainfluenza virus, and Nipah virus.

Human metapneumovirus is a ubiquitous seasonal virus circulating during late winter to early spring. It is divided into subgroups A and B. Metapneumovirus accounted for 7.3% of childhood (younger than 16 years old) pneumonia in a Norwegian series of 3650 patients in which RSV accounted for 28.7%. Clinical presentations range from mild upper respiratory tract infections to severe lower respiratory tract infections (eg, bronchiolitis, croup, and pneumonia). Lower respiratory tract (sometimes severe) infections are observed among immunocompromised and older adults, especially residents of nursing homes. In lung transplant recipients, human metapneumovirus is a common cause of respiratory illness and may increase the risk of acute and chronic graft rejection. Ribavirin appears to be well tolerated in lung transplant recipients with metapneumovirus infection. The control of RSV infection in modeling studies reduces the incidence of human metapneumovirus infection.

Human parainfluenza viruses (HPIVs) are commonly seen in children and are the most common cause of laryngotracheitis (croup). Four different serotypes are described, and they differ in their clinical presentations as well as epidemiology. HPIV-1 and HPIV-2 are responsible for croup. HPIV-3 is associated with bronchiolitis and pneumonia. HPIV-4 is a less frequently reported pathogen. Reinfections are common throughout life. HPIVs can also cause severe disease in older individuals, immunocompromised persons, and patients with chronic illnesses.

Nipah virus is a highly virulent paramyxovirus first described in 1999. Cases are concentrated mainly in Southeast Asia (Malaysia, Singapore, Bangladesh, and India). Fruit bats are identified as the natural host of the virus. An outbreak of 14 cases, 8 fatal, occurred in Bangladesh associated with drinking date palm sap between 2010 and 2014. Direct pig-human, cow-human, human-human, and nosocomial transmission are reported. Nipah virus causes acute encephalitis with a high fatality rate (67–92%), although respiratory symptoms are also described. Cranial nerve palsies, encephalopathy, and dystonia are among neurologic sequelae (15–32%) seen in infected individuals. Relapses occurring weeks and months after initial infection are described (3.4–7.5%).

Clinical Findings

A. Symptoms and Signs

In RSV bronchiolitis, proliferation and necrosis of bronchiolar epithelium develop, producing obstruction from sloughed epithelium and increased mucus secretion. Signs of infection include low-grade fever, tachypnea, and wheezes. Apnea is a common presenting symptom. Hyperinflated lungs, decreased gas exchange, and increased work of breathing are present. Pulmonary hemorrhage is reported. *In children, RSV is globally a common cause of acute lower respiratory infection and acute and recurrent otitis media.*

B. Laboratory Findings

A rapid diagnosis of RSV infection is made by viral antigen identification of nasal washings using an ELISA or immunofluorescent assay; molecular rapid tests are also used. Multiplex assays in conjunction with other respiratory viruses, most commonly influenza and SARS-CoV-2, are available commercially. RSV viral load assay values at day 3 of infection may correlate with requirement of intensive care and respiratory failure in children.

Human metapneumovirus is best diagnosed by PCR. Tests for rapid detection of viral antigens with immunofluorescence, ELISA, and PCR techniques are widely available for detection of HPIV. Culture may also be used. ELISA (serum and CSF) and PCR (urine and respiratory secretions but not blood) are both used for Nipah virus infection diagnosis.

Treatment & Prevention

Treatment of RSV consists of supportive care, including hydration, humidification of inspired air, monoclonal antibody therapy in neonates, antibiotic therapy (to reduce other respiratory morbidity) if concomitant bacterial pneumonia is suspected, and ventilatory support as needed. Neither bronchodilating agents nor corticosteroids show efficacy in bronchiolitis although individual patients with significant bronchospasm or history of asthma may respond to them.

The use of aerosolized ribavirin or RSV-enriched IVIG, or both, can be considered in high-risk patients, such as those with a history of bone marrow transplantation, and appears to lessen mortality.

Several additional agents are under study for treatment of RSV. They include small-molecule RSV fusion inhibitors that bind to the surface F protein (such as rilematovir, presatovir, ziresovir, and sisunatovir). Compounds targeting viral replication also have been under study.

The monoclonal antibody **nirsevimab** is currently available in the United States, Europe, and the United Kingdom to prevent RSV in neonates during their first season at risk (and extended in the United States through their second at-risk season). The antibody targets the F fusion protein on the surface of RSV and is generally tolerated well (8% incidence of adverse effects).

The prophylactic monoclonal antibody palivizumab, while recommended for and effective in high-risk infants (premature infants < 32 weeks' gestation as well as infants 32–25 weeks' gestation with additional risk factors such as congenital heart and lung diseases and Down syndrome), is not of proven efficacy among adults with RSV. The monoclonal antibody nirsevimab also effectively prevents RSV-associated lower respiratory tract infections in premature and term infants. Another monoclonal antibody with a distinct mechanism of action, clesrovimab, is undergoing phase 3 trials.

While at least 24 vaccines are currently in development, 3 vaccines are currently approved and available for use in adults in the United States: Arexvy (GSK), Abrysvo (Pfizer), and mRESVIA (Moderna). The CDC recommends that one of these agents be given to all adults age 75 and older and adults 70–75 with certain immunosuppressive or chronic disease states such as asthma. The vaccines are well tolerated and can be given with the influenza vaccines. Vaccination of pregnant women between 30 and 34 weeks of pregnancy is recommended to reduce the incidence of neonatal RSV infection.

Prevention in hospitals entails rapid diagnosis, hand washing, contact isolation, and perhaps passive immunization. (Passive immunization is costly but is associated with improved antiviral titers in hematologic stem cell transplant recipients.) The use of conjugated pneumococcal vaccination appears to decrease the incidence of concomitant pneumonia associated with viral infections in children in some countries. Viral shedding averages 11 days and correlates inversely with age and directly with severity of infection.

Therapeutic modalities for human metapneumovirus and parainfluenza virus infections under investigation include intravenous ribavirin administration.

3. Seasonal Influenza

ESSENTIALS OF DIAGNOSIS

- *Cases usually in epidemic pattern.*
- Onset with fever, chills, malaise, cough, coryza, and myalgias.
- Aching, fever, and prostration out of proportion to catarrhal symptoms.
- Leukopenia.

General Considerations

Influenza (an orthomyxovirus) is a highly contagious disease transmitted by the respiratory route in humans. Transmission occurs primarily by *droplet nuclei* rather than fomites or direct contact. Three types of influenza viruses infect humans. While type A can infect a variety of mammals (humans, swine, horses, etc) and birds, types B and C almost exclusively infect humans. Type A viruses are further divided into subtypes based on the hemagglutinin (H) and the neuraminidase (N) expressed on their surface. Eighteen subtypes of hemagglutinin and 11 subtypes of neuraminidase are identified. Type B virus neuraminidase has fewer subtypes.

Annual epidemics usually appear in the fall or winter in temperate climates. Up to 5 million cases of severe influenza and 500,000 deaths are estimated by the WHO to occur annually, with approximately 0.5 million annual deaths. Influenza epidemics affect 10–20% of the global population (3–11% with a mean of 8% in the United States) on average each year and are typically the result of minor antigenic variations of the virus, or **antigenic drift**, which occur often in influenza A virus. On the other hand, pandemics—associated with higher mortality—appear at longer and varying intervals (decades) as a consequence of major genetic reassortment of the virus (**antigenic shift**) or adaptation of an avian or swine virus to humans (as with the pandemic H1N1 virus of 1918).

The highly pathogenic avian influenza subtypes are discussed in the next section. The novel swine-origin influenza A (pandemic H1N1) virus emerged in Mexico in 2009 and quickly spread throughout North America and the world causing a pandemic. This virus originated from triple-reassortment of North American swine, human, and avian virus lineages and Eurasian swine virus lineages and replaced the previous H1N1 seasonal virus.

Clinical Findings

A. Symptoms and Signs

Type A and B seasonal influenza viruses produce clinically indistinguishable infections, whereas type C usually causes mild illness. The incubation period is 1–4 days. In unvaccinated persons, uncomplicated influenza often begins abruptly. Symptoms range widely from nearly asymptomatic to a constellation of systemic symptoms (including fever, chills, headache, malaise, and myalgias) and respiratory symptoms (including rhinorrhea, congestion, pharyngitis, hoarseness, nonproductive cough, and substernal soreness). GI symptoms and signs may occur, particularly among young children with influenza B virus infections. Fever lasts 1–7 days (usually 3–5). Older patients especially may present with lassitude and confusion, often without fever or respiratory symptoms. Signs include mild pharyngeal injection, flushed face, and conjunctival redness. Moderate enlargement of the cervical lymph nodes and tracheal tenderness may be observed. The presence of fever (higher than 38.2°C) and cough during influenza season is highly predictive of influenza infection in those older than 4 years. Idiopathic thrombocytopenic purpura also is a recognized complication.

Influenza is also a travel-associated illness, and providers need be aware of the differential seasonality of the disease in assessing potential travel-associated illnesses.

B. Laboratory Findings

Rapid influenza diagnostic tests for detecting influenza antigens from nasal or throat swabs are widely available, highly specific, and produce fast results but have low sensitivity leading to high false-negative results. Because of this, *the CDC recommends empirically treating patients in whom influenza is suspected.* Not all commercial rapid influenza diagnostic tests can differentiate between influenza A and influenza B, and none of the available rapid influenza diagnostic tests can provide information on influenza A subtypes. Newer digital immunoassays and rapid nucleic acid amplification tests are more sensitive than traditional rapid influenza diagnostic tests; however, the sensitivity and specificity of newer PCR techniques are compromised early in the season during low prevalence periods. A nasopharyngeal swab, nasal aspirate, combined nasopharyngeal swab with oropharyngeal swab, or material from a bronchoalveolar lavage can be tested for any influenza strain. When influenza pneumonia is suspected, lower respiratory tract specimens should be collected and tested for influenza viruses by RT-PCR or the above assays.

Differential Diagnosis

The differential diagnoses for influenza-like infections include a variety of viral respiratory infections (SARS-CoV-2, parainfluenza, RSV, atypical dengue, adenovirus, enterovirus, coronavirus) or other viral infections (flavivirus, CMV, EBV, acute HIV infection), as well as bacterial infections such as mycobacterial infection (atypical pneumonia), pertussis, and Legionnaire disease. Epidemiologic factors can suggest Legionnaire (older adults who smoke cigarettes). Chronicity of cough may suggest adenovirus, mycobacterial, or pertussis infection. Leukocytosis and lymphadenopathy are more often seen with CMV and EBV. Distinguishing influenza from dengue requires attention to rhinitis (influenza) and thrombocytopenia (dengue) and travel history.

Complications

Hospitalization or ICU admission for influenza is often a consequence of diffuse viral pneumonitis with severe hypoxemia and sometimes shock. Patients with asthma, residents of nursing homes and long-term care facilities, adults aged 65 years or older, persons who have morbid obesity, and persons with underlying medical conditions (pulmonary, renal, cardiovascular, hepatic, hematologic, neurologic, and neurodevelopmental conditions; and immune-deficient conditions, such as HIV, diabetes, and cirrhosis) are at high risk for complications. Infection during pregnancy increases the risk for hospitalization and may be associated with severe illness, sepsis, pneumothorax and respiratory failure, spontaneous abortion, preterm labor, and fetal distress.

Influenza causes necrosis of the respiratory epithelium, increased adherence of bacteria to infected cells, and ciliary dysfunction, which predispose to secondary bacterial infections. Pneumococcal pneumonia is the most common secondary infection, and staphylococcal pneumonia is the most serious. *Haemophilus* spp infections also occur. Other frequent complications are acute sinusitis, otitis media, and purulent bronchitis.

CVDs are a complication of influenza infection, in particular among older adults, and influenza is postulated to be a significant trigger for MI, cerebrovascular disease, and sudden death. Several studies suggest that influenza vaccination protects against major adverse cardiovascular events. Neurologic complications, including seizures and encephalopathy, may occur. Encephalopathic complications of influenza are uncommon.

Reye syndrome is a rare and severe complication of influenza (usually B type) and other viral diseases (especially varicella), particularly in young children. It consists of rapidly progressive hepatic failure and encephalopathy, and the mortality rate is 30%. The pathogenesis is unknown, but the syndrome is associated with aspirin use in the management of viral infections.

Prevention

Annual administration of influenza vaccine is the most effective measure for preventing influenza and its complications. Seasonal influenza vaccines can reduce influenza hospitalizations by up to an estimated 60%, although the efficacy varies considerably by year (as low as 19% during the 2014–2015 season, but 60% from the 2010–2011 season). Vaccination of health care workers is associated with decreased mortality among hospitalized patients and those in long-term care facilities. Vaccination prevents influenza illness among pregnant patients and their infants during the first months of life.

Multiple measures of CVD are improved with influenza vaccinations including the incidence of myocardial infarction, TIA, cardiac arrest, stroke, and overall mortality.

The ACIP and the American College of Obstetricians and Gynecologists Committee recommend annual influenza vaccination for all persons > 6 months of age with no contraindications. Vaccination is emphasized for high-risk groups and their contacts and caregivers.

Several Cochrane database analyses have examined the efficacy of the influenza vaccines in select populations. The studied groups include patients with COPD (a documented reduction in exacerbations with inactivated vaccine), older adults (where vaccination shows some efficacy), adults with cancer (weak evidence, some lower mortality and influenza-related outcomes), healthy adults (established efficacy with inactivated vaccine, but only modest effects in pregnant patients and newborns), and healthy children (where both live and inactivated vaccines lower the rate of influenza infections).

Other reviews establish the efficacy and safety of influenza vaccination in patients with rheumatoid arthritis, asthma, or myasthenia gravis, and older nursing home patients. Patients with obesity have an impaired response to the influenza vaccine.

Multiple influenza vaccine products are licensed in the United States and available from different manufacturers (see Table 35–8). As of the 2024–2025 influenza season, quadrivalent vaccines are no longer recommended. Available vaccines include the standard- or high-dose vaccine. The CDC does not endorse one influenza vaccine product over another, although each influenza vaccine product has different age indications and contraindications. The CDC publishes its annual influenza recommendations in the late summer (https://www.cdc.gov/mmwr/).

Adults > 18 years, including pregnant patients, can receive any influenza vaccine, with few exceptions. Patients 65 years or older should receive a high-dose trivalent inactivated influenza vaccine containing several times more hemagglutinin than standard-dose influenza vaccines. Some data suggest intradermal vaccination is more effective than intramuscular vaccination in older adults. *The COVID-19 vaccines can be safely coadministered with the inactivated seasonal influenza vaccines with an acceptable reactogenicity profile and without evidence of immunointerference.* Several combined influenza and SARS-CoV-2 vaccines are under study.

Vaccination is contraindicated for persons with a history of severe allergic reaction to an influenza vaccine. Precautions should be taken if patients report a history of Guillain-Barré syndrome 6 weeks following an influenza vaccine and if patients have a moderate to severe acute illness with or without fever until clinical improvement. The new recommendation for those with egg allergy is that only those with urticarial reactions should be observed closely but all vaccinated patients should be followed for possible reactions regardless of egg allergy history. Dendritic targeting is a new form of vaccine strategy. Additional vaccine information can be found at https://www.cdc.gov/flu/professionals/.

When antiviral chemoprophylaxis is used, it prevents 70–90% of influenza infections. *Chemoprophylaxis is not routinely recommended and is not recommended prior to exposure to prevent development of resistance.* Chemoprophylaxis may be considered for persons at increased risk for complications from infection who are exposed to an infected patient within 2 weeks of vaccination, for persons unlikely to respond to vaccination because of immunosuppression after exposure to an infected person, for persons for whom vaccination is contraindicated and who are at high risk for complications after exposure to an infected person, and for prevention of infection in residents of institutions during an outbreak. Alternatively, a person can be monitored closely, and antiviral therapy initiated at the first onset of symptoms after exposure. Initiation of chemoprophylaxis is not recommended > 48 hours after exposure. Patients taking chemoprophylaxis should seek urgent medical care if an influenza-like illness develops.

Chemoprophylaxis against influenza A and B is accomplished with daily administration of the neuraminidase inhibitors oseltamivir (75 mg/day, oral) or zanamivir (10 mg/day, inhaled) to continue through 7 days after last known exposure. For outbreak control in long-term care facilities and hospitals, a minimum of 2 weeks is recommended, including in vaccinated persons if the seasonal vaccine is not well matched to the circulating strain, to continue until 1 week after identification of the last known case. Zanamivir should not be given as chemoprophylaxis to asthmatic persons, nursing home residents, or children younger than 5 years.

Breakthrough infections with influenza occur with neuraminidase inhibitors (in a study with zanamivir) and with vaccination. The efficacy of chemoprophylaxis is proven for individuals and households but not community settings.

Hand hygiene and surgical facemasks appear to prevent household transmission of influenza virus isolates when implemented within 36 hours of recognition of symptoms in an index patient. Such nonpharmaceutical interventions assist in mitigating the spread of pandemic and interpandemic influenza to unvaccinated persons. In one study, patients with seasonal H1N1 influenza infection were infectious from 1 day before through ~7 days following illness onset. Children and immunosuppressed persons exhibit prolonged viral shedding and may be infectious longer. Winter school breaks during periods of high influenza transmission appear to decrease rates of visits to primary care practitioners for influenza illness among children and adults.

Any hospital patient with suspected infection should be isolated in an individual room with standard and droplet precautions. CDC guidelines recommend the equivalent of N95 masks for aerosol-generating procedures (eg, bronchoscopy, elective intubation, suctioning, administering nebulized medications). For such procedures, an airborne infection isolation room can be used, with air exhausted directly outside or recirculated after filtration by a HEPA filter. Strict adherence to hand hygiene with soap and water or an alcohol-based hand sanitizer and immediate removal of gloves and other equipment after contact with respiratory secretions is essential. Precautions should be maintained until 7 days from symptom onset or until 24 hours after symptom resolution, whichever is longer. Postexposure prophylaxis or close monitoring and early treatment should be considered for close contacts of patients who are at high risk for complications of influenza and may be considered for healthcare personnel, public health workers, or first responders who experienced a recognized, unprotected close contact exposure to a person with influenza virus infection during that person's infectious period.

Treatment

Treatment is supportive. While no one antiviral agent is comprehensively inclusive, antiviral therapy should be considered for all persons with acute illness, in particular those at high risk for developing complications who have a suggestive clinical presentation or with laboratory-confirmed influenza. Clinical trials show a reduction in the duration of symptoms, hospital admissions, and secondary complications such as otitis, sinusitis, or pneumonia, but not mortality when using these agents. Maximum benefit is expected with the earliest initiation of therapy. Although the benefit of antiviral therapy after 48 hours of illness is reduced, it should be initiated if the patient is hospitalized or critically ill. Benefit has been noted up to 4–5 days into illness.

The antiviral treatment of choice should be based on the susceptibility of the circulating virus. Since high levels of resistance to the adamantanes (amantadine and rimantadine) persist among seasonal H1N1 and H3N2 influenza A viruses and these agents are not effective against influenza B viruses, amantadine and rimantadine are not recommended for treatment.

Three neuraminidase inhibitors are FDA-approved for treatment of influenza A and B: oral oseltamivir, inhaled zanamivir, and intravenous peramivir. The CDC recommends treatment with **oral oseltamivir** (75 mg twice daily for 5 days) as the medication of choice for patients of any age, pregnant persons, and patients who are hospitalized or have complicated infection. Absorption of oral oseltamivir is considered reliable, except in patients with impaired gastric motility or GI bleeding. Oseltamivir is, however, not shown to reduce hospitalization when used by otherwise healthy adults.

Inhaled zanamivir (10 mg, two inhalations twice daily for 5 days) is indicated for uncomplicated acute influenza in patients aged 7 years or older, is relatively contraindicated among persons with asthma because of the risk of bronchospasm and is not formulated for use in mechanically ventilated patients. Inhaled zanamivir lacks efficacy in pneumonia, probably due to poor bioavailability in the peripheral lungs.

Intravenous peramivir (600 mg in single dose) is used for outpatient treatment of uncomplicated infection in patients aged 18 years or older. It is also recommended if concern exists about inadequate oral absorption of oseltamivir. The efficacy of peramivir in patients with severe illness and patients with influenza B is not well established. Some studies showed that repeated doses of intravenous peramivir for up to 5 days are safe and effective and shorten the duration of influenza illness.

Resistance to neuraminidase inhibitors (oseltamivir, zanamivir, and peramivir) can occur during or after prolonged use in immunocompromised patients, particularly in persons who have undergone hematopoietic stem cell transplant. **Intravenous zanamivir** is an investigational drug that could be requested for clinical use if concern exists for an oseltamivir-resistant influenza strain. **Laninamivir** is a long-acting inhaled neuraminidase inhibitor used for the treatment of seasonal influenza, including infection caused by oseltamivir-resistant virus. It is licensed in Japan and South Korea but not in the United States, although advanced development studies are underway with Biota Technology.

Baloxavir (a selective inhibitor of influenza cap-dependent endonuclease given as a single oral dose) is FDA-approved for treating uncomplicated influenza A and B infections and postexposure prophylaxis. It is given as 40 mg or 80 mg orally as a single dose depending on weight (the higher dose for persons 80 kg or more) and should be given within the first 48 hours of infection. Its side effects include diarrhea, headache, sinusitis, and bronchitis. The unique mechanism of baloxavir may be beneficial as part of multidrug therapy for resistant or severe disease, however, an RCT (FLAGSTONE) of patients hospitalized with severe influenza, comparing baloxavir plus a neuraminidase inhibitor versus placebo plus a neuraminidase inhibitor did not indicate that combining antivirals improved outcomes. For complicated disease, especially in immunosuppressed patients, the combination of oseltamivir, amantadine, and ribavirin appears to produce faster viral clearance but no definite clinical improvement.

Updated advice is available at http://www.cdc.gov/flu/.

Prognosis

The duration of the uncomplicated illness is 1–7 days, and the prognosis is excellent in healthy adults and children. Hospitalization typically occurs in those with underlying medical disease, at the extremes of age, and in pregnant patients. *Most fatalities are due to bacterial pneumonia, although exacerbations of other disease processes, in particular cardiac diseases, occur.* Pneumonia resulting from influenza has a high mortality rate among pregnant patients and persons with a history of rheumatic heart disease. Mortality among adults hospitalized with influenza ranges from 4% to 8%, although higher mortality (> 10–15%) may be seen during pandemics and among immunocompromised individuals. At least 64% of pneumonia and influenza deaths occurred among older persons in the United States, who comprised only 16% of the population.

If the fever recurs or persists for > 4 days with productive cough and white cell count > 10,000/mcL (10.0×10^9/L), secondary bacterial infection should be suspected.

When to Admit

- Limited availability of supporting services.
- Pneumonia or decreased oxygen saturation.
- Changes in mental status.
- Consider with pregnancy.

4. Avian Influenza

ESSENTIALS OF DIAGNOSIS

- Most human cases occur after exposure to infected poultry.
- Clinically indistinguishable from seasonal influenza.
- Epidemiologic factors assist in diagnosis.
- Rapid antigen assays confirm diagnosis but do not distinguish avian from seasonal influenza.

General Considerations

Zoonotic influenza viruses are distinct from human seasonal influenza viruses and do not traditionally easily transmit between humans. The WHO reports increasing numbers of H5, H7, and H9 subtypes including HPA (highly pathogenic H5 infections) and in 2024 reported > 28,800 cases and 1000 deaths from at least 28 countries worldwide from H5 and H7 subtypes. In addition, a number of viral genetic changes are required for adaptation to humans. For avian influenza viruses, birds are the natural hosts. Around the world and in North America, avian influenza A outbreaks occur in poultry from time to time, and the virus has become endemic in poultry in some countries, mostly China and Egypt. Avian influenza viruses may occasionally infect humans or other mammals, including domestic cats and dogs. Illness in humans ranges from mild disease to rapid progressive severe disease and death depending on the subtype.

The primary risk factor for human infection is direct or indirect exposure to infected live or dead poultry or contaminated environments, such as live bird markets. Slaughtering and handling carcasses of infected poultry are also risk factors.

The emergence of H5, H7, and H9 avian influenza virus subtypes in humans raises concern that the virus may undergo genetic reassortment or mutations in some of the genes and develop greater human-to-human transmissibility with the potential to produce a global pandemic. Fatal avian influenza virus infections acquire their internal gene segments usually but not exclusively from H9N2 viruses.

Human cases of H5N1 have been reported since 1997, and H1N2 was reported from Mexico in 2024. Advanced H4N’ cases are often fatal, and to date, highly pathogenic H5N1 avian isolates (HPA), which are typically associated with the clade 2.3.4.4b, have been reported in mammals since 2003 with spread from originally birds to terrestrial and marine mammals. H5N1 cases have been reported sporadically in 912 cases with a 51.5% mortality from 24 countries. This unique clade has been reported as of late 2024 from 15 patients, 12 with bird, 3 with cattle, and 1 with unknown exposure. The widespread and increasing prevalence of H5N1 isolates from a variety of birds and mammals necessitates the need for surveillance and additional studies.

Clinical Findings

A. Symptoms and Signs

Distinguishing avian influenza from regular influenza is difficult. History of exposure to dead or ill birds or live poultry markets in the prior 10 days, recent travel to Southeast Asia or Egypt, or contact with known cases should be investigated. Patients infected by H5N1 or H7N9 avian influenza A viruses have an aggressive clinical course, and neurovirulence is especially seen with H5Nx subtypes. The symptoms and signs include fever followed by lower respiratory symptoms (cough, dyspnea). Upper respiratory tract symptoms occur less often. GI symptoms are reported more frequently in H5N1 infections. Conjunctivitis is reported in influenza H7 infections. Other systems can also be involved leading to neurologic manifestations (encephalopathy, seizure) and liver impairment. Prolonged febrile states and generalized malaise are common. Respiratory failure, multiorgan dysfunction, and septic shock are the usual causes of death. Bacterial superinfections are reported.

B. Laboratory Findings

Commercial rapid antigen tests are not optimally sensitive or specific for detecting H5N1 influenza and should *not* be the definitive test for influenza. More sensitive RT-PCR assays are available through many hospitals and state health departments. Diagnostic yield can be improved by early collection of samples, preferably within 7 days of illness onset. Throat swabs or lower respiratory specimens (such as tracheal aspirate or bronchoalveolar lavage fluid) may provide higher yield of detection than nasal swabs. When highly pathogenic strains, such as H5N1 influenza virus infections, are suspected, extreme care in the handling of these samples must be observed during preliminary testing. Positive samples must then be forwarded to the appropriate public health authorities for further investigation (eg, culture) in laboratories with the adequate level of biosafety (level 3). With the spread of avian influenza isolates to a variety of mammals, it is important that a variety of reliable diagnostic methods be made available.

Prevention

The most effective method of prevention is *avoidance of exposure*. Those who work with poultry should practice good hand hygiene and use appropriate personal protective equipment. These workers should also be vaccinated against seasonal influenza since this can reduce the likelihood of coinfection with avian and seasonal influenza. All persons, especially those with influenza risk factors, should avoid visiting live poultry markets and contact with ill birds. No risk exists for acquiring avian influenza by consuming well-cooked poultry products. The US government bans the importation of poultry from infected areas. Culling of animals has been effective in ending outbreaks of highly pathogenic avian influenza but is difficult with H7-infected poultry because most are asymptomatic. Policies regarding the closure of live poultry markets during avian epidemics are controversial. The H5N1 avian influenza strain that got into dairy cows was found in pasteurized milk in the spring of 2024 but was not live or considered contagious.

Persons with exposure should monitor themselves for 10 days after the last known exposure and seek prompt medical attention if new fever or respiratory symptoms develop. Postexposure prophylaxis is not recommended for persons working with noninfected birds or who have used appropriate personal protective equipment while working with infected birds. For persons with exposure to infected persons, postexposure prophylaxis is recommended for household and family members and may be considered for health care personnel with close unprotected contact. Postexposure prophylaxis regimens include oseltamivir, 75 mg orally, or zanamivir, 10 mg inhaled twice daily for 5 or 10 days from the last known exposure, depending on the length of the exposure. Careful surveillance for human cases and prudent stockpiling of medications with establishment of an infrastructure for dissemination are essential control modalities. Nonpharmacologic means of control include masks, social distancing, quarantine, travel limitations, and infrastructure development, particularly for emergency departments.

Vaccines do not provide cross-protection against strains of the H5, H7, and H9 influenza viruses. The US government has prepandemic stockpiles of adjuvanted H5N1 and H7N9 vaccines that are not available to the public. The highly diverse genetic nature and the rapid evolution of the avian influenza viruses have resulted in the emergence of viruses that are not covered by stockpiled vaccines. The FDA approved an adjuvanted influenza A (H5N1) monovalent vaccine (Audenz) in January 2020. It is approved for patients 6 months of age and older. An adjuvanted recombinant hemagglutinin H7 vaccine against avian influenza A subtype H7N9 has been shown to be safe and immunogenic in healthy adults. The global increase in H5N8 in birds is a particular concern.

Because the potential for pandemic influenza for many of the new reassortment viruses is not fully known, continued surveillance is essential, and stockpiling of vaccines, adjuvant, and medications (oseltamivir and zanamivir) is warranted at the public health level.

Treatment

Persons with severe illness and confirmed and probable cases with mild disease should receive treatment as soon as possible. The first-line recommendation is to use the neuraminidase inhibitor oseltamivir, 75 mg orally twice daily for 5 days administered within 48 hours from onset of illness. Longer courses of therapy (eg, 10 days) should be considered in hospitalized patients with severe illness and persistent viral shedding. Data are lacking for inhaled zanamivir or peramivir for severe avian influenza. Overall oseltamivir, by modeling, is associated with a 49% reduction in mortality from H5N1 avian influenza virus infections. As with seasonal influenza, enteric oseltamivir is well absorbed in critically ill persons without gastric stasis, known malabsorption, or GI bleeding. Daily intravenous peramivir (600 mg, reduced to 200 mg for kidney dysfunction) for a minimum of 5 days and a maximum of 10 or more days (depending on severity of illness) or zanamivir (10 mg inhaled daily for 10 days) may be considered in such patients. Combination therapy with amantadine or rimantadine (in countries where H5N1 influenza virus A strains are likely susceptible to adamantanes) may be considered in patients with pneumonia or progressive disease. Resistance of avian H5N1 influenza strains to amantadine and rimantadine is present in most geographic areas. Resistance to neuraminidase inhibitors (oseltamivir, zanamivir, and peramivir) can occur in patients with H5NA and H7N9 avian infection. Successful treatment with administration of convalescent plasma is reported.

5. Severe Acute Respiratory Syndrome (SARS-CoV-1)

ESSENTIALS OF DIAGNOSIS

- Mild, moderate, or severe respiratory illness.
- Travel to endemic areas within 10 days before symptom onset, including mainland China, Hong Kong, Singapore, Taiwan, Vietnam, and Toronto.
- Persistent fever; dry cough, dyspnea in most.
- Diagnosis confirmed by antibody testing or isolation of virus.
- There is no specific treatment; mortality is as high as 14% in clinically diagnosed cases.

General Considerations

SARS-CoV-1 (previously referred to as "SARS") is a respiratory syndrome caused by a coronavirus, transmitted through direct or indirect contact of mucous membranes with infectious respiratory droplets. The virus is shed in stools, but the role of fecal-oral transmission is unknown. The natural reservoir appears to be the horseshoe bat (which eats and drops fruits ingested by civets, the earlier presumed reservoir and a likely amplifying host), which can carry a variety of different coronavirus strains.

The earliest cases were traced to a healthcare worker in Guangdong Province in China in late 2002, with rapid spread thereafter throughout Asia and Canada, considered a consequence of spread through travel. The last cases were reported in 2004. The 2003 outbreak involved 8098 probable cases from 29 countries, with 774 fatalities. Nine additional cases associated with a research laboratory were reported in China in 2004 with no further cases reported since then anywhere in the world. A 29-base pair deletion evolved during the course of human-to-human transmission, and it is thought to be responsible in part for the abeyance of the outbreak.

6. Middle East Respiratory Syndrome–Coronavirus (MERS-CoV)

ESSENTIALS OF DIAGNOSIS

- Mild, moderate, or severe respiratory illness.
- Travel to endemic areas, including the Arabian Peninsula and neighboring countries, within 14 days before symptom onset.
- Contact with camels has been reported in many cases.
- Fever, cough, and dyspnea.
- CDC can assist with RT-PCR.
- Supportive treatment; mortality 36–45%.

General Considerations

MERS is a syndrome associated with a coronavirus similar to the cause of SARS. Patients with MERS have had a history of residence or travel in the Middle East, in particular Saudi Arabia, or contact with such patients. The virus is transmitted between humans through direct or indirect contact of mucous membranes with infectious respiratory droplets. The virus is shed in stool, but the role of fecal-oral transmission is unknown. The earliest cases were identified in 2012 in the Kingdom of Saudi Arabia, and 75% of all cases have occurred there. Additional cases have occurred throughout the Middle East, Africa, and Europe, with a reported death rate of 36% (http://www.who.int/emergencies/mers-cov/en/). Only two cases have ever been identified in the United States; both were reported in 2014 in health care providers who lived and worked in Saudi Arabia. As of October 2022, 2600 cases of MERS had been reported to the WHO, including 935 deaths (case fatality rate of 36%); most were reported from Saudi Arabia.

So-called superspreaders are often responsible for propagating the pathogen in the early stages of an outbreak. It is also recognized more often that asymptomatic cases are frequent, especially among children, and they may contribute to disease transmission. Person-to-person transmission can occur within families; hospital-associated cases comprise 10–25% of reported infections. The median incubation period is 5 days (range, 2–14) with the mean age of 50 (range 9 months to 99 years) and 65% occurring among men. Over 90% of patients have an underlying medical condition, including diabetes mellitus (68%), hypertension (34%), or chronic heart or kidney disease. Those with diabetes, kidney disease, chronic lung disease, or other immunocompromising conditions likely are at highest risk for severe disease.

Camels (especially female camels) appear to be the principal reservoir, and several studies show that contact with dromedary herds of camels is greater among cases than controls. Raw camel milk is considered a potential source. Persons who work with camels are more likely to have antibody evidence of past infection. Camels most commonly infected with MERS are females, dromedary, young, in free herds, and imported.

Clinical Findings

A. Symptoms and Signs

MERS is an acute respiratory syndrome, with the most common symptoms being fever (98%), cough (83%), and dyspnea (72%). Chills and rigors are common (87%). GI symptoms may occur, with diarrhea being most common (26%), followed by nausea and abdominal pain, and may precede respiratory symptoms. Mild and asymptomatic cases are reported.

B. Laboratory Findings and Imaging

Hematologic findings in the largest series to date include thrombocytopenia (36%), lymphopenia (34%), and lymphocytosis (11%). Moderate elevations in LD (49%), AST (15%), and ALT (11%) are recognized. CXR abnormalities are nearly universal and include increased bronchovascular markings, patchy infiltrates or consolidations, interstitial changes, opacities (reticular and nodular) and pleural effusions, and total lung opacification. Ground-glass opacities and consolidation are most commonly seen. The findings mimic those of many other causes of pneumonia.

Serum serologies and RT-PCR are available through CDC (https://www.cdc.gov/coronavirus/mers/lab/index.html). Highest viral loads are found in lower respiratory tract specimens, including bronchoalveolar lavage fluid, sputum, and tracheal aspirates. These samples are preferred for diagnosis. The CDC recommends sending lower respiratory tract specimens, nasopharyngeal and oropharyngeal swabs, and serum for testing. In confirmed cases, serial sample collection (perhaps every 2–4 days) from multiple sites is recommended to increase understanding of virus shedding kinetics. In cases where symptom onset occurred > 14 days prior and symptoms are ongoing, serum should be sent to the CDC for serologic testing and the above specimens should be sent for RT-PCR.

C. Case Definition

A patient with severe illness shows the following characteristics: fever (38°C, 100.4°F or higher) and pneumonia or ARDS (based on clinical or radiologic evidence); and either history of travel in or near the Arabian Peninsula within 14 days before symptom onset; or close contact with a symptomatic traveler in whom fever and acute respiratory illness (not necessarily pneumonia) developed within 14 days after traveling in or near the Arabian Peninsula (above); or is a member of a cluster of patients with severe acute respiratory illness (eg, fever and pneumonia requiring hospitalization) of unknown etiology in which MERS-CoV is being evaluated, in consultation with state and local health departments.

In milder illness, patients have fever and symptoms of respiratory illness (not necessarily pneumonia; eg, cough, shortness of breath) and history of having close contact with a confirmed MERS case as well as a history of being in a health care facility (as a patient, worker, or visitor) within 14 days of symptom onset in a country or territory within the Arabian Peninsula in which recent healthcare-associated cases of MERS have been identified.

Of note, fever may *not* be present in certain patients, including very young, older adults, immunosuppressed individuals, or those taking certain medications.

Complications

Respiratory failure is such a common complication that in a series from Saudi Arabia, 89% of patients required intensive care and mechanical ventilation. Patients with MERS-CoV appear to advance faster to respiratory failure than do those with SARS.

Prevention

Isolation and quarantine of cases are authorized by the CDC. Strict infection control measures are essential as well as care and management of household contacts and hospital workers engaged in the care of patients. Travelers to Saudi Arabia (including the many pilgrims to the holy sites) should practice frequent hand washing and avoid contact with those who have respiratory symptoms. Evaluation of patients with suspect symptoms within 14 days of return from Saudi Arabia is essential. Because healthcare workers engaged in procedures that involve contact with respiratory droplets are at risk, isolation of high-risk patients is essential, as are simple hygienic measures. Limiting the number of hospital contacts and visits is important. Control measures, including quarantining in the home for high-risk exposed persons and using facemasks to prevent hospital-acquired infections, are important. Assisting public health authorities with case reporting and surveillance is essential. Postexposure prophylaxis with ribavirin and lopinavir/ritonavir for healthcare workers is associated with a 40% decrease in the risk of acquiring infection.

Camel workers including slaughterhouse and market workers, veterinarians, and racing personnel should wear facial protection and protective clothing, practice good personal hygiene, including frequent hand washing after touching animals, and receive education about the syndrome. Family members of such personnel should not be exposed to work paraphernalia including clothing and shoes and workers should shower at the site of employment rather than the home. Avoiding direct contact with camels (who may be asymptomatic but can transmit the virus through nasal or ocular discharge, milk, urine, and feces) is important. Infected camels should be segregated from other livestock and kept off the market, including their meat products, and buried or destroyed. Epidemiologic factors addressed above can be used to avoid contact with most likely infected camels.

Treatment

Respiratory support is essential. No vaccine or known antiviral therapy exists to combat MERS. Therapies are adapted from SARS treatments, which include IFNs, ribavirin, lopinavir-ritonavir, or mycophenolate mofetil. The use of macrolides is not associated with a reduction in mortality. A small retrospective study found improved survival at 14 days with ribavirin and IFN-α but not at 28 days.

Prognosis

The overall mortality rate of identified cases is about 36%. Factors associated with mortality include the use of corticosteroids and also the use of continuous renal replacement therapy. A set of radiographic criteria (diffuse involvement, fibrosing sequela) are associated with a worse prognosis and the need for intubation. Advanced age is associated with a poor prognosis. Functional outcomes of survivors are similar to those of other non-MERS severe acute respiratory virus illnesses.

Kandeel M. An overview of the recent progress in Middle East respiratory syndrome coronavirus (MERS-CoV) drug discovery. Expert Opin Drug Discov. 2023;18:385. [PMID: 36971501]

ADENOVIRUS INFECTIONS

General Considerations

Adenovirus is a non-enveloped double-stranded DNA virus comprising 7 species, 51 serotypes, and 116 genotypes. The species A–D are most pathogenic among the species A–G. Adenoviruses show a worldwide distribution and occur throughout the year. These infections are usually self-limited or clinically inapparent and occur most commonly among infants, young children, and military recruits and are responsible for about 5–10% of pediatric viral respiratory infections and 1–4% of adult respiratory disease. These infections cause particular morbidity and mortality in immunocompromised persons, such as patients living with HIV infection and COPD, as well as in patients who have undergone solid organ and hematopoietic stem cell transplantation or chimeric antigen receptor T cell (CAR T) therapy or in those who have received cancer chemotherapy or cardiac surgery. A few cases of donor-transmitted adenoviral infection have been reported in past years.

Adenoviruses, although a common cause of human disease, also receive particular recognition through their *role as vectors in gene therapy and vaccine development.*

Clinical Findings

A. Symptoms and Signs

The incubation period is 4–9 days. Adenovirus infection presents as various overlapping clinical syndromes. **The common cold** is characterized by rhinitis, pharyngitis, and mild malaise without fever, often accompanied by conjunctivitis. Nonstreptococcal exudative pharyngitis manifests as fever lasting 2–12 days, malaise and myalgia. Lower respiratory tract infection may occur, including bronchiolitis, suggested by cough and rales, or pneumonia. Species B and C, and types 1, 2, 3, 4, 7, 55, and 66, commonly cause acute respiratory disease and atypical pneumonia with documented co-infections or serial infections. Infections are especially severe in Native American children. Adenovirus B14 is a cause of severe and sometimes fatal pneumonia in those with chronic lung disease but is also seen in healthy young adults and military recruit outbreaks. Viral or bacterial coinfections occur with adenovirus in 15–20% of cases. Pharyngoconjunctival fever presents with fever and malaise, conjunctivitis (often unilateral), mild pharyngitis, and cervical adenitis. Epidemic keratoconjunctivitis (transmissible person to person and caused by species D, types 8, 37, 53, 54, 64) manifests in adults with bilateral conjunctival redness, pain, tearing, and an enlarged preauricular lymph node (often involving multiple types in a single outbreak). Keratitis may lead to subepithelial opacities (especially with the above types).

Sexually transmitted genitourinary ulcers and urethritis may be caused by species C and D, types 2, 8, and 37. Enteric adenovirus (species F, types 40 and 11) causes acute gastroenteritis, mesenteric adenitis, acute appendicitis, rhabdomyolysis, and intussusception. Rare associations include encephalitis, meningitis, cerebellitis, ARDS, acute flaccid myelitis, and pericarditis. Adenovirus is commonly identified in endomyocardial tissue of patients with myocarditis and dilated cardiomyopathy. Factors contributing to severity of infection include youth, chronic underlying infections, recent transplantation, and serotypes 5 or 21. Increased obesity rates in children are associated with higher seroprevalence of adenovirus 36.

Hepatitis (C5 adenovirus), pneumonia, and hemorrhagic cystitis (species B, types 11 and 34) tend to develop in infected liver, lung, or kidney transplant recipients, respectively. Patients undergoing hematopoietic stem cell transplant and CAR T therapy are at risk of developing hepatitis, pneumonia, diarrhea, hemorrhagic cystitis, tubulointerstitial nephritis, colitis, and encephalitis.

B. Laboratory Findings and Imaging

Antigen detection assays including direct fluorescence assay or enzyme immunoassay are rapid and show sensitivity of 60–77%% compared with viral culture (considered the standard). Samples with negative rapid assays require PCR assays or viral cultures for diagnosis. Quantitative real-time rapid-cycle PCR is useful in distinguishing disease from colonization, especially in hematopoietic stem cell transplant patients. Multiplex nucleic acid amplification assays can test for multiple respiratory viruses simultaneously with increased sensitivity. Adenovirus differs from other viral and bacterial respiratory infections seen on chest CT imaging, appearing as a multifocal consolidation or ground-glass opacity without airway inflammatory findings.

Treatment & Prognosis

Treatment is symptomatic. Ribavirin or cidofovir is used in immunocompromised individuals with occasional success, although cidofovir is attendant with significant renal toxicity. Brincidofovir, the lipid-conjugated prodrug of cidofovir, has better oral bioavailability, is better tolerated, and achieves higher intracellular concentrations of active drug than cidofovir but is only available through compassionate use policies since its primary indicated use remains for Ebola virus infections. IVIG is used in immunocompromised patients, particularly those with hypogammaglobulinemia, and can be used in combination with other therapies, but data are still limited. Typing of isolates is useful epidemiologically and in distinguishing transmission from endogenous reactivation. Topical steroids or tacrolimus may be used to treat adenoviral keratoconjunctivitis. The commercially available synthetic corticosteroid mifepristone shows some in vitro activity against adenoviruses. Complications of adenovirus pneumonia in children include bronchiolitis obliterans. Deaths are reported on occasion.

The control of epidemic adenoviral conjunctivitis is often difficult and requires meticulous attention to hand hygiene, use of disposable gloves, sterilization of equipment (isopropyl alcohol is insufficient, recommendations of manufacturers are preferred), cohorting of cases, and furloughing of employees. Treatment with a combination of povidone-iodine 1.0% eyedrops and dexamethasone 0.1% eyedrops four times a day can reduce symptoms and expedite recovery. Prolonged shedding of adenovirus type 55 is reported.

Vaccines are not available for general use. The use of live oral vaccines containing attenuated type 4 and type 7 was reinstated in military personnel in 2013 and has been associated with a significant decrease in adenoviral disease.

POXVIRUSES & OTHER EXANTHEMATOUS VIRAL INFECTIONS

1. Mpox

ESSENTIALS OF DIAGNOSIS

- Characteristic rash and lymphadenopathy in most unvaccinated persons.
- Previous smallpox vaccination provides protection.
- Transmission is mainly by skin-to-skin contact.

General Considerations

Mpox (previously known as the monkeypox virus) is an orthopoxvirus. Two clades, I and II, are recognized, previously known as Congo Basin and West African, respectively. Clade IIb caused a global outbreak in 2022 and is still currently circulating in low levels. A clade I mpox outbreak began in 2023 in the Democratic Republic of the Congo and spread to neighboring countries in 2024. It can be transmitted when humans encounter infected animals (primates, rodents, rabbits) and by direct contact with infected humans including sexual and skin-to-skin contact.

Mpox was first diagnosed in 1970 in the Democratic Republic of the Congo and later in Central Africa (particularly Nigeria) and West Africa. Occasional travel-related outbreaks appeared over the following decades. Since 2017, confirmed cases of mpox have occurred in Cameroon, Central African Republic, Côte d'Ivoire, Democratic Republic of the Congo, Republic of the Congo, Gabon, Liberia, Nigeria (where cases occurred after a 40-year hiatus), Sierra Leone, and South Sudan. Risk factors identified from the Democratic Republic of Congo include being bitten by rodents, working as a hunter, and being male > 18 years of age. The giant pouched rat is a particular reservoir for disease in Central Africa, although the full spectrum of reservoirs remains unknown.

In May 2022, outbreaks of clade II mpox were reported in several nonendemic countries, including Spain, Portugal, and the United Kingdom. As of September 30, 2024, 109,699 cases have been reported globally. Gay, bisexual, and other men who have sex with men make up the majority of cases; deaths have occurred. The largest caseloads were in the United States (34,063 cases and 63 deaths), Brazil, and Spain. The WHO's global situation update can be accessed at https://worldhealthorg.shinyapps.io/mpx_global/#2_Global_situation_update.

Clinical Findings

The incubation period averages 13 days with a range of 1–21 days in the current outbreak. The prodromal period includes a host of symptoms from fever and chills (62%) to lethargy (41%), myalgias (31%), and headaches (27%). Lymphadenopathy is prominent (56%) and can be generalized or localized. Skin lesions occur in almost all cases 1–3 days after the fever starts. The lesions are deep seated and well circumscribed at all stages of development and progress centrifugally. Classic lesions appear in four stages, from macules, to papules, to vesicles, to pustules, eventually scabbing over and resolving. Historically, rashes were seen on the face or the palms and soles; in the current outbreak, lesions on the trunk and anogenital regions and mucosal lesions are more common. Lesions vary in number from 1 to 10, although they can be diffuse. Rash may be confined to one location and may not be disseminated in the current outbreak. Anorectal lesions, common in the current outbreak, present with intense pain, tenesmus, and possibly diarrhea. Keratitis is a recognized ocular manifestation, and a congenital syndrome may occur.

Laboratory Findings

Mpox virus DNA can be detected for prolonged periods in upper respiratory isolates. If skin lesions are present, swabs should be collected and sent for PCR. Electron microscopy, viral culture, ELISA, PCR, and a GeneXpert assay (referred to as MPX/OPX [mpox/orthodox]) of lesions can be used for confirmation. PCR and GeneXpert are preferred but not recommended for use with blood specimens. False-positive assays occur among those recently vaccinated and serologies are not routinely used for diagnosis. Clinicians should notify state and local health officials and the CDC for assistance with diagnostic confirmation.

Differential Diagnosis

The differential includes varicella (which shares all stages of rash development), syphilis, scabies, herpes, and measles. Confusion with smallpox and varicella occurs; however, both lymphadenopathy (seen in up to 90% of unvaccinated persons) and a febrile prodrome are distinct features of mpox infection. The mpox rash is distinguished by its deep-seated and well-circumscribed nature, lesions at various stages of development (like varicella but unlike smallpox), and centrifugal progression (including palms and soles).

Prevention

Three vaccines are currently available. The preferred is JYNNEOS (Imvamune or Imvanex), a live, replication-incompetent vaccinia virus (modified Ankara virus). It was first developed as a smallpox vaccine and is effective and FDA-approved to prevent mpox. It is usually given subcutaneously (0.5 mL) as two doses 1 month apart and can be given intradermally (0.1 mL). A delay in administration of the second dose may increase the duration of protection. Postexposure vaccination is advised for documented contacts of infected persons or animals within 3–4 days up to 14 days of exposure.

The second vaccine is ACAM2000 (a live, replication-competent vaccinia virus), which historically was used for smallpox eradication and is available only under the CDC's expanded-access investigational new drug protocol. This vaccine should not be given to those with eczema or severe immune deficiency including bone marrow transplant patients. The side effects associated with this vaccine include rare instances of myocarditis, encephalitis, and blindness. Thus, it should not be used in those who are at risk for such complications including patients with cardiac disease, eye disease treated with steroids, congenital or acquired immune deficiency, those with eczema, infants under 1 year of age, and pregnant persons.

The third vaccine, available in Japan and known as LC16m18, is a live-attenuated replicating vaccine with a favorable safety profile. Cases should be placed on standard, contact, and droplet precautions. *Hospitalized patients should be housed in single rooms with dedicated staff and respiratory equipment, PPE for staff, and airflow isolation for respiratory procedures.* No bedclothes or personal equipment should be shared. Cases are considered infectious until all scabs have fallen off.

People living in endemic areas should avoid ingesting bushmeats as well as contact with infected individuals (any case before scabs appear) with attention also to funeral precautionary contact with infected cadavers. A full set of guidelines are available from the WHO and CDC.

US federal agencies prohibit the importation of African rodents.

Treatment

Most patients with mpox will have mild, self-limited disease. However, persons with severe illness or those at risk for severe illness (including immunocompromised persons, persons having conditions associated with a compromised skin barrier such as atopic dermatitis, children, and pregnant persons) should be considered for antiviral therapy (https://www.cdc.gov/mpox/hcp/clinical-care/). No treatments currently have FDA approval for mpox treatment, but therapies developed for smallpox have been used in some cases.

Tecovirimat (TPOXX; 600 mg orally twice daily for 2 weeks) is available in the United States through the CDC's expanded access investigational new drug (IND) protocol. Clinical studies have shown that tecovirimat is generally well tolerated, but it has not been associated with faster resolution of skin lesions or pain among persons with mild to moderate disease severity. Other possible systemic therapies for mpox include vaccinia immunoglobulin, cidofovir, and brincidofovir. Cidofovir use is limited by potential nephrotoxicity. Clinical experience with brincidofovir in the management of mpox is limited. Brincidofovir is available through an FDA-authorized single-patient emergency use IND for persons (1) with severe mpox or at risk for severe disease and (2) who have no durable response to tecovirimat, are ineligible for tecovirimat, or are severely immunocompromised. **Expert consultation should be sought to guide decision-making when mpox therapeutics are considered.**

Vaccinia immunoglobulin intravenous (VIGIV) may be considered in severe cases when there is insufficient antibody response and is available upon request to CDC on a case-by-case basis.

Prognosis

Though acute disease may last several weeks, the prognosis is generally excellent. Rare fatalities have been reported in the 2022–2023 outbreak and fatalities have been somewhat higher in the 2023–2024 ongoing outbreak (where the case fatality rate is about 3.6%). The immunosuppressed are more prone to complications, including bronchopneumonia, sepsis, encephalitis, and keratitis with rare visual loss.

When to Refer

Any patient with suspicious lesions should be referred to an infectious diseases consultant or the local health department. Patients with severe disease (particularly those presenting with oral or anogenital disease) should immediately be referred to the emergency department.

When to Admit

Any patient at risk for development of severe complications such as sepsis, pneumonia, encephalitis, or keratitis should be admitted.

2. Variola (Smallpox) & Vaccinia

ESSENTIALS OF DIAGNOSIS

- Prodromal high fever.
- Eruption progressing from papules to vesicles to pustules, then crusts.
- All lesions in the same stage.
- Face and distal extremities (including palms and soles) favored.

Historically, smallpox caused millions of deaths worldwide before its eradication in 1980. Concern for the use of smallpox virus as a bioterrorist weapon has led to the reintroduction of vaccination in some segments of the population (first responders and the military).

The face is the initial site of involvement, followed by the upper and lower extremities and trunk, with complete evolution over 1 week. Lesions exhibit relative uniformity within each anatomic region.

3. Molluscum Contagiosum

Molluscum contagiosum is caused by a pox virus, also known as *Molluscipoxvirus*, that may be transmitted sexually or by close contact or contaminated fomites.

The incubation period averages 2–3 months and is self-limited in most people. The disease presents as pearly, raised, umbilicated skin nodules sparing the palms and soles. Keratoconjunctivitis can occur. Most ocular lesions are typical umbilicated dome-shaped lesions, but a variety of atypical ocular lesions are reported often in immunocompetent patients, more often in women and young adults (mean age 19 years). Rare anal and scalp lesions are reported.

There may be an association with atopic dermatitis or eczema. Molluscum contagiosum is also reported as a complication of therapy with dupilumab for atopic dermatitis. Marked and persistent lesions in patients with AIDS respond readily to combination ART. Treatment options include destructive therapies (curettage, cryotherapy, cantharidin, 10–15% hydrogen peroxide, 10% potassium hydroxide, and keratolytics [ingenol mebutate and SB206/berdazimer sodium gel are under study], among others), immunomodulators (imiquimod, cimetidine, tuberculin-purified protein derivatives [PPDs], and *Candida* antigen), and antiviral agents (topical cidofovir is effective anecdotally in refractory cases; brincidofovir is approved for the treatment of Ebola but is still off-label for molluscum contagiosum, where it shows some efficacy). No treatment is uniformly effective. Multiple courses of therapy are often needed. One meta-analysis recommends natural resolution of lesions if normal immunity can be restored. Two promising agents under investigation include topical cantharidin, called VP-102, and a topical nitric oxide (NO)-releasing product containing berdazimer, called SB206. One meta-analysis found that berdazimer had a higher rate of clearance of lesion and decreased scarring. They have the potential to be the first FDA-approved agents for the treatment of molluscum contagiosum. Cryptococcal skin lesions can mimic molluscum contagiosum.

Pera Calvi I et al. Safety and efficacy of topical nitric oxide-releasing berdazimer gel for molluscum contagiosum clearance: a systematic review and meta-analysis of randomized controlled trials. Pediatr Dermatol. 2023;40:1060. [PMID: 377210250]

4. Orf and Paravaccinia

Orf (contagious pustular dermatitis, or ecthyma contagiosa) and paravaccinia (milker's nodules) are occupational diseases acquired by contact with sheep/goats and cattle, respectively. Household meat processing and animal slaughter are identified as risk factors. Orf is a common infection in sheep, goats, and reindeer globally, with farmers, veterinarians, and hunters at heightened risk. The incubation period ranges from 3 to 7 days. Clinically it presents as a solitary 1-cm hand pustule. It progresses through six clinically distinct dermatologic stages, and typically heal in 3–6 weeks without scarring. The use of nonporous gloves for persons handling animals is recommended, especially if the persons are immunosuppressed. Molecular tests are used to confirm clinical diagnosis. Although orf has no specific treatment, it anecdotally responds to imiquimod. Cidofovir has been suggested as potential treatment as well. A live vaccine is available for animals, and the orf virus, which has immunomodulatory properties, is increasingly used as a vector and as an oncolytic agent in human vaccine trials.

Incubation period for paravaccinia is 5–15 days. The lesion progresses as papules (reddish blue, firm) to painless vesicular nodules with erythematous ring, then to exudative nodules followed by dry, crusting formation. It then becomes papillomatous nodules and finally involutes without a scar. Management is usually supportive treatment. Treatment of domestic pet animals is recommended to ensure complete management.

5. Erythroparvovirus Infections

Primate erythroparvovirus 1, more commonly known as **parvovirus B19,** infects human erythroid precursor cells. It is quite widespread (by age 20 years about 50% of adults have detectable IgG), and its transmission occurs through respiratory secretions and saliva, through the placenta, and through administration of blood products. The incubation period is 4–14 days. Chronic forms of the infection can occur. Bocavirus, another erythroparvovirus, is a cause of winter acute respiratory disease in children and adults.

▶ Clinical Findings

A. Symptoms and Signs

Parvovirus B19 causes several syndromes and manifests differently in various populations. Presentation is biphasic with the first phase (most contagious, lasting for ~5 days) developing ~7 days after illness characterized by fever, myalgia, and malaise and the second phase 7–10 days after the first presenting as rash, joint pain, anemia, thrombocytopenia, or leukopenia.

1. Children—In children, an exanthematous illness ("**fifth disease**," **erythema infectiosum**) is characterized by a fiery red "slapped cheek" appearance, circumoral pallor, and a subsequent lacy, maculopapular, evanescent rash on the trunk and limbs. Eosinophilic cellulitis (**Well syndrome**) is also reported with parvovirus B19, as are microvesicular eruptions and atypical rashes. Parvovirus B19 infection is also one of the most common causes of myocarditis in childhood.

2. Immunocompromised patients—A transient aplastic crisis and pure RBC aplasia may occur, although symptoms and signs may be less classic among the immunocompromised populations. Bone marrow aspirates reveal absence of mature erythroid precursors and characteristic giant pronormoblasts. The parvovirus B19 gene is detected in 16–19% of patients with acute leukemia and chronic myeloid leukemia. Patients undergoing chronic dialysis also show a high prevalence of parvovirus infection.

3. Adults—A limited nonerosive symmetric polyarthritis resembling SLE and rheumatoid arthritis, which may in some cases be a type II mixed cryoglobulinemia, can develop in middle-aged persons (especially women). Rashes, especially facial, are less common in adults.

Chloroquine and its derivatives exacerbate parvovirus B19–associated anemia and corelates with significantly lower hematocrit in hospital admissions in malaria endemic areas. Rare reported presentations include myocarditis with infarction, constrictive pericarditis, chronic dilated cardiomyopathy, uveitis, meningitis, encephalitis (from India), CNS vasculitis, stroke (usually in sickle cell anemia patients with aplastic crises), autoimmune (Hashimoto) thyroiditis, hepatitis and liver failure, pneumonitis, neutropenia, thrombocytopenia, a lupus-like syndrome, glomerulonephritis, papular-purpuric "gloves and socks" syndrome, peripheral neuropathy (brachial plexitis and carpal tunnel syndrome), complications of drug hypersensitivity, and a chronic fatigue syndrome. A subclinical infection is documented among patients with sickle cell disease.

Parvovirus B19 infection can simulate autoimmune states such as lupus, systemic sclerosis, antiphospholipid syndrome, or vasculitis and influenza-like illnesses in children. The cross reactivity of anti-B19 antibodies with human proteins, B19-induced apoptosis, and the phospholipase activity of the B19 VP1 protein have been documented for pathogenesis for autoimmune presentation.

In pregnancy, transplacental transmission occurs in 30% of cases of maternal infection leading to complications such as premature labor, hydrops fetalis, fetal anemia, and fetal loss necessitating testing and monitoring for symptomatic pregnant individuals.

A serosurvey from France suggests parvovirus B19 infection may occur more commonly in patients with schizophrenia.

B. Laboratory Findings

The diagnosis is clinical (Table 37–2) but may be confirmed by either an elevated titer of IgM anti-parvovirus B19 antibodies in serum or with PCR in serum or bone marrow. By the time common presenting symptoms manifest, in particular a rash or polyarthropathy in an immunocompetent patient, the viremia may have cleared but IgM antibodies are likely present. In immunocompromised patients, RT-PCR is the optimal test. Autoimmune antibodies (antiphospholipid and antineutrophil cytoplasmic antibodies) can be present and are thought to be a consequence of molecular mimicry. False-positive serologies also occur in the presence of recent IVIG and anti–B-cell therapy. Also, remnant parvovirus B19, from tissue and serum, is thought to explain some false-positive findings. Assays on marrow tissue are indicated only if a marrow is deemed necessary for other hematologic reasons.

Treatment

Treatment in healthy persons is symptomatic (NSAIDs are used to treat arthralgias, and transfusions are used to treat transient aplastic crises). In immunosuppressed patients including those with HIV, IVIG is very effective in the short-term reduction of anemia. Relapses tend to occur about 4 months after administration of IVIG. Administration of IVIG does not reduce encephalitic complications. Intrauterine blood transfusion can be considered in severe fetal anemia especially during 18–35 weeks of gestation.

Cidofovir and brincidofovir have been successfully used in some studies to inhibit B19 viral replication. Foscarnet has been used in one study in kidney transplant patients with red cell aplasia secondary to Parvo B19 infection. Hydroxyurea and telbivudine (thymidine analog used in hepatitis B virus infection) have demonstrated effectiveness in in vitro studies.

Prevention & Prognosis

Several nosocomial outbreaks are documented. In these cases, standard and droplet precautions, including hand washing after patient exposure and avoiding contact with pregnant persons, are paramount. Pregnant and immunocompromised patients should be monitored for Parvo B19 infection especially during outbreaks. Among infected, pregnant persons, the presence of hydrops is associated with a poor prognosis. Serologic data show that daycare attendants are at higher risk for infection and need to practice hygienic principles in particular.

Because transfusion-transmitted parvovirus is very rare, blood banks do *not* routinely screen for parvovirus in the United States or abroad. Most infected donor patients have concomitant antibodies, most recipients have had prior parvovirus infection, and the levels of viremia are considered too low in infected patients to transmit the virus. Transfusion specialists recommend DNA screening of vulnerable patients after transfusion.

The prognosis is generally excellent in immunocompetent individuals. In immunosuppressed patients, persistent anemia may require prolonged transfusion dependence. Remission of parvovirus B19 infection in AIDS patients may occur with ART, though the immune reconstitution inflammatory syndrome is also reported.

There is no vaccine available for Parvo B19 infection.

Lopes TS et al. Antiviral alternatives against important members of the subfamily Parvovirinae: a review. Arch Virol. 2024;169:52. [PMID: 38378929]

6. Novel Orthopoxviruses

Several novel pox viruses have been discovered in the past few years after infection in humans or in domestic animals. Three newly identified species are Orthopoxvirus Abatino (outbreak in captive macaques in Italy in 2015 and a cat in 2017), Akhmeta virus in Georgia, Europe (exposure to cattle in 2010 and 2013), and Alaska isolate (wild small mammals) in 2015. Another novel orthopoxvirus was identified in a patient who had undergone kidney transplantation in North America in 2015. The seroprevalence of orthopoxviruses is high in veterinary workers and those with cat exposures.

Gigante CM et al. Genome of Alaskapox virus, a novel orthopoxvirus isolated from Alaska. Viruses. 2019;11:708. [PMID: 31375015]

VIRUSES & GASTROENTERITIS

Viruses are responsible for at least 30–40% of cases of infectious diarrhea in the United States. These agents include rotaviruses; caliciviruses, including noroviruses such as Norwalk virus; astroviruses; enteric adenoviruses; and, less often, toroviruses, coronaviruses, picornaviruses (including the Aichi virus), sapoviruses, and pestiviruses. Rotaviruses and noroviruses are responsible for most nonbacterial cases of gastroenteritis.

Rotaviruses are reoviruses associated with significant morbidity and mortality. In 2021, 108,322 deaths were attributed to rotavirus compared with 316,382 in 2000. Children age 6 months to 2 years are the most affected, although adults also are affected occasionally. By age 5, virtually every child has been infected with this pathogen. The diverse set of rotaviruses (classified by glycoproteins and protease-sensitive proteins [G-type and P-type antigens], which segregate independently) results in a constellation of serotypes, although only five cause > 90% of disease. Rotavirus infections follow an endemic pattern, especially in the tropics and low-income countries, but they peak during the winter in temperate regions. The virus is transmitted by fecal-oral route and can be shed in feces for up to 3 weeks in severe infections. In outbreak settings (eg, daycare centers), the virus is ubiquitously found in the environment, and secondary attack rates are between 16% and 30% (including household contacts). Nosocomial outbreaks are reported.

The disease is usually mild and self-limiting. A 2- to 3-day prodrome of fever and vomiting is followed by nonbloody diarrhea (up to 10–20 bowel movements per day) lasting for 1–4 days. It is thought that systemic disease occurs rarely, and unusual reported presentations include cerebellitis and pancreatitis. Patients with gastroenteritis are not routinely tested for rotavirus because the results do not alter treatment. Oral and intravenous rehydration solutions are the primary treatment options. Neurologic complications are rare but include encephalitis, cerebellitis, and encephalo-cerebellitis, with long-term complications more common with older age at diagnosis or the presence of encephalo-cerebellitis.

Vaccines have been highly successful in reducing the global burden of rotavirus. Four oral, live, attenuated rotavirus vaccines—Rotarix (derived from a single common strain of human rotavirus), RotaTeq (a reassorted bovine-human rotavirus), Rotavac (naturally occurring bovine-human reassortant neonatal G9P, also called 116E), and RotaSiil (bovine-human reassortant with human G1, G2, G3, and G4 bovine UK G6P[5] backbone)—are available internationally and WHO prequalified. All four vaccines are considered highly effective in preventing severe GI disease. In the United States, two rotavirus vaccines have been approved since 2006: RotaTeq (given at 2, 4, and 6 months of age) and a live, oral attenuated monovalent human rotavirus vaccine (HRV, Rotarix or RV1; given at 2 and 4 months of age). One advantage of these vaccines is the evidence of *heterotypic immunity* (prevention against rotavirus strains not included in the vaccine). Accordingly, some data suggest that rotavirus vaccination confers herd immunity to children under 1 year of age.

A meta-analysis of 15 randomized controlled studies showed no statistically significant increase in intussusception.

Vaccine coverage is inadequate in the United States for rotavirus (75.6% among children born in 2017 and 2018, according to the National Immunization Survey). National immunization programs of > 80 countries include rotavirus vaccine, and the different rotavirus vaccines are available commercially in 100 countries.

With the control of rotavirus, **noroviruses**, such as Norwalk virus (one of a variety of small round viruses divided into six genogroups [three causing disease in man] and at least 25 genotypes), are now *the major cause of diarrhea globally*. Noroviruses are a leading cause of foodborne disease in the United States (with food handlers largely responsible and associated foods most often leafy vegetables, fruits, nuts, and mollusks) and are significantly associated with military deployment as well as travel-associated and nosocomial infections.

Globally, each year, norovirus gastroenteritis is responsible for nearly 700 million infections and up to 20% of all cases of diarrhea in children and adults, with an estimated 200,000 deaths, 900 of which are in the United States (primarily among older adults). The efficacy of the rotavirus vaccination has increased the percentage of gastroenteritis caused by norovirus. The noroviruses appear to evolve by antigenic drift (similar to influenza). While 90% of transmission in young children is fecal-oral, airborne, person-to-person, and water-borne transmission also have been documented. A short incubation period (24–48 hours), a short symptomatic illness (12–60 hours, but up to 5 days in hospital-associated cases), a high frequency (> 50%) of vomiting, and absence of bacterial pathogens in stool samples are highly predictive of norovirus gastroenteritis. Rare neurologic complications of norovirus infection occur, with seizures the most common symptoms and encephalitis the most serious complication.

RT-PCR of stool samples is used for diagnostic and epidemiologic purposes. Adults show serologic evidence of past infection, no long-lasting protective immunity develops, and reinfections are common.

Outbreak environments include long-term care facilities (nursing homes in particular), restaurants, hospitals (including a surge in outbreaks in Chinese cities), schools, daycare centers, vacation destinations (including cruise ships), and military bases. Persons at particular risk are younger individuals, older adults, those who are institutionalized, and those who are immunosuppressed. Asymptomatic cases are thought to be responsible for community transmission. Immunochromatographic assays for rotavirus are highly sensitive. Several licensed multiple pathogen platform assays are available, but they are expensive, and interpreting the cause of illness in a given patient may be difficult. Treatment options are similar to rotavirus (see above) and rely mostly on oral and intravenous rehydration. Deaths are rare in the developed world, and the more common associated diseases are aspiration pneumonia, septicemia, and necrotizing enterocolitis.

Outbreak control for both rotavirus and norovirus infections include strict adherence to general hygienic measures. Despite the promise of alcohol-based sanitizers to control pathogen transmission, *such cleansers may be relatively ineffective against the noroviruses compared with antibacterial soap and water*, reinforcing the need for new hygienic agents against this prevalent group of viruses. Cohorting of sick patients, contact precautions for symptomatic hospitalized patients, and proper decontamination procedures are crucial. Symptomatic staff should be excluded from work until symptom resolution (or 48–72 hours after this for norovirus disease). Global surveillance for noroviruses is especially important in the seafood industry.

ENTEROVIRUSES THAT PRODUCE SEVERAL SYNDROMES

The most famous enterovirus, the poliomyelitis virus, is discussed above under Major Vaccine-Preventable Viral Infections. The best-known nonpolio enteroviruses (enterovirus D68, enterovirus A71, and coxsackie viruses A6 and A16) and other clinically relevant enteroviral infections are discussed in this section.

1. Coxsackievirus Infections

Coxsackievirus infections cause several clinical syndromes. As with other enteroviruses, infections are most common during the summer. Two groups, A and B, are defined either serologically or by mouse bioassay. More than 50 serotypes are identified.

Clinical Findings

A. Symptoms and Signs

The clinical syndromes associated with coxsackievirus infection are summer grippe; herpangina; epidemic pleurodynia; aseptic meningitis and other neurologic syndromes; acute nonspecific pericarditis; myocarditis; hand, foot, and mouth disease; epidemic conjunctivitis; and other syndromes.

1. Summer grippe (A and B)—A febrile illness, principally of children, summer grippe usually lasts 1–4 days. Minor upper respiratory tract infection symptoms are often present.

2. Herpangina (A2–6, 10; B3)—There is sudden onset of fever, which may be as high as 40.6°C, sometimes with febrile convulsions. Other symptoms are headache, myalgia, and vomiting. The sore throat is characterized early by petechiae or papules on the soft palate that ulcerate in about 3 days and then heal. Treatment is symptomatic.

3. Epidemic pleurodynia (Bornholm disease) (B1–5)—Pleuritic pain is prominent. Tenderness, hyperesthesia, and muscle swelling are present over the area of diaphragmatic attachment. Other findings include headache, sore throat, malaise, nausea, and fever. Orchitis and aseptic meningitis occur in < 10% of patients. Most patients are ill for 4–6 days.

4. Aseptic meningitis (A and B) and other neurologic syndromes—Fever, headache, nausea, vomiting, stiff neck, drowsiness, and CSF lymphocytosis without chemical abnormalities may occur, and pediatric clusters of group B (especially B5) meningitis are reported. Focal encephalitis and transverse myelitis are reported with coxsackievirus group A and acute flaccid myelitis with group B in India. Disseminated encephalitis occurs after group B infection, and acute flaccid myelitis is reported in both coxsackievirus groups A and B.

5. Acute nonspecific pericarditis (B types)—Sudden onset of anterior chest pain, often worse with inspiration and in the supine position, is typical. Fever, myalgia, headache, and pericardial friction rub appear early and are often transient. Evidence for pericardial effusion on imaging studies is often present, and the occasional patient has a paradoxical pulse. Electrocardiographic evidence of pericarditis is often present. Relapses may occur.

6. Myocarditis (B1–5)—HF in the neonatal period is secondary to in utero myocarditis, and > 20% of adult cases of myocarditis and dilated cardiomyopathy are associated with group B (especially B3) infections.

7. Hand, foot, and mouth disease (A5, 6, 10, 12, and 16, B5)—This disease can be epidemic. It is characterized by stomatitis, vesicular rash on hands and feet (Figure 37–6),

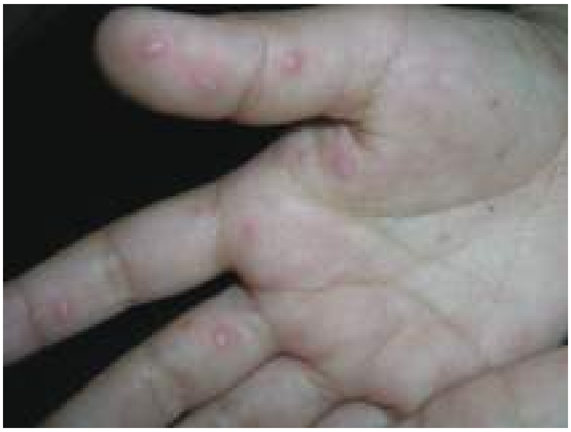

Figure 37–6. Rash of hand, foot, and mouth disease. Typical flat, gray, oval vesicular lesions on the ventral hand and fingers. (Reproduced with permission from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas and Synopsis of Family Medicine*, 3rd ed. McGraw-Hill, 2019.)

nail dystrophies, and onychomadesis (nail shedding), with some cases showing higher fevers, long duration, and more severe skin manifestations. Enteroviruses 71 and 33 are also causative agents, the former of usually more severe disease. A16 disease is usually mild. A6 may be atypical but is usually self-limited. Rare fatalities are reported among surveillance programs in China where recombinant patterns between coxsackieviruses and echoviruses are reported.

8. Epidemic conjunctivitis—As with enterovirus 70, the A24 variant of coxsackievirus is associated with acute epidemic hemorrhagic conjunctivitis in tropical areas with outbreaks reported in southern China, Pakistan, southern Sudan, the Comoros, Uganda, Cuba, and Thailand. It is also reported as a cause of corneal endotheliitis after cataract surgery.

9. Myalgic encephalitis/chronic fatigue syndrome—This is associated in one Korean series with Borna disease virus, while searches for associations with other enteroviruses (as well as herpes and parvoviruses) were unsuccessful.

10. Other syndromes associated with coxsackievirus infections—These include rhabdomyolysis, fulminant neonatal hepatitis (occurs rarely), pancreatitis with concomitant hepatitis and myocarditis (A4), glomerulopathy (group B infections), onychomadesis (B1), neonatal hemophagocytic lymphohistiocytosis (B1), types 1 and 2 diabetes mellitus (mainly group B infections), and thyroid disease (group B4), although definitive causality is not established. A pathogenic role in primary Sjögren syndrome and acute MI has also been proposed for group B coxsackievirus infections. A report of confirmed infective endocarditis due to coxsackievirus B2 in a patient with a prosthetic cardiac patch used in repair of a child with complete atrial ventricular septic defect suggests that viral etiologies of culture-negative infective endocarditis should be considered even in cases of cardiac surgery.

B. Laboratory Findings

Routine laboratory studies show no characteristic abnormalities. Neutralizing antibodies appear during convalescence. The virus may be isolated from throat washings or stools inoculated into suckling mice. Viral culture is expensive, labor intensive, and requires several days for results. A PCR test for enterovirus RNA is available and, although it cannot identify the serotype, may be useful, particularly in cases of meningitis.

▶ Treatment & Prognosis

Treatment is symptomatic. Except for meningitis, myocarditis, pericarditis, diabetes, and rare illnesses such as pancreatitis or poliomyelitis-like states, the most common syndromes caused by coxsackieviruses are benign and self-limited. Two controlled trials showed a potential clinical benefit with pleconaril for patients with enteroviral meningitis although the compassionate use of this medication has stopped (clinicians can contact ViroPharma). Anecdotal reports describe success with IVIG in severe disease. Vaccines against the most common etiologic agents in a given country, including three hand foot and mouth vaccines in China in 2016, have been developed, but simultaneous circulation of more than one virus makes coxsackievirus vaccines based on a single agent relatively ineffective. Due to its possible association with type 1 diabetes, a multivalent coxsackie B virus vaccine has been developed with good safety, tolerability, and immunogenicity in a phase 1 clinical trial.

2. Echovirus Infections

Echoviruses are enteroviruses that produce several clinical syndromes, particularly in children. Infection is most common during summer. Among reported specimens, death ensues in about 3%. Adolescents and men younger than 20 years are more commonly infected than other persons.

Over 30 serotypes of echoviruses are recognized and the most common serotypes for disease are A types 6, 9, 11, 19, 29, 30, and 33 as well as C99. Most can cause aseptic meningitis, which may be associated with a rubelliform rash. A highly pathogenic variant of echovirus 11 was reported in France and other European countries from 2022 to 2023. Transmission is primarily fecal-oral. Hand washing is an effective control measure in outbreaks of aseptic meningitis. Outbreaks related to fecal contamination of water sources, including drinking water and swimming and bathing pools, were reported previously.

Besides meningitis, other conditions associated with echoviruses range from common respiratory diseases (which increased significantly during the SARS-2 pandemic) and epidemic diarrhea to myocarditis, a hemorrhagic obstetric syndrome, keratoconjunctivitis, severe hepatitis with coagulopathy, leukocytoclastic vasculitis, encephalitis with sepsis, interstitial pneumonitis, pleurodynia, rhabdomyolysis, hemophagocytic syndromes (in children with cancer), sudden deafness, encephalitis, acute flaccid myelitis (a leading cause in India), optic neuritis, uveitis, neonatal sepsis, and septic shock. Echoviruses and enteroviruses are also a common cause of nonspecific exanthems.

As with other enterovirus infections, diagnosis is best established by correlation of clinical, epidemiologic, and laboratory evidence. Cytopathic effects are produced in tissue culture after recovery of the virus from throat washings, blood, or CSF. An enterovirus PCR of the CSF can assist in the diagnosis and is associated with a shorter duration of hospitalization in febrile neonates. Fourfold or greater rises in antibody titers signify systemic infection.

Treatment is usually symptomatic, and the prognosis is excellent, although mild paralysis after CNS infection is reported. In vitro data suggest some role for amantadine or ribavirin, but clinical studies supporting these findings are not available.

From a public health standpoint, clustered illnesses, such as among travelers swimming in sewage-infested seawater, suggest point-source exposure. Prevention of fecal-oral contamination and maintaining pool hygiene through chlorination and pH control are important public health control measures.

Chandran D et al. France reports rise in severe neonatal infections caused by a new enterovirus (echovirus-11) variant. Clin Pathol. 2023;16:2632010. [PMID: 38022906]

3. Enteroviruses 68, 70, 71, & Related Agents

Enteroviruses are nonenveloped, single-stranded viruses in the *Picornaviridae* family. They are divided into 12 species (A to L; human enteroviruses include species A to D). Several distinct clinical syndromes are described in association with enteroviruses.

Enterovirus D68 (EV-D68) is a unique enterovirus that shares epidemiologic characteristics with human rhinovirus and is typically associated with respiratory illness including asthma exacerbations. Outbreaks have occurred worldwide, including in Asia, Europe, South America, West Africa, and the United States. Outbreaks associated with acute flaccid myelitis occurred in the United States in 2014, 2016, and 2018. The virus is also implicated in aseptic meningitis and encephalitis. After removing public health restrictions targeting SARS-CoV-2 in 2021, an increase in EV-D68 cases was reported, including 139 cases in eight European countries between July and October 2021. Between March and September 2022, 260 EV-D68 cases were identified in US hospitals via active surveillance, with several cases severe enough to require PICU admission. Wastewater surveillance is an effective means of monitoring, with levels correlating to confirmed cases.

Enterovirus 70 (EV-A70), a ubiquitous virus responsible for abrupt bilateral eye discharge and subconjunctival hemorrhage with occasional systemic symptoms, is most commonly associated with acute hemorrhagic conjunctivitis.

Enterovirus 71 (EV-A71) almost always occurs in the Asia-Pacific region (but with reports from the United States since the 1980s) and is associated with (1) hand, foot, and mouth disease, which can be severe or even fatal; (2) herpangina; (3) a form of epidemic encephalitis associated on occasion with pulmonary edema; and (4) acute flaccid myelitis mimicking poliomyelitis (see Acute Flaccid Myelitis, above).

Human enteroviruses are neurotropic. They may have a role in amyotrophic lateral sclerosis. EV-D68 has been reported in a case of fatal meningitis/encephalitis. A number of non-polio type C enteroviruses are associated with polio-like syndromes, and surveillance for these is most active in China. Enterovirus infection of the pancreas can trigger cell-mediated autoimmune destruction of β cells resulting in diabetes. Enterovirus myocarditis can be a serious infection in neonates, complicated by cardiac dysfunction and arrhythmias. An association with hemophagocytosis is also reported.

Mortality is especially high in EV-A71–associated brainstem encephalitis, which is often complicated by pulmonary edema, particularly when it occurs in children younger than 5 years. A complication is autonomic nervous system dysregulation, which may precede the pulmonary edema. Because of lower herd immunity, hand, foot, and mouth disease tends to infect children under age 5 in nonendemic areas. Clinical and epidemiologic findings aided by isolating the suspect agent from conjunctival scraping for EV-A70; vesicle swabs, body secretions, or CSF for EV-A71; and respiratory secretions for D68 facilitate diagnosis of these enteroviral entities. Enzyme immunoassays and complement fixation tests show good specificity but poor sensitivity (< 80%). RT-PCR may increase the detection rate in enterovirus infections and is useful in the analysis of CSF samples among patients with meningitis and of blood samples among infants with a sepsis-like illness.

Treatment of these entities remains largely symptomatic. A study in China showed that recombinant human IFN-α 1b in EV-A71–associated hand, foot, and mouth disease was associated with decreased fever duration, healing time of typical skin or oral mucosal lesions, and EV-A71 viral load. Clinicians report anecdotal success in managing myocarditis with immunoglobulins. In vitro studies show reduced viral replication when exposed to doxycycline, but clinical studies are lacking.

The major complication associated with EV-A70 is the rare development of an acute neurologic illness with motor paralysis akin to poliomyelitis. Treatment of acute flaccid myelitis related to EV-A71 with IVIG does not appear to improve neurologic outcomes. Attention deficit with hyperactivity occurs in about 20% of confirmed infections.

EV-D68 requires supportive care with particular attention to respiratory support. The CDC's National Enterovirus Surveillance System should receive reports of disease at https://www.cdc.gov/ness/contact/.

Household contacts, especially children < 6 months of age, are at particular risk for EV-A71 acquisition. A commercial disinfectant, Virkon S at 1–2% application, appears to reduce infectivity of fomites. A stage-based supportive treatment for EV-A71 infections, recognizing the potential for late-onset CNS disease and cardiopulmonary failure is important. No EV-A71 vaccine is commercially available in the United States, although vaccines produced in China appear to be successful against EV-A71–associated hand, foot, and mouth disease and herpangina (efficacy 63.2–90.8%). Decreases in antibody titers suggest booster doses of these vaccines may be needed.

Enterovirus 72 (EV-A72) is another term for hepatitis A virus (see Chapter 16). **Enterovirus EV-A104** is related to rhinoviruses and associated with respiratory illness in reports from Italy and Switzerland.

4. Human Parechovirus Infection

Human parechovirus is classified among 19 genotypes among a distinct genus of picornaviruses and causes a wide variety of disease in humans, especially in infants. The pathogen is present worldwide and mainly affects small children during the summer and early fall, although disease can also occur in older adults. Virus type A3 is the most commonly reported isolate in the United States. A parechovirus outbreak occurred in the United States (Tennessee) between April and May 2022 involving 29 infants, including 23 with meningoencephalitis. A 2022 meta-analysis of 41 studies found an overall prevalence of parechovirus A of 10.4% among pediatric patients with gastroenteritis, with genotype 1 most frequently identified. Clinical presentation is mainly driven by GI and respiratory illness, although otitis, neonatal sepsis, fever without a detectable source, gastroenteritis, flaccid paralysis, myalgias (which may be epidemic), diffuse maculopapular and palmar-plantar rashes, aseptic meningitis, intracranial hemorrhage, seizures, pericarditis, and an acute disseminated encephalitis are described in the literature. Co-infection with other pathogens is common. Mortality and long-term morbidity are exceedingly rare, although a recent retrospective cohort reports double the baseline prevalence of attention-deficit/hyperactivity disorder by age 8 in children with severe parechovirus infection as infants.

Type A6 typically affects individuals older than 20 years, while type A3 is responsible for meningitis/encephalitis and neonatal sepsis (13% of late-onset neonatal sepsis [between 4 and 120 days of life] in one series was due to parechovirus) and was reported in association with necrotizing enterocolitis and hepatitis. It is the most common cause of neonatal meningitis and is the picornavirus most often found in CSF samples of CNS-related infections in very young children. The encephalitis can be severe, and Guillain-Barré syndrome is also reported with parechovirus type A6. CSF parameters include a normal count in > 90% and an abnormal protein in < 50%. CNS infection may be seen with virus type A4 as well. Respiratory and GI illnesses are seen with types A4–A6, A10, A13, and A15.

Treatment is largely supportive and rapid identification of the viral antigen by PCR in stools, respiratory samples, and CSF may decrease use of unnecessary antibiotics and shorten hospital stay, although current PCR assays are not always sufficiently sensitive to exclude parechoviruses. Intravenous immunoglobulin was anecdotally successful in one case of parechovirus dilated cardiomyopathy and maternal antibodies to parechovirus type 3 are protective. Reported complications of neonatal cerebral infections include learning disabilities, epilepsy, and cerebral palsy. Because intrafamilial transmission is well documented, diagnosis may help isolate the affected children.

RICKETTSIAL DISEASES

TYPHUS GROUP

1. Epidemic (Louse-Borne) Typhus

ESSENTIALS OF DIAGNOSIS

- Prodrome of headache, then chills and fever.
- Severe, intractable headaches, prostration, persistent high fever.
- Macular rash appearing on days 4–7 on the trunk and in the axillae, spreading to the rest of the body but sparing the face, palms, and soles.
- Diagnosis confirmed by complement fixation, microagglutination, or immunofluorescence.

General Considerations

Epidemic louse-borne typhus is caused by *Rickettsia prowazekii* and transmitted by the body louse *Pediculus humanus* (Table 37–3). Transmission is favored by crowded, unsanitary living conditions such as those seen during wartime and among persons experiencing homelessness. After biting a person infected with *R prowazekii*, the louse becomes infected by the organism, which persists in the louse gut and is excreted in its feces. When the infected louse bites an uninfected individual, the feces enter the bloodstream when the person scratches the wound. Louse feces may also enter via the respiratory tract; because of aerosol transmissibility, *R prowazekii* is considered a possible bioterrorism agent.

R prowazekii can survive in lymphoid and adipose (in endothelial reservoirs) tissues after primary infection, and years later, produce recrudescence of disease (**Brill-Zinsser disease**) without exposure to infected lice. This phenomenon can serve as a point-source for future outbreaks.

Flying squirrels (*Glaucomys volans*) are a zoonotic reservoir of *R prowazekii* in the United States. Transmission to humans, known as sylvatic typhus, usually causes mild disease. Foci of sylvatic typhus are found in the eastern United States and are reported to occur in Brazil, Ethiopia, and Mexico.

Table 37–3. Rickettsial diseases (listed in alphabetical order, within groups).

Disease	Rickettsial Pathogen	Geographic Areas of Prevalence	Insect Vector	Mammalian Reservoir	Travel Association
Typhus Group					
Endemic (murine) typhus	*Rickettsia typhi*	Worldwide; small foci (United States: southeastern Gulf Coast)	Flea	Rodents, opossums	Often
Epidemic (louse-borne) typhus	*Rickettsia prowazekii*	South America, Northeastern and Central Africa	Louse	Humans, flying squirrels	Rare
Scrub Typhus Group					
Scrub typhus	*Orientia tsutsugamushi*	Southeast Asia, Japan, Australia, Western Siberia	Mite[1]	Rodents	Often
Spotted Fever Group					
African tick bite fever	*Rickettsia africae*	Rural sub-Saharan Africa, Eastern Caribbean	Tick[1]	Cattle	Often
California flea rickettsiosis	*Rickettsia felis*	Worldwide	Flea	Cats, opossums	
Lymphangitis-associated rickettsiosis	*R sibirica mongolitimonae*	Europe, Africa, Mongolia	Tick[1]	Unknown	Unknown
Mediterranean spotted fever, Boutonneuse fever, Kenya tick typhus, South African tick fever, Indian tick typhus	*Rickettsia conorii*	Africa, India, Mediterranean regions	Tick[1]	Rodents, dogs	Often
Queensland tick typhus	*Rickettsia australis*	Eastern Australia	Tick[1]	Rodents, marsupials	Rare
Rocky Mountain spotted fever, Brazilian spotted fever	*Rickettsia rickettsii*	Western Hemisphere; United States (especially mid-Atlantic coast region) Southeastern Brazil	Tick[1]	Rodents, dogs, porcupines, capybaras for Brazilian spotted fever	Rare
Siberian Asian tick typhus	*Rickettsia sibirica*	Siberia, Mongolia	Tick[1]	Rodents	Rare
Tick-borne lymphadenopathy/*Dermacentor*-borne necrosis erythema lymphadenopathy/scalp eschar neck lymphadenopathy	*R slovaca, R raoultii, Candidatus R rioja*	Europe	Tick	Unknown	Occasional
Transitional Group					
Rickettsialpox	*Rickettsia akari*	United States, Korea, former USSR	Mite[1]	Mice	Occasional
Ehrlichiosis/Anaplasmosis					
Human granulocytic anaplasmosis	*Anaplasma phagocytophilum, Ehrlichia ewingii, Ehrlichia muris eauclairensis*[2] *Neorickettsia sennetsu*[2]	Northeastern United States and upper Midwest (*E muris eauclairensis*) Southeast Asia (*N sennetsu)*	Tick[1]	Rodents, deer, sheep	Occasional
Human monocytic ehrlichiosis	*Ehrlichia chaffeensis, Ehrlichia canis*	Southeastern United States	Tick[1]	Dogs	Occasional
Q fever	*Coxiella burnetii*	Worldwide	None[3]	Cattle, sheep, goats	Occasional

[1] Also serve as arthropod reservoirs by maintaining rickettsiae through transovarian transmission.
[2] Limited data available on exact cell involved in pathogenesis.
[3] Human infection results from inhalation of dust.

Clinical Findings

A. Symptoms and Signs

Prodromal malaise, cough, headache, backache, arthralgia, myalgia, and chest pain begin after an incubation period of 10–14 days, followed by an abrupt onset of chills, high fever, and prostration, with flu-like symptoms progressing to delirium and stupor. Headache is severe, and fever is prolonged (Table 37–2).

Facial flushing and macular rash (that may become confluent) appear; the rash appears first in the axillae and then over the trunk, spreading to the extremities but sparing the palms and soles. Severely ill patients may develop hemorrhagic rash and hypotension. Pneumonia, thromboses, vasculitis, myocarditis, uremia, and seizure may occur. Improvement begins 13–16 days after onset.

B. Laboratory Findings

The WBC count is variable. Thrombocytopenia, elevated liver enzymes, proteinuria, and hematuria commonly occur. Serum obtained 5–12 days after onset of symptoms usually shows specific antibodies for *R prowazekii* antigens as demonstrated by complement fixation, microagglutination, or immunofluorescence. In primary rickettsial infection, early antibodies are IgM; in recrudescence (Brill-Zinsser disease), early antibodies are predominantly IgG. A PCR test exists, but its availability is limited.

C. Imaging

Radiographs of the chest may show patchy consolidation.

Differential Diagnosis

The prodromal symptoms and the early febrile stage lack enough specificity to permit diagnosis in nonepidemic situations. The rash is sufficiently distinctive for diagnosis, but it may be absent in up to 50% of cases or may be difficult to observe in dark-skinned persons. A variety of other acute febrile diseases should be considered, including typhoid fever, meningococcemia, dengue, leptospirosis, and measles.

Prevention

Prevention consists of louse control with insecticides, particularly by applying chemicals to clothing or treating it with heat, and frequent bathing. A deloused and bathed typhus patient is not infectious. The disease is not transmitted from person to person. No vaccine is available to prevent *R prowazekii* infection.

Treatment

Treatment consists of doxycycline, 100 mg orally twice daily, for 7–10 days or for at least 3 days after the fever subsides. A single dose of 200 mg of doxycycline may be effective; however, some patients may relapse. Chloramphenicol is considered less effective than doxycycline, but it is still the drug of choice in pregnancy.

Prognosis

The prognosis depends greatly on the patient's age and immune status. The mortality rate is 10% in the second and third decades of life but has in the past reached 60% in the sixth decade. Brill-Zinsser disease is rarely fatal.

Centers for Disease Control and Prevention (CDC). About epidemic typhus. https://www.cdc.gov/typhus/about/epidemic.html

Deng YP et al. Emerging bacterial infectious diseases/pathogens vectored by human lice. Travel Med Infect Dis. 2023;55:102630. [PMID: 37567429]

2. Endemic (Murine) Typhus

Rickettsia typhi, a ubiquitous pathogen recognized on all continents, is transmitted between rats via fleas (Table 37–3). Serosurveys of animals show high prevalence of antibodies to *R typhi* in opossums, dogs, and cats. Humans usually acquire the infection in an urban or suburban setting when bitten by an infected flea. Rare human cases in the developed world occur in travelers, usually to Southeast Asia, Africa, or the Mediterranean area, although other pockets of infection are also known to occur. Murine typhus is recognized in the United States along the Gulf Coast, Southern California, and Hawaii.

Clinical Findings

A. Symptoms and Signs

The presentation is nonspecific, including fever, headache, myalgia, and chills. Relative bradycardia is reported. Maculopapular rash occurs in around 50% of cases; it is concentrated on the trunk, mostly sparing the palms and soles, and fades rapidly. Rare presentations include pain or painful genital (Lipschutz) ulcers, meningitis, and meningoencephalitis. Untreated infections last an average of 12–15 days.

Even if untreated, endemic typhus is usually self-limited, and the prognosis is excellent. Murine typhus in pregnancy is often associated with transaminitis and usually has a favorable prognosis. However, it can be associated with maternal death, miscarriage, preterm birth, and low birth weight if acquired early during pregnancy.

B. Laboratory Findings

A fourfold rise in serum antibody titers between the acute and the convalescent phase is diagnostic. It is important to note that *R. typhi* serologic tests frequently cross-react with *R. prowazekii.* During the first week of illness, PCR is the most sensitive test if samples are taken before doxycycline administration. Anemia, thrombocytopenia, leukopenia, hyponatremia, and elevated levels of liver enzymes commonly occur.

Differential Diagnosis

The most common differential diagnosis is Rocky Mountain spotted fever, usually occurring after rural exposure and with a different rash (centripetal rather than the centrifugal rash seen in epidemic or endemic typhus). Murine typhus has been confused with COVID and is also associated with a multisystem inflammatory syndrome.

Complications

Murine typhus can be associated with pneumonia, pleural effusion, and respiratory failure. Other complications include neurologic (facial nerve paralysis, meningitis, ataxia, and seizures), renal (acute kidney injury and focal segmental glomerulosclerosis), myocarditis, and ocular disease. Less commonly, multiorgan failure, disseminated intravascular coagulation, and hemophagocytic lymphohistiocytosis may occur.

Treatment

Doxycycline, 100 mg orally twice daily, for 3 days (or until the patient is afebrile for 48 hours) is the medication of choice, except during pregnancy. Ciprofloxacin (500–750 mg orally twice daily) and ampicillin (500 mg orally three times a day) are reportedly successful in pregnant patients. Azithromycin is frequently used but is inferior to doxycycline and is not associated with improved fetal outcomes.

Prevention

Preventive measures are directed at control of rats and fleas.

Prognosis

Endemic typhus is usually a self-limited disease. A large case series from Texas reported a fatality rate of 0.4%.

Blanton LS. Murine typhus: a review of a reemerging flea-borne rickettsiosis with potential for neurologic manifestations and sequalae. Infect Dis Rep. 2023;15:700. [PMID: 37987401]

3. Scrub Typhus

ESSENTIALS OF DIAGNOSIS

- Exposure to mites in endemic South and East Asia, the western Pacific (including Korea), and Australia.
- Black eschar at site of the bite, with regional and generalized lymphadenopathy.
- High fever, relative bradycardia, headache, myalgia, and a short-lived macular rash.
- Frequent pneumonitis, encephalitis, and myocarditis.

General Considerations

Scrub typhus is caused by *Orientia tsutsugamushi* and is transmitted by mites (chiggers). The mites live on vegetation but complete their maturation cycle by biting humans. The disease is endemic in Southeast Asia (Table 37–3) in an area known as the "tsutsugamushi triangle." Scrub typhus is a cause of acute febrile illness in India and China and is a recognized cause of fever of unknown origin. The disease is more common in rural areas, but urban cases have also been described. Vertical transmission may occur, and transmission has also been recognized via transfusion and occupational exposures (eg, among laboratory workers). Cases among travelers are increasingly recognized.

Clinical Findings

A. Symptoms and Signs

After a 1- to 3-week incubation period, malaise, chills, headache, and backache develop. At the site of the bite, a papule evolves into a black eschar; this finding is suggestive when it is present but was recognized in only 19% of patients in a South Korean series. Regional (and sometimes generalized) lymphadenopathy occurs. Fever rises during the first week of infection, and the rash is usually macular and primarily on the trunk. The rash can be fleeting or more severe, peaking at 8 days but lasting up to 21 days after onset of infection. Relative bradycardia frequently accompanies scrub typhus infection. GI symptoms, including nausea, vomiting, and diarrhea, occur in nearly two-thirds of patients and correspond to the presence of superficial mucosal hemorrhage, multiple erosions, or ulcers in the GI tract. Acute kidney injury and other renal abnormalities are frequently present.

A wide range of complications can be seen in association with scrub typhus including pneumonitis, myocarditis, encephalitis or aseptic meningitis, and acute kidney injury among other less common manifestations. ARDS or hemophagocytosis may develop during the second or third week. Infection confers prolonged immunity against homologous strains and transient immunity against heterologous strains.

B. Laboratory Findings

Thrombocytopenia and elevation of liver enzymes, bilirubin, and creatinine are common. Indirect immunofluorescent assay and indirect immunoperoxidase assays are the gold standard for scrub typhus diagnosis. These tests are expensive and have limited availability. An ELISA detecting *Orientia*-specific antibodies in serum is available. PCR (from the eschar or blood) is the most sensitive diagnostic test. Culture of the organism from blood obtained in the first few days of illness can be done but requires a specialized BSL 3 laboratory. Use of both ELISA and PCR is recommended.

Differential Diagnosis

Leptospirosis, typhoid, dengue, malaria, Q fever, hemorrhagic fevers, meningitis, and other rickettsial infections should be considered. The headache may mimic trigeminal neuralgia. Scrub typhus is a recognized cause of obscure tropical fevers, especially in children. The presence of an eschar, lymphocytosis, and elevated CRP may help distinguish scrub typhus from dengue. Coinfection with malaria may exist.

Prevention

Insect repellents on clothing and skin and protective clothing are effective preventive measures. Although chemoprophylaxis with doxycycline has been used, the CDC does not recommend antibiotic prophylaxis for asymptomatic travelers. No effective vaccines are available.

Treatment & Prognosis

Without treatment, fever subsides spontaneously after 2 weeks, but the mortality rate may be 10–30%. Poor prognostic factors include hypotension requiring vasopressors, ICU care, age > 60 years, absence of an eschar (making the diagnosis difficult), pregnancy, and laboratory findings such as leukocytosis or hypoalbuminemia. Most patients recover without neurologic sequelae.

The treatment of choice is doxycycline (100 mg twice daily) or minocycline (100 mg twice daily). Patients should be treated for at least 3 days after their fever subsides. Shorter duration of therapy is associated with relapse. A clinical trial comparing doxycycline, azithromycin, and both for severe scrub typhus showed no difference between doxycycline and azithromycin monotherapy, but found lower incidence of 28-day mortality, complications at day 7, and persistent fever at day 5 with combination therapy. Alternative therapies for pregnant patients and those with doxycycline allergy include chloramphenicol and azithromycin. Azithromycin appears to have similar efficacy to doxycycline with fewer adverse effects.

SPOTTED FEVERS

1. Tick Typhus (Rickettsial Fever)

The term *tick typhus* denotes a variety of spotted rickettsial fevers, often named by their geographic location (including Rocky Mountain spotted fever, Mediterranean spotted fever, and African tick bite fever, among others) or by morphology (eg, boutonneuse fever). More than 30 species of spotted fever group rickettsioses are found worldwide, 21 of which are pathogenic in humans. These illnesses are caused by various rickettsial organisms (eg, *R rickettsii*, *R africae*, *R australis*, *R conorii*, *R japonica*, *R massiliae*, *R parkeri*, *R sibirica*, and *R 364D*) and are transmitted by various tick species. Dogs and wild animals, usually rodents and even reptiles, may serve as reservoirs for rickettsial fevers. Travel is a risk factor for disease, particularly among older adult ecotourists.

The pathogens may produce an eschar or black spot ("tache noire") at the site of the tick bite that may be useful in diagnosis. Common symptoms include fever, headache, myalgias, and rash. **The severity of illness varies by *Rickettsia* species, and infections not caused by *R. rickettsiae* tend to have a better prognosis (detailed further below).** Painful lymphadenopathy or lymphangitis also may occur. Rarely, papulovesicular lesions may be present (as described with Rickettsialpox). Regional adenopathy, kidney disease, splenic rupture, hepatitis, and retinitis have been reported. Neurologic complications, coronary involvement, purpura fulminans, and hemophagocytic syndrome are rare.

The diagnosis is clinical, with serologic methods or PCR of the buffy coat of blood or an eschar used for confirmation. Oral treatment with doxycycline (100 mg twice daily) or chloramphenicol (50–75 mg/kg/day in four divided doses) for 7–10 days is indicated. Fluoroquinolones or macrolides can be considered as alternatives for less severely ill persons when doxycycline cannot be given, though data are more limited.

Prevention entails protective clothing, repellents, and inspection for and removal of ticks.

Ando N et al. Imported African tick bite fever in Japan: a literature review and report of three cases. Intern Med. 2022;61:1093. [PMID: 35370251]

2. Rocky Mountain Spotted Fever

ESSENTIALS OF DIAGNOSIS

- Exposure to tick bite in an endemic area.
- Influenza-like prodrome followed by fever, severe headache, and myalgias; occasionally, delirium and coma.
- Red macular rash appears between days 2 and 6 of fever, first on the wrists and ankles and then spreading centrally ("centripetal spread"); it may become petechial.
- Mortality > 70% in untreated patients.
- Serial serologic examinations by indirect fluorescent antibody confirm the diagnosis retrospectively.

General Considerations

Rocky Mountain spotted fever (RMSF) is caused by *R rickettsii* and is endemic in parts of the Americas (Table 37–3). In the United States, the number of RMSF cases has increased over the last two decades. **Despite its name, most cases of RMSF occur *outside* the Rocky Mountain area.** More than half of US cases are from five states: Arkansas, Missouri, North Carolina, Tennessee, and Virginia.

R rickettsii is transmitted to humans by the bite of ticks. Several hours of contact between the tick and the human host are required for transmission. Ticks that can transmit the infection include the Rocky Mountain wood tick, *Dermacentor andersoni*, in the western United States, and the American dog tick, *Dermacentor variabilis*, in the eastern United States. The brown dog tick, *Rhipicephalus sanguineus*, is a vector in eastern Arizona, Southern California, and Mexico, associated with peridomestic habitats. Epidemic RMSF, as described in Arizona and Mexico, is associated with massive local infestations of the brown dog tick in domestic dogs.

Clinical Findings

A. Symptoms and Signs

RMSF can cause severe multiorgan dysfunction and fatality rates of up to 73% if left untreated, making it *the most serious rickettsial disease*. Two to 14 days (mean, 7 days) after the bite of an infectious tick, symptoms begin with the abrupt onset of high fever, chills, headache, nausea and vomiting, myalgias, restlessness, insomnia, and irritability. The characteristic rash (faint macules progressing to maculopapules and then petechiae) appears between days 2 and 6 of fever. It initially involves the wrists and ankles, spreading *centrally* to the arms, legs, and trunk over the next 2–3 days. Involvement of the palms and soles is characteristic. Eschars are not usually seen. Facial flushing, conjunctival injection, and hard palate lesions (Figure 37–7) may occur. In about 10% of cases, however, no rash or only a minimal rash is seen. Cough and pneumonitis may develop, and delirium, lethargy, seizures, stupor, and coma may also appear in more severe cases. Splenomegaly, hepatomegaly, jaundice, myocarditis (which may mimic an ACS), adrenal hemorrhage, polyarticular arthritis, or uremia is occasionally present. ARDS and necrotizing vasculitis, when present, are of greatest concern.

B. Laboratory and Imaging Findings

Thrombocytopenia, hyponatremia, elevated aminotransferases, and hyperbilirubinemia are common. CSF may show hypoglycorrhachia and mild pleocytosis. DIC is observed in severe cases. Diagnosis during the acute phase of the illness can be made by immunohistologic or PCR demonstration of *R rickettsii* in skin biopsy specimens (or cutaneous swabs of skin lesions). Performing such studies as soon as skin lesions become apparent maximizes sensitivity.

A characteristic MRI appearance has been noted among RMSF patients with meningoencephalitis (a “starry sky” appearance with numerous foci showing increased signal on T2 and diffusion-weighted sequences) but may be less common among adult patients.

Diagnosis is most commonly made serologically. Most patients do not mount an antibody response until the second week of illness. The indirect fluorescent antibody IgG test is most commonly used. It is important that paired sera (acute and convalescent) be used when possible to establish an acute infection. **Due to the slow turnaround of testing and risk of mortality, it is important to initiate empirical antibiotic therapy when a diagnosis of RMSF is being considered.**

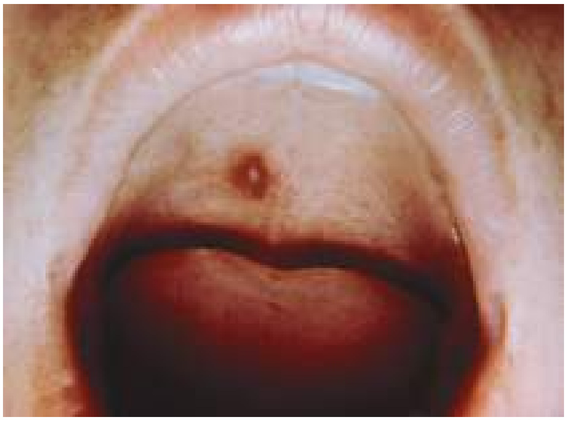

Figure 37–7. Hard palate lesion caused by Rocky Mountain spotted fever. (Public Health Image Library, CDC.)

Differential Diagnosis

The diagnosis is challenging because early symptoms resemble those of many other infections. The classic triad of fever, rash, and tick bite is rarely recognized, with up to 40% of patients not recalling a tick bite. Moreover, the rash may be confused with that of measles, typhoid, ehrlichiosis, or—most importantly—meningococcemia. Co-infections may mask the diagnosis. Some spotted fever rickettsioses may also mimic RMSF but will not be detected by routine serologic testing for RMSF.

Prevention

Protective clothing, tick-repellent chemicals, and the removal of ticks at frequent intervals are helpful measures. Aggressive campaigns to decrease ticks exist in many communities with high RMSF attack rates. Prophylactic therapy after a tick bite is not recommended.

Treatment & Prognosis

Treatment with doxycycline (100 mg orally twice daily for 5–7 days or for at least 3 days after the fever subsides) is recommended for all ages, including pregnant patients. Chloramphenicol (50–100 mg/kg/day in four divided doses, orally or intravenously for 4–10 days) is the only alternative medication to treat RMSF; however, patients who are treated with chloramphenicol may be at higher risk for death than patients treated with a tetracycline. Note that oral formulations of chloramphenicol are not available in the United States and that use of chloramphenicol potentially has adverse risks such as aplastic anemia. Patients usually defervesce within 48–72 hours, and therapy should be continued for at least 3 days after defervescence occurs.

The reported mortality rate for treated patients in the United States is about 3–5%. Complications include seizures, encephalopathy and encephalitis, peripheral neuropathy, paraparesis, bowel and bladder incontinence, cerebellar and vestibular dysfunction, hearing loss, and motor deficits. Features associated with increased risk of poor outcomes include (1) older age; (2) the presence of atypical clinical features (absence of headache, no history of tick attachment, GI symptoms) and underlying chronic diseases; and (3) a delay in initiation of appropriate antibiotic therapy. The usual cause of death is pneumonitis with respiratory or cardiac failure. A fulminant form of RMSF can be seen in patients with glucose-6-phosphate dehydrogenase deficiency.

OTHER RICKETTSIAL & RICKETTSIAL-LIKE DISEASES

1. Ehrlichiosis & Anaplasmosis

ESSENTIALS OF DIAGNOSIS

- Infection of monocyte or granulocyte by tick-borne gram-negative bacteria.
- Nine-day incubation period; clinical disease ranges from asymptomatic to life-threatening.
- Malaise, nausea, fever, and headaches.
- Excellent response to therapy with tetracyclines.

General Considerations

Human ehrlichiosis and anaplasmosis are endemic in the United States.

Ehrlichia chaffeensis (Table 37–3), the most common *Ehrlichia* species infecting humans, is seen primarily in the south-central United States (especially Arkansas, Missouri, and Oklahoma) but also reported from Mexico City and Japan, suggesting it is more widely distributed than was formerly recognized. Human granulocytic anaplasmosis is caused by *Anaplasma phagocytophilum;* most cases in the United States are reported from New England, New York, Minnesota, and Wisconsin. Increasingly, anaplasmosis is reported in Asia and Europe.

In North America, the major tick-borne rickettsial disease vectors for these pathogens are (1) the Lone Star tick (*Amblyomma americanus*), which is the vector for *E chaffeensis* and *E ewingii*; (2) the black-legged tick (*Ixodes scapularis),* which is a vector for *B burgdorferi* (Lyme disease), *Babesia microti* (babesiosis), and *A phagocytophilum* (anaplasmosis), and a possible vector for *Ehrlichia muris eauclairensis*; and (3) the western black-legged tick (*Ixodes pacificus*), which is a vector for *A phagocytophilum* along the Pacific coast of the United States. The principal reservoirs for human monocytic ehrlichiosis and human granulocytic anaplasmosis are the white-tail deer and the white-footed mouse, respectively. Other mammals are implicated as well. Transfusion-transmitted anaplasmosis has been reported.

Clinical Findings

A. Symptoms and Signs

Clinical disease of human monocytic ehrlichiosis ranges from mild to life-threatening. Typically, after a 1- to 2-week incubation period and a prodrome consisting of malaise, myalgias, rigors, and nausea, high fever and headache develop. A pleomorphic rash may occur. Presentation in immunosuppressed patients (including transplant patients) and older patients tends to be more severe. Rare serious sequelae include acute respiratory failure and ARDS; neurologic complications, the most common being meningoencephalitis and aseptic meningitis; acute kidney disease; hemophagocytic syndrome; and multiorgan failure.

The clinical manifestations of human granulocytic anaplasmosis are similar to those of human monocytic ehrlichiosis. Asymptomatic infection is recognized. Rash, however, is infrequent. If a rash is present, coinfection with other tick-borne diseases or an alternative diagnosis should be suspected. Persistent fever and malaise are reported to occur for 2 or more years. Reported complications of anaplasmosis include hyponatremia, leukopenia, thrombocytopenia, and an acute cerebral infarction.

Coinfection with anaplasmosis and Lyme disease or babesiosis has been well described. The clinical manifestations (including fever and cytopenias) are more severe with anaplasmosis than with Lyme disease. A spirochete, *Borrelia miyamotoi*, may mimic anaplasmosis in its clinical manifestations.

B. Laboratory Findings

Diagnosis can be made by the history of tick exposure followed by a characteristic clinical presentation. Leukopenia, absolute lymphopenia, thrombocytopenia, and transaminitis occur often. Thrombocytopenia occurs more often than leukopenia in human granulocytic ehrlichiosis. Hyponatremia from volume depletion is reported. Examination of peripheral blood with Giemsa stain may reveal characteristic intraleukocytic vacuoles (morulae) in up to 20% of patients. An indirect fluorescent antibody assay is available through the CDC and requires acute and convalescent sera. A blood PCR assay can help make the diagnosis early in the disease course. PCR assay is most sensitive in the first week of illness and can be used as a confirmatory test.

Treatment & Prevention

Treatment for human ehrlichiosis and anaplasmosis is with doxycycline, 100 mg twice daily (orally or intravenously) for 10–14 days or until 3 days of defervescence. Rifampin is an alternative for pregnant patients. Treatment should not be withheld while awaiting confirmatory serology when suspicion is high. Lack of clinical improvement and defervescence 48 hours after doxycycline initiation suggests an alternate diagnosis. Some patients may continue to have headache, weakness, and malaise for weeks despite adequate treatment. The case fatality rate is 1% with *E chaffeensis* infections and 0.3% among cases of human anaplasmosis.

Tick control is the essence of prevention. Given the increasing prevalence and recognition of these diseases, screening for solid organ transplants and blood transfusions should be established to prevent posttransplant infections.

Centers for Disease Control and Prevention (CDC). Clinical overview of ehrlichiosis. https://www.cdc.gov/ehrlichiosis/hcp/clinical-overview/

Centers for Disease Control and Prevention (CDC). Clinical Signs and Symptoms of Anaplasmosis. https://www.cdc.gov/anaplasmosis/hcp/clinical-signs/

2. Q Fever (*Coxiella burnetii* Infection)

ESSENTIALS OF DIAGNOSIS

- Exposure to sheep, goats, cattle, or their products; some infections are laboratory acquired.
- Acute or chronic febrile illness: headache, cough, prostration, and abdominal pain.
- Pneumonitis, hepatitis, or encephalopathy; less often, endocarditis, vascular infections, osteomyelitis, or chronic fatigue syndrome.
- A common cause of culture-negative endocarditis.

General Considerations

Q fever, a reportable and significantly underestimated disease in the United States, is caused by the gram-negative intracellular coccobacillus *C burnetii*. *Coxiella* infections occur globally (with increasing recognition in several countries including Brazil and South Korea), mostly in cattle, sheep, and goats, in which they cause mild or subclinical disease (Table 37–3). In these animals, reactivation of the infection occurs during pregnancy and causes abortions or low birth weight offspring. *Coxiella* is resistant to heat and drying and remains infective in the environment for months. Its incidence appears to be increasing and modes of transmission in outbreaks are transitioning from occupational to community acquisition. *C burnetii* is isolated from about 25% of cheese samples.

Human infection occurs via inhalation of aerosolized bacteria (in dust or droplets) from feces, urine, milk, or products of conception of infected animals. Ingestion and skin penetration are other recognized routes of transmission. Animal handlers, slaughterhouse workers, veterinarians, laboratory workers, and other workers exposed to animal products are at risk due to their occupations. Nonetheless, in a review of 81 human outbreaks, over half occurred outside traditional occupational at-risk settings. In the United States, > 60% of cases do not report an exposure to potentially infectious animals, but cases are more than twice as likely as non-cases to report drinking raw milk. An Italian group has identified *Coxiella*-like agents in birds and postulate they may also be involved in the pathogenesis of *C burnetii* infection.

Human-to-human transmission does *not* seem to occur, but maternal-fetal infection can occur and infection after liver transplant is reported. Rare tick-borne transmission is suspected, but ticks may be important in ruminant transmission. In Europe, 4.8% of ticks carry *C burnetii*.

Clinical Findings

A. Symptoms and Signs

Asymptomatic infection is common. For the remaining cases, a febrile illness develops after an incubation period of 2–3 weeks, usually accompanied by headache, relative bradycardia, prostration, and muscle pains. The clinical course may be acute, chronic (6 months or longer), or relapsing. Pneumonia and granulomatous hepatitis are the predominant manifestations in the acute form (and these may vary in incidence geographically), whereas other less common manifestations include skin rashes (maculopapular or purpuric), fever of unknown origin, myocarditis, pericarditis, aortic aneurysms, aseptic meningitis, encephalitis, orchitis, iliopsoas abscess, peripheral neuropathy (from mononeuritis multiplex to plexopathy and Guillain-Barré syndrome), spondylodiscitis, tenosynovitis, granulomatous osteomyelitis (more often seen in children and infrequently associated with full joint recovery), and regional (mediastinal) or diffuse lymphadenopathies.

It has been recommended that the term *chronic Q fever* be abandoned to avoid confusion and be replaced with *persistent localized infections*. The most common presentation in patients with persistent localized infections is culture-negative endocarditis. Risk factors for endocarditis are the immunocompromised state, preexisting valvular conditions, male sex, and age above 40. Valvular prosthesis (mechanical or bioprosthesis) represents the most important risk factor. In a series of post-cardiac surgery patients with culture-negative endocarditis, Q fever is the most common cause (about 40% of cases). In a Dutch series of 107 patients with Q fever endocarditis risk factors and positive serologies, follow-up at a median of 64 months after initial screening showed that 4.7% went on to develop a persistent localized infection (one person despite an intermediate negative serology), while 23.4% became seronegative, and most (72%) showed a pattern of resolved infection.

The clinical manifestations of endocarditis are nonspecific with fever, night sweats, and weight loss. Rarely, urticaria, edema, erythema nodosum, and arthralgias are reported. Sudden cardiac insufficiency, stroke, or other embolic and mycotic aneurysms can also develop. Vascular infections, particularly of the aorta (causing mycotic aneurysms) and of graft prostheses, are the second most common presentation and are associated with a high mortality (25%). Endocarditis due to coinfections occurs rarely. A post–Q fever chronic fatigue syndrome (1 year after acute infection with chronic symptoms) is controversial and of unknown pathophysiology. Cognitive behavioral therapy is effective in reducing fatigue severity in patients with Q fever fatigue syndrome; long-term treatment with doxycycline has not been shown to be effective. Recurrent osteoarticular infections in children can also be due to long-term Q fever infection.

New infection or reactivation of Q fever can occur in pregnant persons and is associated with spontaneous abortions, intrauterine growth retardation, intrauterine fetal death, and premature delivery. *C burnetii* infection during the first trimester can cause oligohydramnios.

B. Laboratory Findings

Laboratory examination during the acute phase may show elevated liver biochemical tests and occasional leukocytosis. Patients with acute Q fever usually produce antibodies to *C burnetii* phase II antigen (phase II antigens are formed in vitro from deleted avirulent mutants and are empirically more commonly seen in acute disease, whereas phase I antigens, seen in nature and laboratory infections, are found in the IgG form in chronic disease). A fourfold rise between acute and convalescent sera by indirect immunofluorescence is diagnostic of the infection. Real-time PCR for *C burnetii* DNA is helpful only in early diagnosis of Q fever. *C burnetii* DNA becomes undetectable in serum as serologic responses develop. The positive predictive value of antibodies to phase II antigens in acute disease is at most 65%, and considerable intertest variability exists with phase 2 antigens. Diagnostic tests combining PCR with ELISA (Immuno-PCR) improve sensitivity and specificity during the first 2 weeks after the onset of symptoms.

While persistent infection can be diagnosed based on serologic tests done at 3- and 6-month intervals (with an IgG titer against phase I antigen of 1:800 or greater), the sensitivity of such serologies is often low, and the diagnosis of Q fever is often made clinically. An automated epifluorescence assay has > 95% sensitivity for detecting phase I antigens in persistent infection. The presence of elevated levels of anticardiolipin antibodies has a high positive predictive value for acute endocarditis.

Diagnosis of Q fever endocarditis is often made during valve replacement with PCR of tissue samples. *C burnetii* may also be isolated from affected valves using the shell-vial technique. Joint material analysis can be facilitated with genomic sequencing techniques.

C. Imaging

Radiographs of the chest can show patchy pulmonary infiltrates. *All patients with acute Q fever should be screened for underlying valvular disease with echocardiography.* Initial imaging and follow-up with serial 18-FDG PET/CT scan may help identify chronic infection and monitor treatment response.

Differential Diagnosis

Viral, *Mycoplasma*, and bacterial pneumonias; viral hepatitis; brucellosis; Legionnaire disease; murine or scrub typhus; Kawasaki disease; tuberculosis; psittacosis; and other animal-borne diseases can have similar clinical presentations to Q fever. Q fever should be considered in cases of unexplained fevers with negative blood cultures in association with embolic or cardiac disease. Cases of Q fever can mimic autoimmune disease. Coinfection with typhus and leptospirosis is reported.

Treatment & Prognosis

Doxycycline is the most effective medication against *C burnetii*; doxycycline resistance is rare. Isolates remain susceptible to levofloxacin, moxifloxacin, and to a lesser extent ciprofloxacin. No resistance to sulfamethoxazole-trimethoprim is reported to date.

For acute infection, treatment with doxycycline (100 mg orally twice daily) for 14 days or at least 3 full days after defervescence is recommended. The mortality rate is usually low in untreated patients, except when endocarditis develops. For children under age 8 years, ciprofloxacin-based therapy is preferred, combined with rifampin or trimethoprim-sulfamethoxazole.

No consensus guidelines exist for the treatment of persistent *C burnetii* infections. Most experts recommend a combination oral therapy with doxycycline (100 mg twice a day) plus hydroxychloroquine for approximately 18 months for native valve endocarditis and 24 months for prosthetic valve endocarditis. The use of alternative combination regimens with a quinolone or rifampin shows some efficacy.

Serologic responses can be monitored during and after completion of therapy and treatment can be extended in the absence of favorable serologic response. The general variability of serologic data, however, limits their usefulness and providers usually rely on clinical criteria. Patients should be monitored for an extended period, generally at least several years per expert opinion, due to risk of relapse.

For patients with endocarditis, clinical cure is possible without valve replacement. Heart valve replacement is *not* associated with better survival, except in patients with a valvular prosthesis. Given the difficulty in treating endocarditis, *transthoracic echocardiography is recommended to screen for predisposing valvulopathy in all patients with acute Q fever*, and the same therapy for 1 year should be offered in the presence of valvulopathy. In addition, patients undergoing routine valve surgery in endemic countries should be evaluated via Q fever serology and treated if positive.

All infected pregnant patients should be given long-term trimethoprim-sulfamethoxazole (320/1600 mg orally for the duration of pregnancy, but not beyond 32 weeks' gestation) to prevent obstetric complications.

In retrospective studies, an increased risk of diffuse B-cell lymphoma and follicular lymphoma was found in patients with Q fever compared with the general population. Patients with persistent focalized infections were at higher risk for lymphadenitis and progression to lymphoma.

Prevention

Prevention is based on detecting infection in livestock, with reduction of contact with infected and parturient animals or contaminated dust; special care when working with animal tissues; and effective pasteurization of milk. A whole-cell Q fever vaccine is available in Australia (Q-VAX) for persons with high-risk exposures (where the overall seroprevalence of antibodies to *Coxiella* is only 19%). Severe reactogenic responses are associated with Q fever vaccines and are a major barrier to use of such vaccines. Clinicians report vaccine failure > 15 days after vaccination, and recipients with a prior exposure to *C burnetii* are at higher risk for adverse reactions that include nodules and abscesses at the injection sites. Because of this the vaccine should never be used as a booster. New vaccines under development target immunogenic, especially cytoplasmic and inner and outer membrane, proteins, and the antigens are formulated as subunit vaccines, multi-epitope DNA vaccines, and synthetic LPS-targeted peptide mimickers.

The organism is highly transmissible to laboratory workers and culture techniques require a biosafety level 3 setting. *C burnetii* is a category B bioterrorism agent. In the setting of a bioterrorist attack, postexposure prophylaxis with doxycycline 100 mg orally twice a day for 5–7 days should be administered within 8–12 days of exposure. Pregnant patients may take trimethoprim-sulfamethoxazole as an alternative.

KAWASAKI DISEASE

ESSENTIALS OF DIAGNOSIS

- Fever, conjunctivitis, oral mucosal changes, rash, cervical lymphadenopathy, peripheral extremity changes.
- Elevated ESR and CRP levels.
- Risk for coronary arteritis and aneurysms.

General Considerations

Kawasaki disease is a worldwide multisystem disease. It is also known as the "**mucocutaneous lymph node syndrome**." It occurs mainly in children between the ages of 3 months and 5 years (with a case reported also in a neonate) but can occur occasionally in adults. Kawasaki disease occurs most often in persons of Asian or native Pacific Islander descent. Its incidence in Japan is twice that of the United States, and in general, cases are more often reported from the developed world, but cases are also reported from developing countries such as Kenya. It occurs among siblings at twice the incidence of cases and at higher rates among parents of cases. These findings plus the known seasonality (higher incidence in winter and early spring) and occasional epidemic pattern of cases point to the inadequate current understanding of the etiology of this disease.

Kawasaki disease is an acute, self-limiting, mucocutaneous vasculitis characterized by the infiltration of vessel walls with mononuclear cells and later by IgA secreting plasma cells that can result in the destruction of the tunica media and aneurysm formation. The cause remains unknown. Epidemiologic studies show an increased risk with advanced maternal age, mother of foreign birth, maternal group B *Streptococcus* colonization, and early infancy hospitalization for a bacterial illness. Genetic factors are considered to play an important role in the pathogenesis of the disease. Ongoing analyses identify many gene polymorphisms, which significantly correlate with Kawasaki disease susceptibility (at least 23 to disease, and 10 to the presence of coronary aneurysms).

The Kawasaki-like disease, called **multisystem inflammatory syndrome in children (MIS-C)**, is described in the section above on SARS-CoV-2. In summary, the chief differences are the age and sex distribution. Kawasaki typically occurs among younger children and men of East Asian ethnicity, whereas MIS-C is more common among children of African and Hispanic heritage. IL-17 is elevated in KD; IL-15 and IFN-γ are elevated in MIS-C.

Clinical Findings

A. Symptoms and Signs

A clinical diagnosis of classic or "**complete**" **Kawasaki disease** requires the presence of at least 5 days of fever, usually high-grade (> 39°C to 40°C) and four of the following five criteria: (1) bilateral nonexudative conjunctivitis (begins shortly after the onset of fever), (2) oral changes of erythema and cracking of lips, strawberry tongue, and erythema of oral and pharyngeal mucosa (ulcers and pharyngeal exudates are not consistent with Kawasaki disease), (3) peripheral extremity changes (erythema and edema of the hands and feet in the acute phase, or periungual desquamation, or both, within 2 to 3 weeks after the onset of fever), (4) polymorphous rash, and (5) cervical lymphadenopathy (larger than 1.5 cm, usually unilateral; least common of the clinical features). The revised case definition allows the diagnosis on day 4 in the presence of more than four principal clinical criteria, particularly when redness and swelling of the hands and feet are present.

A diagnosis of atypical or "**incomplete**" **Kawasaki disease** can be made in patients with unexplained fever and fewer than four principal criteria if accompanied by compatible laboratory tests or findings of aneurysms detected by echocardiography or angiography.

A wide spectrum of rare diagnostic and recognized presentations includes an erythema multiforme rash, onychomycosis, cervical lymphadenopathy, a retropharyngeal abscess, febrile seizures, cheilitis, torticollis, facial nerve palsy, Beau lines of the nails, scrotal and penile edema, inflammation at the site of BCG vaccination, and UTI.

B. Laboratory Findings

Laboratory findings in the acute phase of Kawasaki disease typically include leukocytosis with neutrophilic predominance, anemia, and an elevated ESR and CRP. High platelet counts are characteristic but occur in the second week. N-terminal moiety of BNP (NT-proBNP), likely indicative of myocardial involvement, may be elevated in some patients with Kawasaki disease.

The laboratory components of the CDC's case definition of MIS-C are positivity for current or recent SARS-CoV-2 infection by RT-PCR, serology, or antigen test (or known COVID-19 exposure within the 4 weeks prior to the onset of symptoms) in conjunction with evidence of inflammation (including one or more of the following: elevated CRP, ESR, fibrinogen, procalcitonin, D-dimer, ferritin, lactic acid dehydrogenase, IL-6, or neutrophils; or reduced lymphocytes or albumin).

Major complications include arteritis and aneurysms of the coronary vessels. The arteritis begins 6–8 days after the onset of disease, occurs in about 25% of untreated patients, and occasionally causes MI. Coronary complications are more common among patients older than 6 years or younger than 1 year of age; males; and those unresponsive to IVIG, who received a smaller dose of IVIG, or did not receive treatment within 10 days of symptom onset. According to the 2017 American Heart Association definitions of coronary artery aneurysm, such aneurysms developed in 6.4% of patients with Kawasaki disease despite treatment with IVIG and aspirin. While myocarditis can be found in all patients with Kawasaki disease on histologic specimens and is prominent during the acute stage, only a small percentage of patients are clinically symptomatic.

Cardiac complications include LV dysfunction, which usually normalizes promptly with IVIG therapy, and mitral regurgitation, which occurs early and does not appear to persist. The new cardiac concept of global longitudinal strain may be of diagnostic utility but is especially useful in MIS-C patients.

Noninvasive diagnosis of coronary complications can be made with CT coronary angiography (the most sensitive test), magnetic resonance angiography, or transthoracic echocardiography (advocated for early screening). Kawasaki shock syndrome is a complication, with an estimated incidence of 7%, possibly caused by decrease in peripheral vascular resistance, myocarditis with or without myocardial ischemia, and capillary leakage.

The multisystemic findings of Kawasaki disease show it to be a systemic disease that affects medium-sized arteries of multiple organs, causing elevations in serum transaminases, interstitial pneumonitis, abdominal pain, vomiting, diarrhea, gallbladder hydrops, pancreatitis, lymphadenopathy, hypoalbuminemia, arrhythmias, aseptic meningitis, acute encephalopathy with biphasic seizures and late reduced diffusion, retinal and choroidal detachment, pulmonary complications (effusions, empyema, pneumothorax and an ARDS referred to as "Kawasaki disease shock syndrome"), and pyuria. CSF pleocytosis with a mononuclear cell predominance, normal glucose levels, and protein levels is seen in one-third of children who undergo lumbar puncture.

Other diseases with similar presentation that should be considered include measles in unimmunized children as well as other viral infections, such as SARS-CoV-2, adenovirus, scarlet fever, hemophagocytic lymphohistiocytosis syndrome, and toxic shock syndrome; rickettsial infections; or leptospirosis and drug hypersensitivity reactions.

Treatment & Prevention

All patients meeting the diagnostic criteria for Kawasaki disease (complete and incomplete), including patients with recurrent Kawasaki disease, should be treated as soon as the diagnosis is suspected to reduce inflammation and arterial damage.

A single dose of IVIG should be given in the first 7–10 days of the illness. Patients in whom the diagnosis was made later than the tenth day may still benefit from IVIG treatment if they have elevated inflammatory markers (ESR or CRP), with persistent fever or have coronary artery aneurysms. When IVIG treatment is not given, coronary artery aneurysms occur in 20% of children. Even when treated with IVIG within the first 10 days of illness, coronary artery aneurysms still develop in 5% of patients. In a Cochrane database IVID was most effective in controlling fever and reducing coronary artery aneurysm incidence at 30 days. Rare cases of aseptic meningitis are reported with IVIG. Coombs-positive hemolytic anemia, especially in individuals with AB blood type, and anaphylactic reactions to immunoglobulins with selective IgA deficiency are other complications associated with IVIG administration.

Although aspirin does not lower the frequency of development of coronary abnormalities, it has important anti-inflammatory and antiplatelet activity. Concomitant aspirin with IVIG should be started at 80–100 mg/kg/day orally (divided into four doses and not exceeding 4 g/day) until the patient is afebrile for 48 hours and then reduced to 3–5 mg/kg/day until markers of acute inflammation normalize. A 2019 meta-analysis indicates that low-dose aspirin (3–5 mg/kg/day) may be as effective as high-dose aspirin (30 mg/kg/day or more) for the initial treatment of Kawasaki disease. Since ibuprofen antagonizes the irreversible platelet inhibition induced by aspirin, it should be avoided when aspirin is given.

The use of corticosteroids for children with Kawasaki disease is controversial. According to the 2017 published guidelines by the American Heart Association, single-dose pulse methylprednisolone should not be used routinely for patients with Kawasaki disease. A course of corticosteroid therapy with tapering over 2–3 weeks could be considered in addition to IVIG and aspirin for patients at high risk for not responding to IVIG.

Resistant Kawasaki disease, defined as having recrudescent or persistent fever at least 36 hours after the end of the first IVIG infusion when no other source of fever is found, develops in about 10–20% of patients. Coronary artery abnormalities on the initial echocardiogram and their presence before day 5 of fever predict nonresponse to IVIG in one Israeli study. Prognostic markers for resistance to therapy include most prominently CRP to albumin ratio (CAR) but also neutrophil-to-lymphocyte ratio (indicating markers for inflammation versus immune regulatory response), CRP absolute level, platelet-to-lymphocyte ratio (PLR) (megakaryocytes indicate inflammation), and NLR (neutrophil to lymphocyte ratios)/PLR ratio.

Options for refractory cases include a second dose of IVIG (the full validity of which needs further study), high-dose pulse corticosteroids over 3 days with or without a subsequent oral taper course, longer oral tapering course of corticosteroids over 2–3 weeks together with IVIG and aspirin. The TNF-α blocker **infliximab** is safe, well tolerated, and effective in treating patients with IVIG resistant KD and results in shorter duration of fever, reduced need for additional therapy, less severe anemia, prevents the progression of arterial lesions, and shorter hospitalization compared with a second IVIG infusion. The side effects of infliximab include rash, arthritis, respiratory disease, infusion reactions, and hepatomegaly.

Other options include the anti-inflammatory IL-1 receptor antagonist anakinra, low-dose methotrexate, and cyclosporine. Immunomodulatory monoclonal antibody therapy and cytotoxic agents or (rarely) plasma exchange should be considered in highly refractory cases only when other therapy has failed. Variation in two types of available IVIG is shown in Taiwan to affect the outcome.

The most common serious complication in the acute phase is thrombotic occlusion of a coronary artery aneurysm leading to MI or sudden death. An echocardiogram is recommended within 1–2 weeks and 4–6 weeks after treatment for uncomplicated patients, and exercise stress echocardiograms are especially sensitive in assessing myocardial dysfunction. More frequent imaging is recommended for patients with significant and evolving coronary artery abnormalities. Coronary artery aneurysms with smaller diameter, especially smaller than 6 mm, tend to regress earlier, typically within 6 months of infection.

Anticoagulation with warfarin or low-molecular-weight heparin is indicated, along with aspirin, in patients with rapidly expanding coronary artery aneurysms. Aspirin, a second antiplatelet agent, and anticoagulation with warfarin, low-molecular-weight heparin, or DOACs (which need further study in this population) may be considered for patients with large or giant aneurysms (at least 8 mm) (which correlate with delay in diagnosis) and a recent history of coronary artery thrombosis. Platelets from patients with Kawasaki disease treated with antiplatelet agents do show decreased platelet aggregation function. Systemic arterial aneurysms are also recognized and always occur concomitantly with coronary aneurysms, and large systemic aneurysms show a high rate of regression.

If MI occurs, therapy with thrombolytics, percutaneous coronary intervention, coronary artery bypass grafts, and even cardiac transplantation should be considered. Manifestations of coronary artery aneurysms can occur as late as in the third or fourth decade of life with a study showing a prevalence of 5% coronary sequelae from Kawasaki disease among young adults evaluated with angiography. Calcified coronary aneurysms on CT scans are less likely to regress.

Breastfeeding is associated with a reduced risk of Kawasaki disease but not with a reduced risk of coronary artery lesions or with improved resistance to IVIG therapy.

Prognosis

The reported recurrence rate is 3% in one study from Japan. The highest risk of recurrence occurs in the first 2 years after the first episode. The mortality peaks between 15 and 45 days after the onset of fever, at the time of coronary artery vasculitis, thrombocytosis, and a hypercoagulable state.

Over the long-term, the risk for clinical cardiac events in patients with no coronary artery abnormalities is similar to the general population. For patients in whom coronary artery abnormalities developed, the risk for cardiac complications, such as thrombosis, stenosis, MI, and death, ranges between 1% and 48%. Follow-up is especially needed among the subset of patients with neutropenia who have been treated with IVIG. The administration of IVIG is shown to improve LV function. The American Heart Association recommends risk stratification based on the assessment of coronary luminal dimensions by echocardiogram, under cardiologic supervision. The frequency of clinical follow-up, diagnostic testing, reproductive counseling, indications for medical therapy (β-blockers, statins), and thromboprophylaxis (aspirin and anticoagulation) depends on the individual's risk assessment.

When to Refer

All cases of Kawasaki disease merit referral to specialists.

Bacterial & Chlamydial Infections

38

Kelly A. Johnson, MD, MPH
Emma D. Bainbridge, MD, MPH

INFECTIONS CAUSED BY GRAM-POSITIVE BACTERIA

STREPTOCOCCAL INFECTIONS

Group A β-hemolytic streptococci (*Streptococcus pyogenes*) are the most common bacterial cause of pharyngitis, a topic that is covered along with tonsillitis in Chapter 8.

1. Pharyngitis & Tonsillitis (see Chapter 8)

2. Acute Rheumatic Fever & Scarlet Fever

General Considerations

Group A streptococci are gram-positive, β-hemolytic bacteria that can cause infections ranging from pharyngitis to skin infections to endocarditis and osteomyelitis. Streptococcal pyrogenic exotoxins, known as erythrogenic toxins, can cause scarlet fever in susceptible patients. Moreover, acute streptococcal infections, such as pharyngitis and skin infections, can be followed by nonsuppurative complications due to the production of autoantibodies. For instance, acute rheumatic fever may follow pharyngitis beginning 1–4 weeks after the onset of symptoms. Effectively controlling rheumatic fever depends on identification and treatment of primary streptococcal infection and secondary prevention of recurrences. Glomerulonephritis is another rare nonsuppurative complication following acute streptococcal infection with a nephritogenic strain of *Streptococcus* group A (eg, types 4, 12, 2, 49, and 60), more commonly on the skin than in the throat, which can begin 1–3 weeks after the onset of the infection. Group A streptococcal infections must therefore be monitored closely for both acute and, rarely, postacute complications.

Clinical Findings

S pyogenes (group A *Streptococcus* [GAS]) pharyngitis is usually a self-limited condition, lasting 3–5 days. Please see Chapter 8 for a comprehensive discussion of pharyngitis and tonsillitis.

1. Scarlet fever—Scarlet fever may appear 1–2 days after the onset of GAS pharyngitis. The rash of scarlet fever (also called *scarlatina*) is diffusely erythematous and resembles a sunburn, with superimposed fine red papules giving the skin a sandpaper consistency; it can be most intense in the groin and axillary areas. The rash blanches on pressure, may become petechial, and fades in 2–5 days, leaving a fine desquamation. The face is flushed, with circumoral pallor, and the tongue is coated with enlarged red papillae (labeled strawberry tongue). The diagnosis is clinically made in the setting of streptococcal pharyngitis.

2. Rheumatic fever—The diagnosis of acute rheumatic fever relies on a constellation of signs, symptoms, and laboratory findings, known as the Jones criteria: major criteria include presence of pancarditis, polyarthritis, subcutaneous nodules, erythema marginatum, chorea, and minor criteria include presence of heart block, arthralgia, elevated ESR or CRP, fever, leukocytosis, or history of prior rheumatic fever. At least two major Jones criteria or one major and two minor criteria plus evidence of recent GAS infection by either bacterial culture data, rapid strep testing, or elevated anti-strep antibody titers are required to establish a diagnosis. These complications are more common in children. The incidence of acute rhematic fever has declined in most places worldwide, especially in developed countries due to earlier diagnosis, prompt health care, education, and decreased household crowding.

Treatment

Antimicrobial therapy of pharyngitis reduces the risk of complications (see Chapter 8). There is no additional treatment of scarlet fever or acute rheumatic fever beyond that of the underlying streptococcal pharyngitis. Group A streptococcal species are universally susceptible to penicillin.

Prevention of Recurrent Rheumatic Fever

Patients who have had rheumatic fever should be treated with a continuous course of antimicrobial prophylaxis for at least 5 years. Effective oral regimens are penicillin V, 500 mg orally daily or erythromycin, 250 mg orally twice daily in patients allergic to penicillin. Intramuscular penicillin G benzathine given every 28 days may be used where available but should be avoided in patients with severe, symptomatic valvular disease, New York Heart Association class III or IV HF, or ventricular dysfunction.

van Driel ML et al. Different antibiotic treatments for group A streptococcal pharyngitis. Cochrane Database Syst Rev. 2021;3:CD004406. [PMID: 33728634]

3. Streptococcal Skin Infections

Group A β-hemolytic streptococci are not normal skin flora. Streptococcal skin infections result from colonization of normal skin by contact with other infected individuals or by preceding streptococcal upper or lower tract respiratory infection.

Clinical Findings

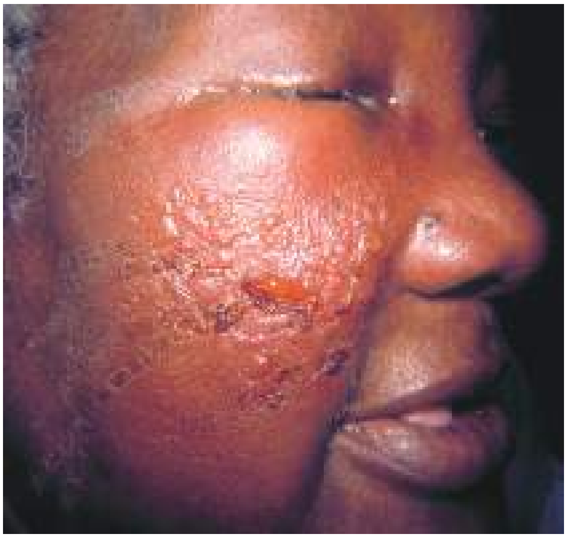
A. Symptoms and Signs

Erysipelas is a painful superficial cellulitis that is well demarcated from the surrounding normal skin and frequently involves the face (Figure 38–1). This manifestation has a proclivity for skin with impaired lymphatic drainage, such as edematous lower extremities or wounds.

Impetigo is a focal, vesicular, pustular lesion with a thick, amber-colored crust with a "stuck-on" appearance (see Chapter 6).

B. Laboratory Findings

Cultures obtained from a wound or pustule are likely to grow group A streptococci. Blood cultures are occasionally positive.



▲ **Figure 38–1.** Erysipelas of the face with edema, bright red erythema, and serosanguineous discharge from the severely swollen cheek. (Public Health Image Library, CDC.)

Treatment

Although penicillin is the treatment of choice for streptococcal infections, it may be difficult to differentiate staphylococcal infections from streptococcal infections. In practice, initial therapy for patients with risk factors for *Staphylococcus aureus* (eg, injection drug use, diabetes mellitus, wound infection) should cover this organism in addition to *Streptococcus pyogenes*. Parenteral therapy with either intravenous nafcillin or cefazolin (which can also be given intramuscularly) is a reasonable choice. In patients at risk for methicillin-resistant *S aureus* (MRSA) infection or with a serious and documented penicillin allergy (ie, anaphylaxis), intravenous vancomycin or daptomycin should be used (Table 38–1).

Patients who do not require parenteral therapy and in whom *S aureus* infection is less likely may be treated only with streptococcal coverage, with amoxicillin, 500 mg three times daily or 875 mg twice daily for 7–10 days. A first-generation oral cephalosporin, eg, cephalexin, or clindamycin is an alternative to amoxicillin (Table 38–1). If MRSA was diagnosed, antibiotics like doxycycline, linezolid, or trimethoprim-sulfamethoxazole often cover the infection. In patients with recurrent cellulitis of the leg, maintenance therapy (for at least 1 year) with penicillin V, 250 mg orally twice daily, may reduce relapses.

Rrapi R et al. Cellulitis: a review of pathogenesis, diagnosis, and management. Med Clin North Am. 2021;105:723. [PMID: 34059247]

4. Necrotizing Fasciitis

Necrotizing fasciitis is a rapidly spreading infection involving the fascia of deep muscle often located on an extremity, head and neck, perianal, or genital area (called "Fournier gangrene" in this region). Some patients have a preceding skin or blunt trauma injury. Patients who are immunosuppressed, have diabetes, are at extremes of age (older adults or neonates), or are affected by liver disease are generally more susceptible.

Necrotizing fasciitis is most often monomicrobial due to *S pyogenes* (group A β-hemolytic streptococci), but it can also be caused by other streptococcal species or *S aureus.* Infections can also be polymicrobial (mixed aerobic and anaerobic bacteria). A history of exposure to brackish water or marine life should raise suspicion for *Vibrio vulnificus, Erysipelothrix rhusiopathiae,* or *Aeromonas* species. Patients with burn injuries are susceptible to *Pseudomonas* species. Necrotizing myositis, which may present similarly and involves both fascia and skeletal muscle, is often caused by *Clostridia* species (clostridial myonecrosis or "gas gangrene"). See Clostridial Diseases, below.

Clinical Findings

A. Symptoms and Signs

The clinical findings at presentation may be those of severe cellulitis, but the presence of systemic toxicity and severe

Table 38–1. Treatment of common skin and soft tissue infections (SSTIs).

SSTI Type	Common Pathogens	Treatment
Purulent (abscess, furuncle, carbuncle, cellulitis with purulence)	*Staphylococcus aureus*	Incision and drainage is the primary treatment Consider the addition of antibiotics in select situations[1] **Oral antibiotic regimens**[2] Dicloxacillin, 500 mg four times daily, *or* cephalexin, 500 mg four times daily Clindamycin, 300 four times daily or 450 mg three times daily *or* trimethoprim-sulfamethoxazole, one double-strength tablet twice daily, *or* doxycycline (or minocycline), 100 mg twice daily **Intravenous antibiotic regimens**[2] Nafcillin, 1–2 g four to six times daily, *or* cefazolin, 1 g three times daily Vancomycin, 1 g twice daily, *or* daptomycin, 4 mg/kg once daily
Nonpurulent (cellulitis, erysipelas)	β-Hemolytic streptococci (*S aureus* less likely)	**Oral antibiotic regimens**[2] Amoxicillin, 500 mg three times daily or 875 mg twice daily Cephalexin, 500 mg four times daily *or* clindamycin, 300 mg four times daily[2] **Intravenous antibiotic regimens**[2] Nafcillin, 1–2 g four to six times daily *or* cefazolin, 1 g three times daily Vancomycin, 1 g twice daily, *or* daptomycin, 4 mg/kg once daily

[1] Antibiotic therapy should be given in addition to incision and drainage for purulent SSTIs if the patient has any of the following: severe or extensive disease, symptoms and signs of systemic illness, purulent cellulitis/wound infection, comorbidities and extremes of age, abscess in area difficult to drain or on face/hand, associated septic phlebitis, or lack of response to incision and drainage alone. Antibiotic doses may vary based on weight and kidney function. Dosages listed assume normal renal and hepatic function, as well as average weight. Reevaluate dosing with renal/hepatic impairment.

[2] Other drugs that are FDA-approved for treating SSTIs include linezolid, 600 mg intravenously or orally twice daily for 10–14 days; daptomycin, 4 mg/kg intravenously once daily for 7–14 days; tedizolid, 200 mg orally once daily for 6 days; tigecycline, 100 mg intravenously once followed by 50 mg intravenously twice a day for 5–14 days; ceftaroline, 600 mg twice a day for 7–14 days; dalbavancin, 1500 mg as a single intravenous dose; oritavancin, 1200 mg as a single intravenous dose; telavancin, 10 mg/kg intravenously once daily for 7–14 days; and delafloxacin, 450 mg orally or 300 mg intravenously twice daily for 5–14 days.

pain, which may be followed by anesthesia of the involved area due to destruction of nerves as infection advances through the fascial planes, is a clue to the diagnosis. Pain is often severe. Infection can progress rapidly, debridement is almost always indicated, and multiorgan failure is common.

B. Laboratory Findings

Nonspecific serum markers include elevated WBC, ESR, and CRP. Elevated creatine kinase may indicate muscle involvement. The Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) score is a diagnostic tool that uses WBC count, hemoglobin, sodium, glucose, creatinine, and C-reactive protein values to predict the likelihood that a soft tissue infection is due to necrotizing fasciitis. Because the sensitivity of the LRINEC score is poor, it should not be used to rule out necrotizing fasciitis, especially when clinical suspicion is high. Blood cultures and wound cultures should be obtained, as well as tissue cultures from surgical specimens during debridement. Histologic specimens may demonstrate extensive tissue destruction, thrombosis of blood vessels, and bacteria spreading along fascial planes.

C. Imaging

CT or MRI of the affected area may show gas in tissues or fascial plane infection. Imaging may also appear normal, so rely on clinical suspicion and surgical evaluation.

Treatment

Timely surgical exploration is mandatory when the diagnosis is suspected. Early, extensive, and often repeated debridement is essential for survival. **Surgical evaluation should not be delayed while awaiting imaging or other diagnostic tests, especially in the setting of rapid progression of clinical manifestations.**

Broad-spectrum antibiotic therapy should be initiated whenever the diagnosis is suspected and should cover aerobic and anaerobic organisms. Initial therapy for patients with normal kidney function typically consists of intravenous therapy with a carbapenem (meropenem, 2 g every 8 hours or imipenem, 1 g every 6 hours) or piperacillin-tazobactam, 3.375 g every 6 hours (unless *Pseudomonas* is suspected, in which case the dose should be increased to 4.5 g every 6 hours), plus an agent with activity against methicillin-resistant *S aureus* (vancomycin, linezolid, or daptomycin), plus clindamycin for its antitoxin effects against toxin-producing strains of streptococci and staphylococci. Clindamycin should be used at high doses, 600–900 mg every 8 hours, for presumptive toxin-mediated illness. Patients with exposure histories that suggest less common etiologies should also have therapy targeted to those organisms. Antibiotic therapy should then be tailored to culture results and continued until all infected tissue has been removed and the patient has stabilized; the final duration depends on individual patient factors.

In addition to surgical and antibiotic therapy, the use of intravenous immunoglobulin for streptococcal necrotizing soft tissue infections has been shown to reduce mortality. The dose is 1 g/kg on day 1, followed by 0.5 g/kg on days 2 and 3.

Urbina T et al. Antibiotics in necrotizing soft tissue infections. Antibiotics (Basel). 2021;10:1104. [PMID: 34572686]

5. Other Group A Streptococcal Infections

Septic arthritis, pneumonia, empyema, endocarditis, and toxic shock–like syndrome are relatively uncommon infections that may be caused by group A streptococci.

Septic arthritis generally occurs in association with cellulitis. In addition to therapy with penicillin G, 3 million units intravenously every 4 hours (or cefazolin or vancomycin if there is a penicillin allergy or less frequent dosing is required), the infected joint effusions should be drained by percutaneous needle aspiration or open surgical drainage. Treatment duration is not well studied but is generally 2–4 weeks, with final duration dependent upon clinical improvement and normalization of inflammatory markers (ESR, CRP).

Pneumonia and **empyema** often are characterized by extensive tissue destruction and an aggressive, rapidly progressive clinical course associated with significant morbidity and mortality. High-dose penicillin G, 4 million units intravenously every 4 hours and chest tube drainage are indicated for treatment of group A streptococcal empyema. Vancomycin is an acceptable substitute in penicillin-allergic patients. Duration of therapy is guided by clinical improvement, with a minimum of 5 days for pneumonia. Adequate drainage is key for the management of empyema and serial imaging is usually necessary to assess for resolution.

Group A streptococci can cause **endocarditis** in rare instances. Endocarditis should be treated with 24 million units of penicillin G intravenously either continuously or in four to six divided doses for 4–6 weeks. Ceftriaxone 2 g daily is an appropriate alternate regimen. Vancomycin, starting at 1 g intravenously every 12 hours but titrated to keep a trough level of 15–20 mcg/mL, is recommended for patients allergic to penicillin. Daptomycin 6 mg/kg/day is an acceptable alternative for the treatment of endocarditis with most gram-positive organisms.

Any streptococcal infection—and necrotizing fasciitis in particular—can be associated with **streptococcal toxic shock syndrome**, typified by invasion of skin or soft tissues, acute respiratory distress syndrome, and kidney failure. Young persons, older adults, and those with underlying medical conditions are at high risk for invasive disease. Accompanying bacteremia occurs in most cases. Skin rash and desquamation may not be present. Mortality rates can be up to 80%. A β-lactam, such as penicillin G, 4 million units intravenously every 4 hours, remains the drug of choice for treatment of serious streptococcal infections, but clindamycin should also be administered at a dose of 900 mg every 8 hours intravenously for invasive disease, especially in the presence of shock. Intravenous immune globulin can be considered for streptococcal toxic shock syndrome for possible therapeutic benefit from specific antibody to streptococcal exotoxins in immune globulin preparations. Many dosing regimens have been used, including 1 g/kg on day 1, followed by 0.5 g/kg on days 2 and 3.

6. Non–Group A Streptococcal Infections

Non–group A β-hemolytic streptococci (eg, groups B, C, and G) produce a spectrum of disease like that of group A streptococci. The treatment of infections caused by these strains is generally similar to treatment regimens for group A streptococci. However, some isolates of groups C and G streptococci can exhibit tolerance to penicillin, so antibiotic susceptibility profiles should be assayed for these species.

Group B streptococci are an important cause of sepsis, bacteremia, and meningitis in the neonate. Antepartum screening to identify carriers and peripartum antimicrobial prophylaxis are recommended in pregnancy. This organism, part of the normal vaginal flora, may cause septic abortion, endometritis, or peripartum infections and, less commonly, cellulitis, bacteremia, and endocarditis in adults. Treatment of infections caused by group B streptococci is with either penicillin or vancomycin in doses recommended for treatment of group A streptococci skin and soft tissue infections (Table 38–1).

Group D streptococci include *Streptococcus gallolyticus* (formerly known as *S bovis*) and bacteria now classified as enterococci. *S gallolyticus* is a cause of endocarditis in association with bowel neoplasia or cirrhosis and is usually treated with β-lactam antibiotics, although susceptibility to penicillin must first be determined. The species described above are generally β-hemolytic, with a clear zone of hemolysis around the bacterial colonies on a blood agar plate.

Viridans streptococci, which are nonhemolytic or α-hemolytic (ie, producing an incomplete or green zone of hemolysis on blood agar), are part of the normal oral and gut flora. Although these strains may produce focal pyogenic infection, they are most notable as the leading cause of native valve endocarditis. Viridans streptococcal species can also be part of mixed bacterial infections at multiple sites or agents of bacteremia with serious GI or genitourinary infections.

PNEUMOCOCCAL (*Streptococcus pneumoniae*) INFECTIONS

1. Pneumococcal Pneumonia

ESSENTIALS OF DIAGNOSIS

- Productive cough, fever, rigors, dyspnea, early pleuritic chest pain.
- Consolidating lobar pneumonia on CXR.
- Gram-positive diplococci on Gram stain of sputum.

General Considerations

Pneumococcus is the most common cause of community-acquired pyogenic bacterial pneumonia. Alcohol use disorder, asthma, HIV infection, sickle cell disease, splenectomy, and hematologic disorders are predisposing factors. Mortality rates remain high in cases of advanced age, multilobar disease, hypoxemia, extrapulmonary complications, and bacteremia.

Clinical Findings

A. Symptoms and Signs

Presenting symptoms and signs include high fever, productive cough, occasional hemoptysis, and pleuritic chest pain. Rigors may occur initially but are uncommon later in the course. Bronchial breath sounds are an early sign.

B. Laboratory Findings

There is often leukocytosis, or occasionally leukopenia, but neither finding should be used to decide whether to admit (see When to Admit, below).

Diagnosis requires isolation of the organism in culture, although the Gram stain of sputum can be suggestive. Sputum and blood cultures, positive in 60% and 25% of cases of pneumococcal pneumonia, respectively, should be obtained prior to initiation of antimicrobial therapy when feasible in patients who are admitted to the hospital. A good-quality sputum sample (< 10 epithelial cells and > 25 polymorphonuclear leukocytes per high-power field) typically shows gram-positive diplococci. A rapid urinary antigen test for *Streptococcus pneumoniae*, with sensitivity of 70–80% and specificity > 95%, can assist with early diagnosis.

C. Imaging

Pneumococcal pneumonia classically is a lobar pneumonia with radiographic findings of consolidation and occasionally effusion. Differentiating it from other pneumonias is not possible radiographically or clinically because of significant overlap in presentations.

Treatment

A. Specific Measures

Initial antimicrobial therapy for pneumonia is empiric (see Table 9–10) pending isolation and identification of the causative agent. Once *S pneumoniae* is identified as the infecting pathogen, any of several antimicrobial agents may be used depending on the clinical setting, community patterns of penicillin resistance, and susceptibility of the particular isolate.

1. Outpatient therapy—Uncomplicated pneumococcal pneumonia (ie, arterial $PO_2 > 60$ mm Hg, no coexisting medical problems, and single-lobe disease without signs of extrapulmonary infection) caused by penicillin-susceptible strains of pneumococcus may be treated on an outpatient basis with amoxicillin, 750 mg orally twice daily for 7–10 days. Cephalosporins including cefpodoxime, 200 mg orally twice daily, also may be used. For penicillin-allergic patients, alternatives include azithromycin, one 500-mg dose orally on the first day and 250 mg for the next 4 days; doxycycline, 100 mg orally twice daily for 7 days; or levofloxacin, 750 mg orally for 5–7 days. Because pneumococcal species have increasing resistance to penicillin, antimicrobial susceptibilities should be examined. Patients should be monitored for clinical response (eg, less cough, defervescence within 2–3 days) on their antibiotic regimen.

Outpatients with high-risk comorbid conditions (such as pulmonary disease, diabetes, cardiac disease, or alcohol use disorder) may benefit from broader combination therapy (eg, amoxicillin/clavulanate or cephalosporin *plus* doxycycline or a macrolide) if anaerobic or other mixed bacteria are suspected in combination with the pneumococcus, unless a fluoroquinolone (eg, levofloxacin or moxifloxacin) is chosen for monotherapy. Fluoroquinolones also cover gram-positive anaerobes and some gram-negative bacteria.

2. Inpatient therapy—Parenteral therapy is generally recommended for the hospitalized patient at least until there has been clinical improvement. Ceftriaxone, 1 g intravenously every 24 hours, is effective for strains that are penicillin-susceptible (ie, strains for which the minimum inhibitory concentration [MIC] of penicillin is 2 mcg/mL or less for non-CNS specimens). For serious penicillin allergy or infection caused by a highly penicillin-resistant strain, vancomycin, 1 g intravenously every 12 hours or a dose to reach a trough level of 15–20 mcg/mL, is effective. Additionally, azithromycin (500 mg orally on the first day and 250 mg for the next 4 days) or doxycycline (100 mg orally twice daily) is typically added for coverage of atypical organisms (eg, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*). Alternatively, a respiratory fluoroquinolone (eg, levofloxacin, 750 mg once daily) can be used. The total duration of therapy is not well defined, but 5–7 days is appropriate for patients who have an uncomplicated infection and demonstrate a good clinical response. Corticosteroid use remains controversial in community-acquired bacterial pneumonia and should not be administered routinely.

B. Penicillin-Resistant Pneumococci

In cases of pneumococcal pneumonia where the isolate is not susceptible to penicillin, cephalosporin cross-resistance is common, and a non–β-lactam antimicrobial, such as vancomycin, 1 g intravenously every 12 hours, or a fluoroquinolone with enhanced gram-positive activity (eg, levofloxacin, 750 mg intravenously or orally once daily, or moxifloxacin, 400 mg intravenously or orally once daily), is recommended. Penicillin-resistant strains of pneumococci may be resistant to macrolides and trimethoprim-sulfamethoxazole, and susceptibility testing must be documented prior to their use. All blood and CSF isolates should be tested for resistance to penicillin.

Complications

Pleural effusions developing after initiation of antimicrobial therapy usually are sterile, and thoracentesis need not be performed if the patient is otherwise improving. Thoracentesis is indicated for an effusion present prior to initiation of therapy and in the patient who has not responded to antibiotics after 3–4 days. Empyema occurs in 5% or less of cases and is differentiated from sympathetic effusion clinically and by the presence of organisms on Gram-stained fluid or positive pleural fluid cultures. Empyema most often requires chest tube drainage for resolution. Echocardiography should be done if pericardial effusion is suspected. Patients with pericardial effusion who are responding to antibiotic therapy and have no signs of tamponade may be monitored and treated with indomethacin, 50 mg orally three times daily, for pain. In patients with increasing effusion, unsatisfactory clinical response, or evidence of tamponade, pericardiocentesis will determine whether the pericardial space is infected. Infected fluid must be drained either percutaneously (by tube placement or needle aspiration), by placement of a pericardial window, or by pericardiectomy. Pericardiectomy eventually may be required to prevent or treat constrictive pericarditis.

Pneumococcal endocarditis usually involves the aortic valve and often occurs in association with meningitis and pneumonia (with the three manifestations sometimes referred to as Austrian or Osler triad). Refer to the Infective Endocarditis section of this chapter for appropriate treatment regimens of pneumococcal endocarditis. Mild HF due to valvular regurgitation may respond to medical therapy, but moderate to severe HF is an indication for prosthetic valve implantation, as are systemic emboli or large friable vegetations as determined by echocardiography.

Prevention

See Chapter 35 for discussion of pneumococcal vaccines. As of 2025, the CDC recommends pneumococcal vaccination for all adults age 50 years or older, and for adults age 19–50 years with certain underlying medical conditions (including HIV) who have not previously received a pneumococcal conjugate vaccine or whose previous vaccination history is unknown. The 20-valent or 21-valent pneumococcal conjugate vaccines (PCV20 or PCV21, respectively) each represents a complete vaccination course; if the 15-valent vaccine (PCV15) is used, then pneumococcal polysaccharide vaccine (PPSV23) must also be administered 1 year later to complete the vaccination course. All patients should be screened for smoking cessation.

When to Refer

- Seriously ill patient with pneumonia, particularly in the setting of comorbid conditions (eg, liver disease).
- Progression of pneumonia or failure to improve on antibiotics.

When to Admit

- Failure of outpatient pneumonia therapy, including inability to maintain oral intake and medications.
- All patients with pneumococcal pneumonia that is multilobar or is associated with significant hypoxemia.
- Exacerbations of underlying disease (eg, HF) by pneumonia that would benefit from hospitalization.
- Risk scores for illness severity using PSI (Pneumonia Severity Index) and CURB-65 (Confusion, Urea, Respiratory rate, Blood pressure, Age ≥ 65 years) can aid in the decision about whether to admit a patient.
- All patients in whom pneumococcal endocarditis or meningitis is suspected or documented should be admitted for observation, infectious disease specialist consultation, and empiric therapy.

Suaya JA et al. Identification of *Streptococcus pneumoniae* in hospital-acquired pneumonia in adults. J Hosp Infect. 2021;108:146. [PMID: 33176175]

2. Pneumococcal Meningitis

ESSENTIALS OF DIAGNOSIS

- Fever, headache, altered mental status.
- Meningismus.
- Gram-positive diplococci on Gram stain of CSF.

General Considerations

S pneumoniae is the most common cause of bacterial meningitis in adults. Head trauma with CSF leaks, sinusitis, and pneumonia may precede it.

Clinical Findings

A. Symptoms and Signs

The onset is rapid, with fever, headache, meningismus, and altered mentation. Pneumonia may be present. Compared with meningitis caused by the meningococcus, pneumococcal meningitis lacks a rash. Obtundation, focal neurologic deficits, and cranial nerve palsies are more prominent features and may lead to long-term sequelae.

B. Laboratory Findings

The CSF has a WBC count typically > 1000/mcL (1.0×10^9/L), more than 60% of which are polymorphonuclear leukocytes; the glucose concentration is < 40 mg/dL (2.22 mmol/L), or < 50% of the simultaneous serum concentration; and the protein usually exceeds 150 mg/dL (1500 mg/L). Not all cases of meningitis will have these typical findings, and alterations in CSF analysis may be surprisingly minimal, overlapping with those of aseptic meningitis.

Gram stain of CSF shows gram-positive cocci in 80–90% of cases, and in untreated cases, blood or CSF cultures are almost always positive. Urine antigen tests may be positive but are not sufficiently sensitive to exclude the diagnosis.

Treatment

Antibiotics should be given as soon as the diagnosis is suspected. If lumbar puncture must be delayed (eg, while awaiting results of an imaging study to exclude a mass lesion), the patient should be treated empirically with ceftriaxone, 2 g intravenously every 12 hours, plus vancomycin, 15 mg/kg every 12 hours to maintain trough levels in the 15–20 mcg/mL range, plus dexamethasone, 0.15 mg/kg every 6 hours administered concomitantly after blood cultures (positive in 50% of cases) have been obtained. Once susceptibility to penicillin has been confirmed, vancomycin may be discontinued and penicillin, 24 million units intravenously daily in six divided doses, or ceftriaxone, 2 g every 12 hours intravenously, is continued for 10–14 days in documented cases.

Susceptibility testing is essential for proper management. Penicillin-resistant strains (MIC > 0.06 mcg/mL) are often cross-resistant to the third-generation cephalosporins as well as other antibiotics. If the MIC of ceftriaxone or cefotaxime is 0.5 mcg/mL or less, single-drug therapy with either of these cephalosporins is likely to be effective; when the MIC is 1 mcg/mL or more, treatment with a combination of ceftriaxone, 2 g intravenously every 12 hours, plus vancomycin, 30 mg/kg/day intravenously in two or three divided doses, is recommended. If a patient with a penicillin-resistant organism is slow to respond clinically, repeat lumbar puncture may be indicated to assess bacteriologic response.

Adjunctive dexamethasone given with antibiotics has been associated with a reduction in mortality and neurologic complications such as hearing loss. It is recommended that dexamethasone be given immediately prior to or concomitantly with the first dose of appropriate antibiotic and continued every 6 hours thereafter for a total of 4 days. The effect of dexamethasone on the outcome of meningitis caused by penicillin-resistant organisms is not known.

ENTEROCOCCAL INFECTIONS

Two species, *Enterococcus faecalis* and *Enterococcus faecium*, are responsible for most human enterococcal infections. Enterococci cause wound infections, UTIs, bacteremia, and endocarditis. Infections caused by penicillin-susceptible strains should be treated with ampicillin, 2 g every 4 hours, or penicillin, 3–4 million units every 4 hours; if the patient is penicillin-allergic, vancomycin, 15–20 mg/kg every 12 hours intravenously, can be given to achieve a trough level of 15–20 mcg/mL. Refer to the Infective Endocarditis section of this chapter for appropriate treatment regimens of enterococcal endocarditis.

Resistance to vancomycin, penicillin, and gentamicin is common among enterococcal isolates, especially *E faecium;* it is essential to determine antimicrobial susceptibility patterns of isolates. Consultation with an infectious disease specialist is strongly advised when treating infections caused by resistant strains of enterococci. Linezolid is active against both *E faecalis* and *E faecium* and approved by the FDA for treatment of infections caused by vancomycin-resistant strains of enterococci. The dose is 600 mg twice daily, and both intravenous and oral preparations are available. Daptomycin, tigecycline, tedizolid, and oritavancin are not specifically approved for the treatment for vancomycin-resistant strains of enterococci, although they are frequently active in vitro.

STAPHYLOCOCCUS AUREUS INFECTIONS

1. Skin & Soft Tissue Infections

ESSENTIALS OF DIAGNOSIS

- Localized erythema with induration and purulent drainage.
- Abscess formation.
- Gram stain of pus shows gram-positive cocci in clusters; cultures usually positive.

General Considerations

About one-quarter of individuals are asymptomatic nasal carriers of *S aureus*, which is spread by direct contact. Carriage often precedes infection, which occurs as a consequence of disruption of the cutaneous barrier or impairment of host defenses. *S aureus* tends to cause more purulent skin infections than streptococci; abscess formation is common. The prevalence of methicillin-resistant strains in many communities is high and should influence antibiotic choices when antimicrobial therapy is needed.

Clinical Findings

A. Symptoms and Signs

S aureus skin infections may begin around one or more hair follicles, causing folliculitis; may become localized to form boils (or furuncles); or may spread to adjacent skin and deeper subcutaneous tissue (ie, a carbuncle). Deep abscesses involving muscle or fascia may occur, often in association with a deep wound or other inoculation or injection (Figure 38–2). Necrotizing fasciitis (discussed above) has been reported with community strains of methicillin-resistant *S aureus*.

B. Laboratory Findings

Cultures of the wound or abscess material will almost always yield the organism. In patients with systemic signs of infection, blood cultures should be obtained because of potential bacteremia, endocarditis, osteomyelitis, or metastatic seeding of other sites. Patients who are bacteremic should have blood cultures repeated every 24–28 hours during therapy to exclude persistent bacteremia, an indicator of severe or complicated infection.

Treatment

Proper drainage of abscess fluid or other focal infections is the mainstay of therapy. Incision and drainage alone is highly effective for the treatment of most uncomplicated, small cutaneous abscesses. A small benefit can be obtained from the addition of antimicrobials following incision and drainage (Table 38–1). In areas where methicillin resistance among community *S aureus* isolates is high, recommended oral antimicrobial agents include clindamycin, trimethoprim-sulfamethoxazole, or doxycycline. When the risk of methicillin resistance is low or methicillin susceptibility has been confirmed by testing of the isolate, consider dicloxacillin or cephalexin. Amoxicillin may be used when strains are both methicillin- and penicillin-sensitive. Treatment for 5–7 days is sufficient in most cases.

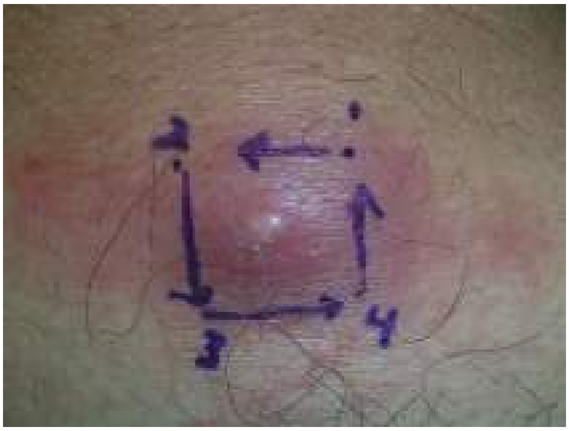

Figure 38–2. Methicillin-resistant *Staphylococcus aureus* (MRSA) abscess on the back of the neck. (Reproduced with permission from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley HS. *The Color Atlas and Synopsis of Family Medicine*, 3rd ed. McGraw-Hill, 2019.)

For complicated infections with extensive cutaneous or deep tissue involvement or systemic symptoms such as fever, initial parenteral therapy is often indicated. When methicillin resistance rates are > 10% in the community, empiric vancomycin is the drug of choice. For infections caused by methicillin-susceptible isolates, cefazolin or a penicillinase-resistant penicillin such as nafcillin or oxacillin administered intravenously is preferred. Total duration of therapy for soft tissue infections depends on clinical response and effectiveness of drainage/debridement. Courses of 7 days with early transition to oral therapy are effective in many cases.

Linezolid is FDA-approved for treatment of skin and skin-structure infections as well as hospital-acquired pneumonia caused by methicillin-resistant strains of *S aureus*; it is clinically as effective as vancomycin for these indications. Intravenous daptomycin is increasingly becoming the drug of choice to treat skin and soft tissue infections with methicillin-resistant *S aureus*. Routine creatinine phosphokinase and CBC monitoring should be done in patients taking daptomycin. Other drugs that are FDA-approved for treating skin and soft tissue infections are listed in Table 38–1.

Hatlen TJ et al. Staphylococcal skin and soft tissue infections. Infect Dis Clin North Am. 2021;35:81. [PMID: 33303329]

2. Osteomyelitis

ESSENTIALS OF DIAGNOSIS

- Fever associated with pain and tenderness of involved bone.
- Microbiologic diagnosis often made from blood cultures.
- Elevated ESR and CRP.
- Radiographs early in the course are typically negative.

General Considerations

S aureus causes approximately 60% of all cases of osteomyelitis. Osteomyelitis may be caused by (1) hematogenous spread, (2) extension from a contiguous focus of infection or open wound (eg, open fracture or as a result of surgery), and (3) skin breakdown in the setting of vascular insufficiency. Long bones and vertebrae are the usual sites. Epidural abscess is a common complication of vertebral osteomyelitis and should be suspected if fever and severe back or neck pain are accompanied by radicular pain or evidence of spinal cord compression (eg, incontinence, extremity weakness, pathologic extremity reflexes).

Clinical Findings

A. Symptoms and Signs

1. Hematogenous osteomyelitis—Osteomyelitis resulting from bacteremia is a disease associated with sickle cell disease, injection drug use, diabetes mellitus, or older age. Patients with this form of osteomyelitis often present with sudden onset of high fever, chills, and pain and tenderness of the involved bone. The site of osteomyelitis and the causative organism depend on the host. Osteomyelitis in injection drug users develops most commonly in the spine. Although in this setting *S aureus* is most common, gram-negative infections, especially *P aeruginosa* and *Serratia* species, are also frequent pathogens. Among patients with hemoglobinopathies such as sickle cell anemia, osteomyelitis is caused most often by salmonellae; *S aureus* is the second most common cause. Rapid progression to epidural abscess causing fever, pain, and sensory and motor loss is not uncommon. In older patients with hematogenous osteomyelitis, the most common sites are the thoracic and lumbar vertebral bodies. Risk factors for these patients include diabetes, intravenous catheters, and indwelling urinary catheters. These patients often have more subtle presentations, with low-grade fever and gradually increasing bone pain, with neurologic abnormalities a late finding.

2. Osteomyelitis from a contiguous focus of infection—Prosthetic joint replacement or other orthopedic surgery, neurosurgery, and trauma most frequently cause soft tissue infections that can spread to bone. *S aureus* and *Staphylococcus epidermidis* are the most common organisms. Polymicrobial infections, rare in hematogenously spread osteomyelitis, are more common in osteomyelitis due to contiguous spread. Localized signs of inflammation are usually evident, but high fever and other signs of toxicity are usually absent. Septic arthritis and cellulitis can also spread to contiguous bone.

3. Osteomyelitis associated with vascular insufficiency—Patients with diabetes mellitus and vascular insufficiency are susceptible to developing a very challenging form of osteomyelitis. The foot and ankle are commonly affected sites, as well as the hip and sacrum due to pressure injury (formerly called pressure ulcer). Infection originates from an ulcer or other break in the skin that is usually still present but may appear disarmingly unimpressive. Polymicrobial infections are common due to contiguous spread, often involving aerobic gram-negative bacilli and anaerobes. Occasionally, *S aureus* may be found as a single pathogen. Bone pain is often absent or muted by the associated neuropathy. Fever is also commonly absent. Two of the best bedside clues to the presence of osteomyelitis are the ability to easily advance a sterile probe to bone through a skin ulcer and an ulcer area > 2 cm × 2 cm.

B. Laboratory Findings

The diagnosis is made by isolation of *S aureus* (or another organism) from the blood, bone, or a contiguous focus of a patient with symptoms and signs of focal bone infection. Blood culture will be positive in approximately 60% of untreated cases. The ESR and serum CRP are almost always elevated and can be useful parameters to follow during the course of therapy. Bone biopsy and culture are valuable to guide targeted therapy. Cultures from overlying ulcers, wounds, or fistulas are unreliable (they often are contaminated with skin flora) and do not correlate with deep tissue or bone culture.

C. Imaging

Plain bone films early in the course of infection are often normal but will become abnormal in most cases even with effective therapy. Spinal infection (unlike malignancy) traverses the disk space to involve the contiguous vertebral body. CT is more sensitive than plain bone radiographs and helps localize associated abscesses. MRI is slightly less sensitive than bone scan but has a specificity of 90%. It is indicated when epidural abscess is suspected in association with vertebral osteomyelitis.

Treatment

Identification of the causative organism and determination of antibiotic susceptibility dictate therapy; consultation with an infectious disease specialist is recommended.

Prolonged therapy (4–6 weeks or longer) is recommended for staphylococcal osteomyelitis. Traditionally, intravenous therapy has been preferred, particularly during the acute phase of the infection for patients with systemic toxicity. Intravenous therapy with cefazolin, 2 g every 8 hours, or alternatively, nafcillin or oxacillin, 9–12 g/day in six divided doses, are the drugs of choice for infection with methicillin-sensitive isolates. Patients with infections due to methicillin-resistant strains of *S aureus* or who have severe penicillin allergies should be treated with vancomycin, 30 mg/kg/day intravenously divided in two or three doses. Doses should be adjusted to achieve a vancomycin trough level of 15–20 mcg/mL. Daptomycin is an alternative agent and should be given in doses of 6–8 mg/kg/dose intravenously every 24 hours.

In terms of shortening the course of intravenous therapy, studies have also demonstrated noninferiority of oral regimens following 2 weeks of intravenous therapy. In patients with *S aureus* isolates susceptible to oral agents, combination oral therapy has been shown to be effective if given for 4–6 weeks following 2 weeks of induction therapy with an intravenous agent as above. Levofloxacin, 750 mg orally daily, or ciprofloxacin, 750 mg orally twice daily, in combination with rifampin, 300 mg twice daily, is an oral regimen with the most data supporting efficacy. Trimethoprim-sulfamethoxazole, doxycycline, or clindamycin may be options for oral therapy depending on the antimicrobial susceptibilities of the organism.

Surgical treatment is often indicated under the following circumstances: (1) staphylococcal osteomyelitis with associated epidural abscess and spinal cord compression (urgent neurosurgical decompression may be required), (2) other abscesses (psoas, paraspinal), (3) extensive disease, or (4) recurrent or persistent infection despite standard medical therapy. Follow-up imaging may not be needed in patients who demonstrate improvement in symptoms and normalization of inflammatory markers.

Urish KL et al. *Staphylococcus aureus* osteomyelitis: bone, bugs, and surgery. Infect Immun. 2020;88:e00932. [PMID: 32094258]

3. Staphylococcal Bacteremia

S aureus readily invades the bloodstream and infects sites distant from the primary site of infection. Whenever *S aureus* is recovered from blood cultures, the possibility of endocarditis, osteomyelitis, or other metastatic deep infection must be considered. Bacteremia that persists for > 48–96 hours after initiation of therapy is strongly predictive of worse outcome and complicated infection. Given the relatively high risk of infective endocarditis in patients with *S aureus* bacteremia, transesophageal echocardiography is recommended for most patients as a sensitive and cost-effective method for excluding underlying endocarditis. However, transthoracic echocardiography may be sufficient in select patients considered to be at low risk for endocarditis, namely those who meet all the following criteria: (1) no permanent intracardiac device, (2) sterile follow-up blood cultures within 4 days after the initial set, (3) no hemodialysis dependence, (4) nosocomial acquisition of *S aureus* bacteremia, and (5) no clinical signs of infective endocarditis or secondary foci of infection. If these conditions are not met, transesophageal echocardiography is more sensitive to exclude endocarditis, especially left-sided valvular endocarditis.

Empiric therapy of staphylococcal bacteremia should be with vancomycin, 15–20 mg/kg/dose intravenously every 8–12 hours (titrated to achieve a trough level of 15–20 mcg/mL), or daptomycin, 6 mg/kg/day intravenously, until results of susceptibility tests are known. If the *S aureus* isolate is methicillin-susceptible, treatment should be narrowed to cefazolin, 2 g every 8 hours, or nafcillin or oxacillin, 2 g intravenously every 4 hours. Cefazolin is as effective as nafcillin or oxacillin and has been associated with fewer adverse events during treatment. In patients with methicillin-resistant *S aureus*, treatment should be with vancomycin, 15–20 mg/kg/dose intravenously every 8–12 hours; a trough level of 15–20 mcg/mL is recommended. Daptomycin 6–10 mg/kg/day is also an FDA-approved option as long as the patient does not require treatment for concomitant *S aureus* pneumonia, as pulmonary surfactant inactivates daptomycin in the lungs. The addition of rifamycins to standard antimicrobial therapy has not been shown to be beneficial in the absence of indwelling prosthetic material and is associated with more adverse events. Duration of antibiotic therapy for *S aureus* bacteremia is 4–6 weeks, but patients with uncomplicated infection may complete treatment within 14 days. A patient with uncomplicated bacteremia must meet all the following criteria: (1) infective endocarditis has been excluded, (2) no implanted prostheses are present, (3) follow-up blood cultures drawn 2–4 days after the initial set are sterile, (4) the patient defervesces within 72 hours of initiation of effective antibiotic therapy, and (5) no evidence of metastatic infection is present on examination. When present at the time of diagnosis, central venous catheters should be removed. Vancomycin treatment failures are relatively common, particularly for complicated bacteremia and among infections involving foreign bodies. Improved outcomes have been demonstrated when consultation with an infectious disease specialist is obtained and is recommended in all cases of *S aureus* bacteremia.

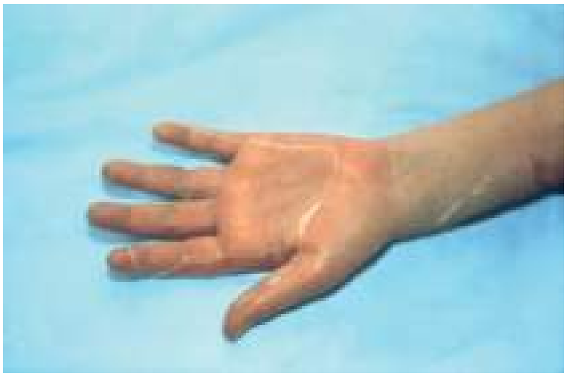
Tong SYC et al. Effect of vancomycin or daptomycin with vs without an antistaphylococcal β-lactam on mortality, bacteremia, relapse, or treatment failure in patients with MRSA bacteremia: a randomized clinical trial. JAMA. 2020;323:527. [PMID: 32044943]

4. Toxic Shock Syndrome

S aureus produces toxins that cause three important entities: “scalded skin syndrome” in children, toxic shock syndrome in adults, and enterotoxin food poisoning. Toxic shock syndrome is characterized by abrupt onset of high fever, vomiting, and watery diarrhea. Sore throat, myalgias, and headache are common. Hypotension with kidney injury and HF is associated with a poor outcome. A diffuse macular erythematous rash and nonpurulent conjunctivitis are common, and desquamation, especially of palms and soles, is typical during recovery (Figure 38–3). Fatality rates may be as high as 15%. Although originally associated with tampon use, any focus (eg, nasopharynx, bone, vagina, rectum, abscess, wound) harboring a toxin-producing *S aureus* strain can cause toxic shock syndrome. Classically, blood cultures are negative because symptoms are due to the effects of the toxin and not systemic



▲ **Figure 38–3.** Marked desquamation due to toxic shock syndrome, which develops late in the disease. (Public Health Image Library, CDC.)

infection. Other entities associated with toxic shock include invasive group A streptococcal infection and certain *Clostridium* species.

Important aspects of treatment include rapid rehydration, targeted antimicrobials (antistaphylococcal therapy when *S aureus* is implicated) (Table 38–1), management of multiorgan failure, and addressing sources of toxin, eg, removal of tampon or drainage of abscess. Clindamycin, 900 mg every 8 hours intravenously, is often added to inhibit toxin production. Intravenous immune globulin may be considered, although there are limited data compared with *Streptococcus* toxic shock syndrome (see above).

5. Infections Caused by Coagulase-Negative Staphylococci

Coagulase-negative staphylococci are an important cause of infections of intravascular and prosthetic devices and of wound infection following cardiothoracic surgery. These organisms infrequently cause infections such as osteomyelitis and endocarditis in the absence of a prosthesis. Most human infections are caused by *Staphylococcus epidermidis*, *S haemolyticus*, *S hominis*, *S saprophyticus*, and *S lugdunensis*. With the exception of *S lugdunensis*, these common pathogens are less virulent than *S aureus*, and the infections they cause tend to be more indolent. *S lugdunensis* may cause severe endocarditis with bulky vegetations similar to *S aureus*; this diagnosis is often missed when the coagulase-negative staphylococcal species is dismissed as a contaminant.

Because coagulase-negative staphylococci are normal inhabitants of human skin, it is difficult to distinguish infection from contamination, the latter perhaps accounting for three-fourths of blood culture isolates. Infection is more likely if the patient has a foreign body (eg, sternal wires, prosthetic joint, prosthetic cardiac valve, pacemaker, intracranial pressure monitor, CSF shunt, peritoneal dialysis catheter) or an intravascular device in place. Purulent or serosanguineous drainage, erythema, pain, or tenderness at the site of the foreign body or device suggests infection. Joint instability and pain are signs of prosthetic joint infection. Fever, a new murmur, instability of the prosthesis, and signs of systemic embolization are evidence of prosthetic valve endocarditis.

Infection is also more likely if the same strain is consistently isolated from two or more blood cultures (particularly if samples were obtained at different times and have the same antimicrobial susceptibility patterns) and from the foreign body site.

Whenever possible, the intravascular device or foreign body suspected of being infected should be removed. However, removal and replacement of some devices (eg, prosthetic joint, prosthetic valve, CSF shunt) can be a difficult or risky procedure, and it may sometimes be preferable to treat with antibiotics alone, knowing that the probability of cure is reduced, that suppressive antibiotics may be needed long term, and that surgical management may eventually be necessary.

Coagulase-negative staphylococci are commonly resistant to β-lactams and multiple other antibiotics. For patients with normal kidney function, the treatment of choice until susceptibility to penicillinase-resistant penicillins or other agents has been confirmed is vancomycin, 1 g intravenously every 12 hours to start, with an increase in dose to achieve trough levels in the 15–20 mcg/mL range. Duration of therapy has not been established for relatively uncomplicated infections, such as those from intravenous devices, which may be eliminated by simply removing the device. Infection involving bone or a prosthetic valve should be treated for 6 weeks. A combination regimen of vancomycin plus rifampin, 300 mg orally twice daily, plus gentamicin, 1 mg/kg intravenously every 8 hours, is recommended for treatment of prosthetic valve endocarditis caused by methicillin-resistant strains.

CLOSTRIDIAL DISEASES

1. Clostridial Myonecrosis (Gas Gangrene)

ESSENTIALS OF DIAGNOSIS

- Sudden onset of pain and edema in and around a contaminated wound.
- Brown to blood-tinged watery exudate, with skin discoloration of surrounding area.
- Gas in the tissue by palpation or radiograph.
- Gram-positive rods in culture or smear of exudate.

General Considerations

Gas gangrene or clostridial myonecrosis is a life-threatening muscle infection produced by any one of several clostridia, which are anaerobic organisms, most commonly *Clostridium perfringens*. Trauma and injection drug use are common predisposing conditions. Toxins produced in devitalized tissues under anaerobic conditions result in shock, hemolysis, and myonecrosis.

Clinical Findings

A. Symptoms and Signs

The onset is usually sudden, with rapidly increasing pain in the affected area, hypotension, and tachycardia. Fever is present but is not proportionate to the severity of the infection. In the last stages of the disease, severe prostration, stupor, delirium, and coma occur.

The wound becomes swollen, and the surrounding skin is pale. There is a foul-smelling brown, blood-tinged serous discharge. As the disease advances, the surrounding tissue changes from pale to dusky and finally becomes deeply discolored, with coalescent, red, fluid-filled vesicles. Gas may be palpable in the tissues. Pain is often severe, not concomitant with initial findings, which can be diagnostic.

B. Laboratory Findings

Gas gangrene is a clinical diagnosis, and empiric therapy is indicated if the diagnosis is suspected. Radiographic studies may show gas within the soft tissues, but this finding is not sensitive or specific. Anaerobic culture confirms the diagnosis. It is important to inform the microbiology laboratory that an anaerobic organism is suspected so that the cultures can be appropriately handled and grown.

▶ Differential Diagnosis

Clostridial myonecrosis may present similarly to necrotizing group A streptococcal infections and wound infections due to curved gram-negative organisms, such as *Vibrio vulnificus*. Other bacteria, including enteric gram-negative organisms and anaerobes, can produce gas in infected tissue as well.

▶ Treatment

Emergent surgical debridement of infected areas is essential, with radical surgical excision often necessary. Penicillin, 3–4 million units every 4 hours intravenously, is an effective adjunct, and clindamycin, 600–900 mg every 8 hours intravenously, may decrease production of bacterial toxin.

Hussain H et al. Clostridial myonecrosis: a comprehensive review of toxin pathophysiology and management strategies. Microorganisms. 2024;12:1464. [PMID: 39065232]

Peetermans M et al. Necrotizing skin and soft-tissue infections in the intensive care unit. Clin Microbiol Infect. 2020;26:8. [PMID: 31284035]

2. Tetanus

ESSENTIALS OF DIAGNOSIS

- History of contaminated or penetrating wound.
- Jaw muscle stiffness ("lock jaw"), then spasms (trismus) with spasms of the facial muscles termed "risus sardonicus" and spasm of the back causing arching or "opisthotonos."
- Neck stiffness, dysphagia, irritability, hyperreflexia.
- Finally, painful convulsions precipitated by minimal stimuli.

▶ General Considerations

Tetanus is caused by the neurotoxin tetanospasmin, elaborated by *C tetani*. Spores of this organism are ubiquitous in soil and may germinate when introduced into a wound. The incubation period is 5 days to 15 weeks, with the average being 8–12 days.

Most cases occur in unvaccinated individuals. Tetanus toxoid vaccine boosters should be provided every 10 years. Older adults, migrant workers, newborns, and persons who inject drugs are at risk. While puncture wounds are prone to causing tetanus, any wound, including bites or decubiti, may become infected by *C tetani*.

▶ Clinical Findings

A. Symptoms and Signs

The first symptom may be pain and tingling at the site of inoculation, followed by spasticity of the muscles nearby. Stiffness of the jaw, neck stiffness, dysphagia, and irritability are other early signs. Hyperreflexia develops later, with spasms of the jaw muscles (trismus) or facial muscles ("risus sardonicus") and rigidity and spasm of the muscles of the abdomen, neck, and back (opisthotonos). Painful tonic convulsions precipitated by minor stimuli are common. Spasms of the glottis and respiratory muscles may cause acute asphyxia and apnea. The patient usually remains conscious and the sensory examination is normal. The temperature is normal or only slightly elevated.

B. Laboratory Findings

The diagnosis of tetanus is made clinically.

▶ Differential Diagnosis

Tetanus must be differentiated from various acute CNS infections such as meningitis. Trismus may occasionally develop with odontogenic infections or the use of phenothiazines. Strychnine poisoning should also be considered.

▶ Complications

Airway obstruction is common. Urinary retention and constipation may result from spasm of the sphincters. Respiratory arrest and cardiac failure are late events.

▶ Prevention

Active immunization prevents tetanus (see Table 35–7). For primary immunization of adults, Td (tetanus and diphtheria toxoids vaccine) is administered as two doses 4–6 weeks apart, with a third dose 6–12 months later. For one of the three doses, Tdap (tetanus toxoid, reduced-dose diphtheria toxoid, acellular pertussis vaccine) should be substituted for Td. Booster Td doses are given every 10 years or at the time of major injury if it occurs > 5 years after a dose; a single dose of Tdap is preferred to Td for wound management if the patient has not been previously vaccinated with Tdap. Women should receive Tdap with each pregnancy, preferably between 27–36 weeks' gestation, with immunization at 27–30 weeks' gestation associated with the highest antibody concentrations.

Passive immunization with tetanus immune globulin, 250 units intramuscularly, should be used in nonimmunized

Table 38–2. Guide to tetanus prophylaxis in wound management.

History of Absorbed Tetanus Toxoid	Clean, Minor Wounds		All Other Wounds[1]	
	Tdap or Td[2]	TIG[3]	Tdap or Td[2]	TIG[3]
Unknown or < 3 doses	Yes	No	Yes	Yes
3 or more doses	No[4]	No	No[5]	No

[1] Examples include wounds contaminated with dirt, feces, soil, or saliva; puncture wounds; avulsions; and wounds from missiles, crushing, burns, and frostbite.
[2] Td indicates tetanus toxoid and diphtheria toxoid vaccine, adult form. Tdap indicates tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine, which may be substituted as a single dose for Td. Unvaccinated individuals should receive a complete series of three doses, one of which is Tdap.
[3] Human tetanus immune globulin, 250 units intramuscularly.
[4] Yes if > 10 years have elapsed since last dose.
[5] Yes if > 5 years have elapsed since last dose. (More frequent boosters are not needed and can enhance side effects.) Tdap has been safely administered within 2 years of Td vaccination, although local reactions to the vaccine may be increased.

individuals and those whose immunization status is uncertain whenever a wound is contaminated or likely to have devitalized tissue. Active immunization with tetanus toxoid vaccine is started concurrently. Table 38–2 provides a guide to prophylactic management.

Treatment

A. Specific Measures

Human tetanus immune globulin, 500 units, should be administered intramuscularly within the first 24 hours of presentation. Tetanus does not produce natural immunity, so a full course of infection immunization with tetanus toxoid should be administered once the patient has recovered.

B. General Measures

Debridement of wounds should be undertaken if implicated as the source. Metronidazole, 500 mg administered intravenously or orally every 6 hours, is preferred and should be administered to all patients. Penicillin, 3 million units intravenously every 4 hours, is an alternative. Minimal stimuli can provoke spasms, so the patient should be placed on bed rest and excess light and noise should be avoided. Sedation with benzodiazepines, paralysis with curare-like agents, and mechanical ventilation are often necessary. Enteral nutritional support should be given early.

Prognosis

High mortality rates are associated with a short incubation period, early onset of convulsions, and delay in treatment. Contaminated lesions about the head and face are more dangerous than wounds elsewhere.

Pfausler B et al. Toxin-associated infectious diseases: tetanus, botulism and diphtheria. Curr Opin Neurol. 2021;34:432. [PMID: 33840775]

3. Botulism

ESSENTIALS OF DIAGNOSIS

- Recent ingestion of home-canned or smoked foods; recovery of toxin in serum or food.
- Injection drug use.
- Diplopia, dry mouth, dysphagia, dysphonia; muscle weakness leading to respiratory paralysis; normal sensory examination.
- Pupils are fixed and dilated in most cases.

General Considerations

Botulism is a paralytic disease caused by botulinum toxin, which is produced by *Clostridium botulinum*, a ubiquitous, strictly anaerobic, spore-forming bacillus found in soil. Botulinum toxin is extremely potent and is classified by the CDC as a high-priority agent because of its potential for use as an agent of bioterrorism. Naturally occurring botulism exists in three forms: foodborne botulism, infant botulism, or wound botulism. Foodborne botulism is caused by ingestion of preformed toxin present in canned, smoked, or vacuum-packed foods such as home-canned vegetables, smoked meats, and vacuum-packed fish. Commercial foods have been associated with outbreaks of botulism. Infant botulism (associated with ingestion of honey) and wound botulism (often in association with injection drug use) result from *C tetani* organisms present in the gut or wound that secrete toxin.

Clinical Findings

A. Symptoms and Signs

Twelve to 36 hours after ingestion of the toxin, visual disturbances appear, particularly diplopia and loss of accommodation. Ptosis, cranial nerve palsies with impairment of extraocular muscles, and fixed dilated pupils are characteristic signs. The sensory examination is normal. Other symptoms are dry mouth, dysphagia, and dysphonia. Nausea and vomiting may be present, particularly with type E toxin. The sensorium remains clear and the temperature normal. Symmetric, descending flaccid paralysis progressing to respiratory failure and death may occur unless mechanical assistance is provided.

B. Laboratory Findings

A presumptive diagnosis should be made based on clinical findings. Toxin in foods and patients' serum can be demonstrated by mouse inoculation and identified with specific antiserum, but confirmation of results may take several days.

Differential Diagnosis

Because the clinical presentation of botulism is so distinctive and the differential diagnosis limited, botulism once considered is not easily confused with other diseases. Cranial nerve involvement may be seen with vertebrobasilar insufficiency, the Miller Fisher variant of Guillain-Barré syndrome, myasthenia gravis, or any basilar meningitis (infectious or carcinomatous).

Treatment

If botulism is suspected, the clinician should contact health authorities or the CDC for advice, procurement of equine serum heptavalent botulism antitoxin, and assistance in obtaining assays for toxin in serum, stool, or food. Skin testing is recommended to exclude hypersensitivity to the antitoxin preparation. Antitoxin should be administered as early as possible, ideally within 24 hours of symptom onset; its administration should not be delayed for laboratory confirmation of the diagnosis. Respiratory failure is managed with intubation and mechanical ventilation. Parenteral fluids or alimentation should be given while swallowing difficulty persists. The removal of unabsorbed toxin from the gut may be attempted. In the case of wound botulism, penicillin, 3 g intravenously every 4 hours, or metronidazole, 500 mg intravenously every 8 hours, may be helpful in arresting the organism.

Rao AK et al. Clinical guidelines for diagnosis and treatment of botulism, 2021. MMWR Recomm Rep. 2021;70:1. [PMID: 33956777]

LISTERIOSIS

ESSENTIALS OF DIAGNOSIS

- Ingestion of contaminated food product.
- Fever in a pregnant woman in her third trimester.
- Altered mental status and fever in an older or immunocompromised patient.
- Blood and CSF cultures confirm the diagnosis.

General Considerations

Listeria monocytogenes is a facultative, motile, gram-positive rod. Most cases of infection caused by *L monocytogenes* are sporadic, but outbreaks have been traced to eating contaminated food, including unpasteurized dairy products, hot dogs, delicatessen meats, cantaloupes, and soft cheeses, such as queso fresco, brie, and ricotta. Outbreaks have been associated with significant morbidity and mortality in patients with infection.

Clinical Findings

Five types of infection are recognized:

1. **Infection during pregnancy**, usually in the last trimester, is a mild febrile illness without an apparent primary focus and may resolve without specific therapy. However, approximately one in five pregnancies complicated by listeriosis result in spontaneous abortion or stillbirth and surviving infants are at risk for clinical neonatal listeriosis.
2. **Granulomatosis infantisepticum** is a neonatal infection acquired in utero, characterized by disseminated abscesses, granulomas, and a high mortality rate.
3. **Bacteremia** with or without sepsis syndrome is an infection of neonates or immunocompromised adults. Presentation is a febrile illness without a recognized source.
4. **Meningitis** caused by *L monocytogenes* affects infants under 2 months of age as well as older adults, ranking third after pneumococcus and meningococcus as common causes of bacterial meningitis. CSF often shows *lymphocytic* pleocytosis, with variable protein and glucose findings. Adults with meningitis are often immunocompromised, and cases have been associated with advanced HIV as well as the use of glucocorticoids and TNF inhibitors such as infliximab.
5. **Focal infections**, including adenitis, brain abscess, endocarditis, osteomyelitis, and arthritis, occur rarely.

Prevention

At-risk patients (eg, pregnant women people living with HIV) should avoid unpasteurized milk products, including raw cheeses. Smoked seafoods, cold cuts, hot dogs, and meat spreads also carry risk. Thoroughly cook animal source food and wash raw vegetables.

Treatment

Ampicillin, 8–12 g/day intravenously in four to six divided doses (the higher dose for meningitis), is the treatment of choice. Gentamicin, 5 mg/kg/day intravenously once or in divided doses, is synergistic with ampicillin against *Listeria* in vitro and in animal models, and the use of combination therapy may be considered during the first few days of treatment to enhance eradication of organisms. In patients with penicillin allergies, trimethoprim-sulfamethoxazole has excellent intracellular and CSF penetration and is an appropriate alternative. The dose is 10–20 mg/kg/day intravenously divided every 6–12 hours of the trimethoprim component. Mortality and morbidity rates still are high. Therapy should be administered for at least 2–3 weeks. Longer durations—between 3 and 6 weeks—have been recommended for treatment of meningitis, especially in immunocompromised patients.

Koopmans MM et al. Human listeriosis. Clin Microbiol Rev. 2023;36:e0006019. [PMID: 36475874]

INFECTIVE ENDOCARDITIS

ESSENTIALS OF DIAGNOSIS

- Fever.
- Underlying valvular disease or prosthetic endovascular material.
- Positive blood cultures.
- Evidence of vegetation on echocardiography.
- Evidence of systemic emboli.

General Considerations

Endocarditis is a bacterial or fungal (or rarely aseptic) infection of the valvular or endocardial surface of the heart. The clinical presentation depends on the infecting organism and the valve or valves that are infected. More virulent organisms—*S aureus* in particular—tend to produce a more rapidly progressive and destructive infection. Endocarditis caused by more virulent organisms often presents as an acute febrile illness and is complicated by early embolization, acute valvular regurgitation, and myocardial abscess formation. Viridans strains of streptococci, enterococci, other bacteria (including intracellular bacteria), yeasts, and fungi tend to cause a more subacute picture.

Predisposing valvular abnormalities include a variety of congenital heart disorders, rheumatic involvement of any valve, bicuspid aortic valves, calcific or sclerotic aortic valves, hypertrophic subaortic stenosis, and mitral valve prolapse. Regurgitation lesions are more susceptible than stenotic ones.

The initiating event in native valve endocarditis is colonization of the valve by bacteria or yeast that gain access to the bloodstream. Transient bacteremia is common during dental, upper respiratory, urologic, and lower GI diagnostic and surgical procedures. Intravascular devices are also a portal of access of microorganisms into the bloodstream. A large proportion of cases of *S aureus* endocarditis are attributable to health care–associated bacteremia.

Native valve endocarditis is usually caused by *S aureus*, viridans streptococci, enterococci, or HACEK organisms (an acronym for *Haemophilus aphrophilus* [now *Aggregatibacter aphrophilus*], *Actinobacillus actinomycetemcomitans* [now *Aggregatibacter actinomycetemcomitans*], *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella* species). *S aureus* is the leading cause of native valve endocarditis. Gram-negative organisms and fungi account for a small percentage.

In injection drug users, *S aureus* accounts for > 60% of all endocarditis cases and for 80–90% of cases in which the tricuspid valve is infected. Enterococci and streptococci comprise most of the balance in about equal proportions. Other causative organisms are gram-negative aerobic bacilli, fungi, and unusual organisms, such as *Bartonella* and *Coxiella* species.

The microbiology of **prosthetic valve endocarditis** is distinctive. Early infections (ie, those occurring within 2 months after valve implantation) are commonly caused by staphylococci—both coagulase-positive and coagulase-negative—gram-negative organisms, and fungi. In late prosthetic valve endocarditis, streptococci are commonly identified, although coagulase-negative and coagulase-positive staphylococci still cause many cases.

Clinical Findings

A. Symptoms and Signs

Virtually all patients have fever at some point in the illness, although it may be very low grade (< 38°C) in older individuals and in patients with HF or kidney failure. Rarely, there may be no fever at all.

The duration of illness typically is a few days to a few weeks. Nonspecific constitutional symptoms are common. The initial symptoms and signs of endocarditis may be caused by direct arterial, valvular, or cardiac damage. Although a changing regurgitant murmur is significant diagnostically, it is the exception rather than the rule. Symptoms also may occur as a result of embolization, metastatic infection or immunologically mediated phenomena. These include cough; dyspnea; arthralgias or arthritis; diarrhea; and abdominal, back, or flank pain.

The characteristic peripheral lesions—petechiae (on the palate, conjunctiva, or beneath the fingernails), subungual ("splinter") hemorrhages (Figure 38–4), Osler nodes (painful, violaceous raised lesions of the fingers, toes, or feet), Janeway lesions (painless erythematous lesions of the palms or soles, and Roth spots (exudative lesions in the retina)—occur in about 25% of patients. Strokes and major systemic embolic events are present in about 25% of patients and tend to occur before or within the first week of antimicrobial therapy. Hematuria and proteinuria may result from emboli or immunologically mediated glomerulonephritis. Septic emboli to the lungs are common in endocarditis affecting the right-sided values (eg, tricuspid, pulmonary).

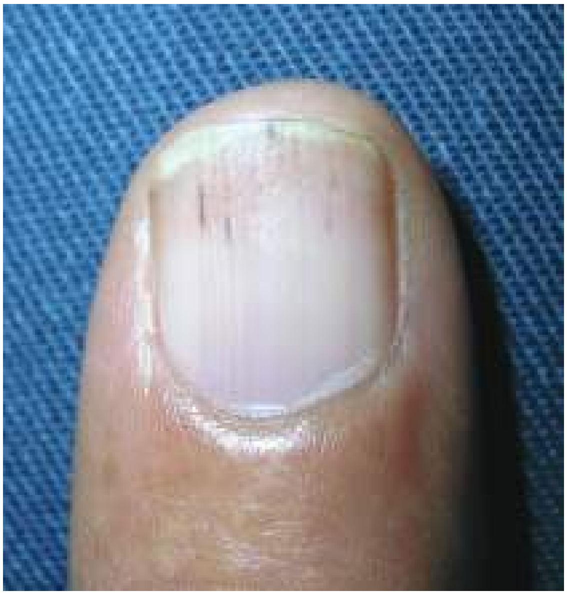

Figure 38–4. Splinter hemorrhages appearing as red lineal streaks under the nail plate and within the nail bed, in endocarditis, psoriasis, and trauma. (Reproduced with permission from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

B. Imaging

Echocardiography is useful in identifying vegetations and other characteristic features suspicious for endocarditis and may provide adjunctive information about the specific valve or valves that are infected. The sensitivity of transthoracic echocardiography is between 55% and 65%; it cannot reliably rule out endocarditis but may confirm a clinical suspicion. Transesophageal echocardiography is 90% sensitive in detecting vegetations and is useful for identifying valve ring abscesses as well as prosthetic valve endocarditis. CXR may show evidence for the underlying cardiac abnormality and, in right-sided endocarditis, pulmonary infiltrates. New conduction abnormalities on ECG, such as prolongation of the PR interval, suggest myocardial abscess formation.

C. Diagnostic Studies

1. Blood cultures—Three sets of blood cultures from different venipuncture sites (which may be collected simultaneously or several hours apart) are recommended before starting antibiotics to maximize microbiologic diagnosis. Adequate volume is important; each culture bottle should be filled with 10 mL of blood since half of adults have < 1 colony forming unit of bacteria per mL blood.

Approximately 5% of cases will be culture-negative, usually attributable to administration of antimicrobials prior to cultures. If antimicrobial therapy has been administered prior to obtaining cultures and the patient is clinically stable, it is reasonable to withhold antimicrobial therapy for 2–3 days so that appropriate cultures can be obtained. Culture-negative endocarditis may also be due to organisms that require special media for growth (eg, *Legionella, Bartonella, Abiotrophia* species, formerly referred to as nutritionally deficient streptococci), organisms that do not grow on artificial media and most often require serologic diagnosis (eg, *Tropheryma whipplei*, *Coxiella burnetii*, *Chlamydia psittaci*), or those that may require prolonged incubation (eg, *Brucella*, anaerobes, HACEK organisms). *B quintana* and *B henselae* are important causes of culture-negative endocarditis, which is most frequent among those with marginal housing status and are typically diagnosed by serologies.

2. 2023 Duke-International Society for Cardiovascular Infectious Disease (ISCVID) criteria—The 2023 Duke-ISCVID criteria establish a diagnosis of endocarditis by pathologic criteria (ie, microorganisms or histopathologic findings of endocarditis identified on tissue, such as a vegetation, cardiac tissue, or an explanted prosthetic valve or cardiac device) in the context of clinical signs of endocarditis. A definite diagnosis can also be made by meeting two major clinical criteria, one major and three minor clinical criteria, or five minor clinical criteria. **Major criteria** include (1) two positive blood cultures for a microorganism that typically causes infective endocarditis or persistent bacteremia, three or more positive blood cultures for a microorganism that occasionally or rarely causes endocarditis, or blood tests consistent with acute infection with *Coxiella burnetii*, *Bartonella* species, or *Tropheryma whipplei;* (2) evidence of endocardial involvement documented by echocardiography showing definite vegetation, myocardial abscess, new partial dehiscence of a prosthetic valve, or new valvular regurgitation or FDG PET/CT imaging demonstrating abnormal metabolic activity involving cardiac tissue or prosthetic material; and (3) directly observed evidence of endocarditis during cardiac surgery. **Minor criteria** include the presence of a predisposing condition; fever of 38°C or higher; vascular phenomena, such as cutaneous hemorrhages, aneurysm, systemic emboli, or pulmonary infarction; immunologic phenomena, such as glomerulonephritis, Osler nodes, Roth spots, or rheumatoid factor; positive blood cultures not meeting the major criteria or other laboratory evidence of an active infection; abnormal FDG PET/CT metabolic activity within 3 months of implantation of endovascular prosthetic material; and new valvular regurgitation (worsening or changing of a preexisting murmur is insufficient). A possible diagnosis of endocarditis is made if one major and one minor criterion or three minor criteria are met. If fewer criteria are found, or a sound alternative explanation for illness is identified, or the patient's febrile illness has resolved within 4 days, endocarditis is unlikely.

Complications

The course of infective endocarditis is determined by the degree of damage to the heart, the site of infection (right-sided versus left-sided, aortic versus mitral valve), the presence of metastatic foci of infection, the occurrence of embolization, and immunologically mediated processes. Destruction of infected heart valves is especially common and precipitous with *S aureus* but can occur with any organism and can progress even after bacteriologic cure. The infection can also extend into the myocardium, resulting in abscesses leading to conduction disturbances, and involving the wall of the aorta, creating sinus of Valsalva aneurysms.

Peripheral embolization to the brain and myocardium may result in infarctions. Embolization to the spleen and kidneys is also common. Peripheral emboli may initiate metastatic infections or may become established in vessel walls, leading to mycotic aneurysms. Right-sided endocarditis (usually the tricuspid valve) causes septic pulmonary emboli, occasionally with infarction and lung abscesses.

Prevention

The American Heart Association recommends antibiotic prophylaxis for infective endocarditis in a relatively small group of patients with predisposing congenital or valvular anomalies undergoing invasive dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of oral mucosa. Prophylaxis is not routinely recommended for other types of procedures.

Treatment

Empiric regimens for endocarditis while culture results are pending should include agents active against staphylococci, streptococci, and enterococci. Vancomycin, 1 g every 12 hours intravenously with a titration of dose up to reach a trough level of 15–20 mcg/mL, plus ceftriaxone, 2 g every 24 hours, provides appropriate coverage pending definitive diagnosis; consultation with an infectious disease expert is strongly recommended when initiating treatment. Intravenous therapy has been the mainstay of treatment for infective endocarditis. Some data, however, support the use of oral antibiotic therapy following 2 weeks of intravenous antibiotic regimens for certain organisms.

A. Viridans Streptococci

For penicillin-susceptible viridans streptococcal endocarditis (ie, MIC 0.12 mcg/mL or less), penicillin G, 18 million units intravenously either continuously or in four to six equally divided doses, or ceftriaxone, 2 g intravenously once daily for 4 weeks, is recommended. For patients unable to tolerate penicillin or ceftriaxone, vancomycin, 15 mg/kg intravenously every 12 hours for 4 weeks, is given with a desired trough level of 15–20 mcg/mL. Prosthetic valve endocarditis is treated with a 6-week course of penicillin or ceftriaxone and the clinician can consider adding 2 weeks of gentamicin at the start of therapy.

Viridans streptococci relatively resistant to penicillin (ie, MIC > 0.12 mcg/mL but ≤ 0.5 mcg/mL) should be treated for 4 weeks. Penicillin G, 24 million units intravenously either continuously or in four to six equally divided doses, is combined with gentamicin, 3 mg/kg intravenously every 24 hours for the first 2 weeks. Ceftriaxone may be a reasonable alternative treatment option. In patients with IgE-mediated allergy to penicillin, vancomycin alone, 15 mg/kg intravenously every 12 hours for 4 weeks with achievement of adequate trough levels, should be administered. Prosthetic valve endocarditis is treated with a 6-week course of penicillin or ceftriaxone plus gentamicin as above.

Endocarditis caused by viridans streptococci with an MIC > 0.5 mcg/mL or by *Abiotrophia* species should be treated the same as enterococcal endocarditis.

B. Enterococci (Formerly Group D Streptococci)

For enterococcal endocarditis, penicillin or ampicillin alone is inadequate. One recommended regimen is ampicillin, 2 g intravenously every 4 hours, or penicillin G, 4 million units intravenously every 4 hours plus gentamicin, 1 mg/kg intravenously every 8 hours. The second recommended regimen is ampicillin, 2 g intravenously every 4 hours, plus ceftriaxone, 2 g intravenously every 12 hours. The recommended duration of therapy is 4–6 weeks (the longer duration for patients with symptoms for > 3 months, relapse, or prosthetic valve endocarditis). The combination of ampicillin plus ceftriaxone is recommended for patients with creatinine clearance < 50 mL/min or whose enterococcal isolates are resistant to gentamicin. In patients who cannot tolerate penicillin and ampicillin or who have an enterococcal isolate resistant to these agents, vancomycin plus gentamicin can be used. Endocarditis caused by strains resistant to penicillin and vancomycin are difficult to treat and should always be managed with an infectious disease specialist.

C. Staphylococci

For methicillin-susceptible *S aureus* isolates, nafcillin or oxacillin, 12 g intravenously daily given continuously or in four to six divided doses, or cefazolin, 6 g intravenously daily given continuously or in three divided doses for 6 weeks, is the preferred therapy. In cases of brain abscess resulting from methicillin-susceptible *S aureus* endocarditis, nafcillin should be used instead of cefazolin. For patients with history of immediate type hypersensitivity to β-lactams, a desensitization protocol should be undertaken. For patients with a history of non-anaphylactoid reactions to penicillins, cefazolin should be used. Patients who are infected with methicillin-resistant *S aureus* or who are unable to tolerate β-lactam therapy should receive vancomycin, 30 mg/kg/day intravenously divided in two or three doses, to achieve a goal trough level of 15–20 mcg/kg, or daptomycin 8–12 mg/kg intravenously once daily. Aminoglycoside combination regimens are not recommended. The effect of rifampin with antistaphylococcal drugs is variable, and its routine use is not recommended.

Because coagulase-negative staphylococci—a common cause of prosthetic valve endocarditis—are routinely resistant to methicillin, β-lactam antibiotics should not be used unless the isolate is demonstrated to be susceptible. A combination of vancomycin, 30 mg/kg/day intravenously divided in two or three doses for 6 weeks; rifampin, 300 mg every 8 hours for 6 weeks; and gentamicin, 3 mg/kg intravenously every 8 hours for the first 2 weeks, is recommended for prosthetic valve infection. If the organism is sensitive to methicillin, nafcillin, oxacillin, or cefazolin can be used in combination with rifampin and gentamicin. Combination therapy with nafcillin or oxacillin (vancomycin or daptomycin for methicillin-resistant strains), rifampin, and gentamicin is also recommended for treatment of *S aureus* prosthetic valve infection.

D. HACEK Organisms

HACEK organisms are slow-growing, fastidious, gram-negative coccobacilli or bacilli that are normal oral flora and cause < 5% of all cases of endocarditis. They may produce β-lactamase, and thus the treatment of choice is ceftriaxone (or another third-generation cephalosporin), 2 g intravenously once daily for 4 weeks. Prosthetic valve endocarditis should be treated for 6 weeks. In penicillin-allergic patients, experience is limited, but fluoroquinolones have in vitro activity and should be considered. HACEK organisms have previously required extended incubation periods but can now grow within the standard incubation period of 5 days due to automated blood culture systems.

E. Culture-Negative Endocarditis

Failure to culture microorganisms from patients with suspected infective endocarditis may be due to infection from organisms not recovered in routine microbiology testing or previous administration of antimicrobial agents before blood cultures were obtained. These cases must be managed with the assistance of an infectious disease specialist. Pathogens that are not able to be cultured by commonly used techniques include *Bartonella* species, *Coxiella* species, *Chlamydia* species, *Brucella* species, and *Tropheryma whipplei*. Serologic testing should be performed in patients who have epidemiologic risk factors for these infections. Increasingly, universal PCR testing is being employed in infectious diseases to make difficult diagnoses. Treatment should be directed at likely pathogens while awaiting serologic results; treatment of patients given prior antimicrobials before cultures were obtained must also consider likely pathogens.

F. Role of Surgery

While many cases can be successfully treated medically, operative management is frequently required. Acute HF unresponsive to medical therapy is an indication for valve replacement even if active infection is present. Infections unresponsive to appropriate antimicrobial therapy after 7–10 days (ie, persistent fevers, positive blood cultures despite therapy) are more likely to be eradicated if the valve is replaced. Surgery is nearly always required for cure of fungal endocarditis and is more often necessary with highly resistant bacteria. It is also indicated when the infection involves the sinus of Valsalva or produces septal abscesses. Recurrent infection with the same organism prompts an operative approach, especially with infected prosthetic valves. Continuing embolization presents a difficult problem when the infection is otherwise responding; surgery may be the proper approach. Particularly challenging is a large and fragile vegetation demonstrated by echocardiography in the absence of embolization. Most clinicians favor an operative approach with vegetectomy and valve repair if the patient is a good candidate. Operation without delay may be considered in patients with endocarditis and an embolic stroke who have an indication for surgery. If not urgent or if intracranial hemorrhage is present, a delay of at least 4 weeks should be considered.

G. Role of Anticoagulation

Anticoagulation is contraindicated in native valve endocarditis because of an increased risk of intracerebral hemorrhage from mycotic aneurysms or embolic phenomena. The role of anticoagulant therapy during prosthetic valve endocarditis is more controversial. Reversal of anticoagulation may result in thrombosis of the mechanical prosthesis, particularly in the mitral position. Conversely, anticoagulation during active prosthetic valve endocarditis caused by *S aureus* has been associated with fatal intracerebral hemorrhage. One approach is to discontinue anticoagulation during the septic phase of *S aureus* prosthetic valve endocarditis. In patients with *S aureus* prosthetic valve endocarditis complicated by a CNS embolic event, anticoagulation should be discontinued for the first 2 weeks of therapy. Indications for anticoagulation following prosthetic valve implantation for endocarditis are the same as for patients with prosthetic valves without endocarditis (eg, nonporcine mechanical valves and valves in the mitral position).

▶ Response to Therapy

If infection is caused by viridans streptococci, enterococci, or coagulase-negative staphylococci, defervescence occurs in 3–4 days on average; with *S aureus* or *Pseudomonas aeruginosa*, fever may persist for longer. Blood cultures should be obtained every 1–2 days to document sterilization. Other causes of persistent fever are myocardial or metastatic abscess, sterile embolization, superimposed hospital-acquired infection, and drug reaction. Most relapses occur within 1–2 months after completion of therapy. Obtaining one or two blood cultures during this period is prudent.

▶ When to Refer

- Consider consulting an infectious diseases specialist in all cases of suspected infective endocarditis.
- Consult a cardiac surgeon as discussed in the Role of Surgery section above to prevent further embolic disease, HF, and other complications, including death.

▶ When to Admit

Patients with infective endocarditis should be hospitalized for expedited evaluation and treatment.

INFECTIONS CAUSED BY GRAM-NEGATIVE BACTERIA

BORDETELLA PERTUSSIS INFECTION (Whooping Cough)

ESSENTIALS OF DIAGNOSIS

- Predominantly in children under age 2 years; adolescents and adults are reservoirs of infection.
- Two-week prodromal catarrhal stage of malaise, cough, coryza, and anorexia.
- Paroxysmal cough ending in a high-pitched inspiratory "whoop."
- Absolute lymphocytosis, often striking; culture confirms diagnosis.

General Considerations

Pertussis is an acute infection of the respiratory tract caused by *B pertussis* that is transmitted by respiratory droplets. The incubation period is 7–17 days. Half of all cases occur before age 2 years. Neither immunization nor disease confers lasting immunity to pertussis, requiring ongoing booster vaccination. Consequently, adults can be an important reservoir of the disease.

Clinical Findings

The symptoms of classic pertussis last about 6 weeks and are divided into three consecutive stages. The catarrhal stage is characterized by its insidious onset, with lacrimation, sneezing, and coryza, anorexia and malaise, and a hacking night cough that becomes diurnal. The paroxysmal stage is characterized by bursts of rapid, consecutive coughs followed by a deep, high-pitched inspiration (whoop). The convalescent stage begins 4 weeks after onset of the illness with a decrease in the frequency and severity of paroxysms of cough. Atypical presentations are more common in adults and individuals who were previously vaccinated. Cough persisting > 2 weeks is suggestive. Infection may also be asymptomatic, and apnea may be the only manifestation in infants.

The WBC count is usually 15,000–20,000/mcL (15–20 × 10^9/L) with lymphocytosis. The diagnosis is established by isolating the organism from a nasopharyngeal culture on special medium (eg, Bordet-Gengou agar). PCR assays for *B pertussis* may be available in some clinical or health department laboratories.

Prevention

Acellular pertussis vaccine is recommended for all infants, combined with diphtheria and tetanus toxoids (DTaP). Infants and susceptible adults with significant exposure should receive prophylaxis with an oral macrolide. In recognition of their importance as a reservoir of disease, vaccination of adolescents and adults against pertussis is recommended (see Table 35–7). Adolescents age 11–18 years (preferably between 11 and 12 years of age) who have completed the DTP or DTaP vaccination series should receive a single dose of either Tdap product instead of Td (tetanus and diphtheria toxoids vaccine) for booster immunization against tetanus, diphtheria, and pertussis. Tdap, which immunizes against the same bacteria as DTaP, is a booster immunization; Tdap contains the same amount of tetanus toxoid (T) as DTaP but reduced diphtheria toxoid and acellular pertussis (hence the lower case -dap). Adults of all ages (including those older than age 64 years) should receive a single dose of Tdap. In addition, pregnant women should receive a dose of Tdap during each pregnancy regardless of prior vaccination history, ideally between 27 and 36 weeks of gestation, to maximize the antibody response of the woman and the passive antibody transfer to the infant. For any woman who was not previously vaccinated with Tdap and for whom the vaccine was not given during her pregnancy, Tdap should be administered immediately postpartum. The CDC has eliminated the recommendation that a 2-year period window is needed between receiving the Td and Tdap vaccines based on data showing that there is not an increased risk of adverse events.

Treatment

Antibiotic treatment should be initiated in all suspected cases. Treatment options include azithromycin, 500 mg orally on day 1 and 250 mg for 4 more days, or clarithromycin, 500 mg orally twice daily for 7 days. Trimethoprim-sulfamethoxazole, 160–800 mg orally twice a day for 14 days, also is effective. Treatment shortens the duration of carriage and may diminish the severity of coughing paroxysms. These same regimens are indicated for prophylaxis of contacts to an active case of pertussis who are exposed within 3 weeks of the onset of cough in the index case.

MENINGOCOCCAL MENINGITIS

ESSENTIALS OF DIAGNOSIS

- Fever, headache, vomiting, delirium, convulsions.
- Petechial rash on skin and mucous membranes.
- Neck and back stiffness and positive Kernig and Brudzinski signs are characteristic.
- Purulent spinal fluid with gram-negative intracellular and extracellular diplococci.
- Culture of CSF, blood, or petechial aspiration confirms the diagnosis.

General Considerations

Meningococcal meningitis is caused by *Neisseria meningitidis* of groups A, B, C, Y, and W-135, among others. Up to 40% of persons are nasopharyngeal carriers of meningococci, but disease develops in relatively few of these persons. Infection is transmitted by droplets. Clinical illness may take the form of meningococcemia (a fulminant form of septicemia without meningitis), meningococcemia with meningitis, or meningitis. Recurrent meningococcemia with fever, rash, and arthritis is seen rarely in patients with certain terminal complement deficiencies. Asplenic patients are also at risk.

Clinical Findings

A. Symptoms and Signs

High fever, chills, nausea, vomiting, and headache as well as back, abdominal, and extremity pains are typical. Rapidly developing confusion, delirium, seizures, and coma occur in some. In infants and in older adults, fever or stiff neck is often missing, and altered mental status may dominate the picture. On examination, nuchal and back rigidity are typical. Positive Kernig sign (pain in the hamstrings upon extension of the knee with the hip at 90-degree flexion) and Brudzinski sign (flexion of the knee in response to flexion of the neck) are specific but not sensitive findings of meningitis. A petechial rash appearing all over the body, including on mucous membranes, on the lower extremities, and at pressure points, is found in most cases. Petechiae may vary in size from pinpoint lesions to large ecchymoses or even skin gangrene that may later slough.

B. Laboratory Findings

Lumbar puncture typically reveals a cloudy or purulent CSF, with elevated pressure, increased protein, and decreased glucose content. The fluid usually contains a cell count > 1000/mcL (1.0×10^9/L) with polymorphonuclear cells predominating and containing gram-negative intracellular diplococci. The organism is usually demonstrated by smear and culture of the CSF, oropharynx, blood, or aspirated petechiae. The absence of organisms in a Gram-stained smear of the CSF sediment does not rule out the diagnosis. The capsular polysaccharide can be demonstrated in CSF or urine by latex agglutination; this is useful in partially treated patients, although sensitivity is 60–80%.

Disseminated intravascular coagulation is an important complication of meningococcal infection and is typically present in toxic patients with ecchymotic skin lesions.

Differential Diagnosis

Meningococcal meningitis must be differentiated from other meningitides. Rickettsial, echovirus, and, rarely, other bacterial infections (eg, staphylococcal infections, scarlet fever) also cause petechial rash.

Prevention

There are two quadrivalent vaccines with coverage against meningococcal serogroups A, C, W, and Y, and two monovalent vaccines with coverage against meningococcal serogroup B. The quadrivalent vaccines are conjugate vaccines (MenACWY-TT and MenACWY-CRM, collectively termed MCV4) indicated for persons age 2–55 years. The two monovalent vaccines against meningococcal serogroup B are MenB-FHbp and MenB-4C; they are approved for persons age 10–25 years and are not interchangeable. A pentavalent conjugate vaccine targeting serogroups A, C, W, Y, and B was approved for use in the United States in 2023.

The Advisory Committee on Immunization Practices recommends immunization with a dose of MCV4 for preadolescents age 11–12 years with a booster at age 16 years. For ease of program implementation, persons age 21 years or younger should have documentation of receipt of a dose of MCV4 not more than 5 years before enrollment to college. If the primary dose was administered before the 16th birthday, a booster dose should be administered before enrollment. The vaccine is also recommended as a two-dose primary series administered 2 months apart for persons age 2–54 years with persistent complement deficiency, persons with functional or anatomic asplenia, and adolescents with HIV infection. All other persons at increased risk for meningococcal disease (eg, military recruits, microbiologists routinely exposed to isolates of *N meningitidis*, or travelers to an epidemic or highly endemic country) should receive a single dose. One of the meningococcal serogroup B vaccines may be administered to persons 10 years of age or older who are at increased risk for meningococcal disease. These individuals include those with persistent complement deficiencies, persons with anatomic or functional asplenia, microbiologists, and persons identified to be at increased risk because of a serogroup B meningococcal disease outbreak. Vaccination of persons age 16–23 years may provide short-term protection against most strains of serogroup B meningococcal disease and is indicated if there is a dormitory or school outbreak. Use of the new pentavalent vaccine is recommended when both MCV4 and MenB vaccines are indicated.

Eliminating nasopharyngeal carriage of meningococci is an effective prevention strategy in closed populations and to prevent secondary cases in household or otherwise close contacts. Rifampin, 600 mg orally twice a day for 2 days, ciprofloxacin, 500 mg orally once, or one intramuscular 250-mg dose of ceftriaxone is effective. Ciprofloxacin should not be used as prophylaxis if there have been two or more cases of invasive meningococcal disease due to ciprofloxacin-resistant strains and ≥ 20% of all reported cases are caused by ciprofloxacin-resistant strains in a local catchment area during a rolling 12 month period. School and work contacts ordinarily need not be treated. Hospital contacts receive therapy only if intense exposure has occurred (eg, mouth-to-mouth resuscitation). Accidentally discovered carriers without known close contact with meningococcal disease do not require prophylactic antimicrobials.

Treatment

Blood cultures must be obtained and intravenous antimicrobial therapy started immediately. This may be done prior to lumbar puncture in patients in whom the diagnosis is not straightforward and for those in whom MR or CT imaging is indicated to exclude mass lesions. Aqueous penicillin G is the antibiotic of choice (4 million units intravenously every 4 hours). The prevalence of strains of *N meningitidis* with intermediate resistance to penicillin in vitro (MICs 0.1–1 mcg/mL) is increasing, particularly in Europe. Penicillin-intermediate strains thus far remain fully susceptible to ceftriaxone and other third-generation cephalosporins used to treat meningitis, and these should be effective alternatives to penicillin. In penicillin-allergic patients or those in whom *Haemophilus influenzae* or gram-negative meningitis is a consideration, ceftriaxone, 2 g intravenously every 12 hours, should be used. Treatment should be continued for at least 4 days in adults and 5 days in children and can be extended to 7 days for severe presentations or delayed responses to therapy.

When to Admit

All patients with suspected meningococcal infection should be admitted for evaluation and empiric intravenous antibiotic therapy.

Berry I et al. Selection of antibiotics as prophylaxis for close contacts of patients with meningococcal disease in areas with ciprofloxacin resistance - United States, 2024. MMWR Morb Mortal Wkly Rep. 2024;73:99. [PMID: 38329923]

Collins JP et al. Use of the Pfizer pentavalent meningococcal vaccine among persons age ≥ 10 years: Recommendations of the Advisory Committee on Immunization Practices - United States, 2023. MMWR Morb Mortal Wkly Rep. 2024;73:345. [PMID: 38635488]

McMillan M et al. Effectiveness of meningococcal vaccines at reducing invasive meningococcal disease and pharyngeal Neisseria meningitidis carriage: a systematic review and meta-analysis. Clin Infect Dis. 2021;73:e609. [PMID: 33212510]

INFECTIONS CAUSED BY *HAEMOPHILUS SPECIES*

H influenzae and other *Haemophilus* species may cause sinusitis, otitis, bronchitis, epiglottitis, pneumonia, cellulitis, septic arthritis, meningitis, and endocarditis. Nontypeable strains are responsible for most disease in adults. Alcohol use disorder, smoking, chronic lung disease like COPD, advanced age, and HIV are risk factors.

For adults with sinusitis, otitis, or respiratory tract infections, appropriate oral antibiotics include amoxicillin (500–1000 mg three times daily, if organism is susceptible) or amoxicillin-clavulanate (875/125 mg twice daily, for β-lactamase producing strains). Other oral antibiotic options may include cefuroxime axetil (500 mg twice daily), cefdinir (600 mg once daily), fluroquinolones (levofloxacin 750 mg daily or moxifloxacin 400 mg daily), doxycycline (100 mg twice daily), or azithromycin (500 mg orally once followed by 250 mg daily). Duration of therapy depends on the clinical syndrome; 5–7 days is often adequate. In more seriously ill patients (eg, those with multilobar pneumonia), ceftriaxone, 1 g/day intravenously, or an intravenous fluoroquinolone (also appropriate for penicillin-allergic patients; dosages as above) can be used.

Epiglottitis is characterized by an abrupt onset of high fever, drooling, and inability to handle secretions. A severe sore throat despite an unimpressive examination of the pharynx can be a diagnostic clue. Stridor and respiratory distress result from laryngeal obstruction. The diagnosis is best made by direct visualization of the cherry-red, swollen epiglottis during laryngoscopy. Because laryngoscopy may provoke laryngospasm and obstruction, especially in children, it should be performed in an intensive care unit or similar setting, and only at a time when intubation can be performed promptly if required. Ceftriaxone, 2 g intravenously every 24 hours is the initial drug of choice, with total duration of therapy typically 7–10 days. Fluoroquinolones (see above for dosage) may be used in patients with serious penicillin allergies.

Meningitis, rare in adults, is a consideration in patients who have meningitis associated with sinusitis or otitis. Initial therapy for suspected *H influenzae* meningitis should be with ceftriaxone, 2 g intravenously every 12 hours, unless the strain is proven not to produce β-lactamase. Meningitis due to *H influenzae* is treated for at least 7–10 days. Dexamethasone, 0.15 mg/kg intravenously every 6 hours for the first 4 days of treatment, may reduce the incidence of long-term sequelae, principally hearing loss.

Metlay JP et al. Diagnosis and treatment of adults with community-acquired pneumonia. An official clinical practice guideline of the American Thoracic Society and Infectious Diseases Society of America. Am J Respir Crit Care Med. 2019;200:e45. [PMID: 31573350]

LEGIONNAIRES' DISEASE

ESSENTIALS OF DIAGNOSIS

- Patients are often immunocompromised, smoke cigarettes, or have chronic lung disease.
- Scant sputum production, pleuritic chest pain, toxic appearance.
- CXR: focal patchy infiltrates or consolidation.
- Gram stain of sputum: polymorphonuclear leukocytes and no organisms.

General Considerations

Legionella is an important cause of community or hospital acquired pneumonia and should be considered whenever the etiology of a pneumonia is in question. Legionnaires' disease (*Legionella* pneumonia) is more common in persons who smoke cigarettes and in those with chronic lung disease or who are immunocompromised. Outbreaks have been associated with contaminated water sources, such as showerheads and faucets in patient rooms and air conditioning cooling towers.

Clinical Findings

A. Symptoms and Signs

Legionnaires' disease is one of the atypical pneumonias, so called because a Gram-stained smear of sputum does not show organisms. However, many features of Legionnaires' disease are more like typical pneumonia, with high fevers, toxic appearance, and pleurisy. Associated clinical findings may include nausea, vomiting, diarrhea, and relative bradycardia. Classically, this pneumonia is caused by *Legionella pneumophila*, though other *Legionella* species can cause identical disease.

B. Laboratory Findings

Laboratory findings may include hyponatremia, elevated liver enzymes, and elevated creatine kinase. *Legionella* requires special media (charcoal–yeast extract agar or similar enriched media) and is difficult to detect in culture. PCR testing on respiratory samples (sputum or bronchoalveolar lavage) detects all clinically relevant *Legionella* species/serotypes. *Legionella* urinary antigen testing detects only *L pneumophila* serotype 1, which causes 80–90% of *Legionella* cases in the United States. *Legionella* serology (acute and convalescent) is a less sensitive diagnostic method.

Treatment

Azithromycin (500 mg orally or intravenously once daily) or a fluoroquinolone (eg, once-daily levofloxacin 750 mg or moxifloxacin 400 mg, administered either orally or intravenously) are drugs of choice for treatment of legionellosis. Duration of therapy is generally 7–10 days, although a 14- to 21-day course of therapy is recommended for immunocompromised patients or those with severe disease.

GRAM-NEGATIVE BACTEREMIA & SEPSIS

Gram-negative bacteremia can originate in several sites, the most common being the genitourinary system, hepatobiliary tract, GI tract, and lungs. Less common sources include intravenous lines, infusion fluids, surgical wounds, drains, and pressure injuries. Patients with sepsis secondary to gram-negative bacteremia, particularly those who are immunocompromised, may be severely ill, with mortality rates approaching up to 40% or higher.

Clinical Findings

A. Symptoms and Signs

Most patients have fevers and chills, often with abrupt onset, though some patients may be hypothermic or normothermic. Hyperventilation with respiratory alkalosis and changes in mental status can be early manifestations. Hypotension and shock are unfavorable prognostic signs.

B. Laboratory Findings

Neutropenia or neutrophilia, often with increased numbers of immature forms of polymorphonuclear leukocytes, are the most common laboratory abnormalities in septic patients. Patients may also have thrombocytopenia, laboratory evidence of coagulation abnormalities, or overt disseminated intravascular coagulation. Blood cultures may not always be positive; obtaining two sets of blood cultures from separate sites, ideally prior to starting antibiotics (if there is no substantial delay in starting antibiotics thereafter), can increase culture yield.

Treatment

Several factors are important in the management of sepsis, including that attributable to gram-negative bacteremia.

A. Removal of Predisposing Factors

When possible, this may mean decreasing or stopping immunosuppressive medications and, in certain circumstances, giving granulocyte colony-stimulating factor (filgrastim; G-CSF) to patients with neutropenia.

B. Identifying the Source of Bacteremia

By finding the source of bacteremia and removing (central venous catheter) or draining it (abscess), a potentially fatal disease becomes treatable.

C. Supportive Measures

The use of fluids, vasopressors, and corticosteroids in septic shock is discussed in Chapter 14. Management of disseminated intravascular coagulation is discussed in Chapter 16.

D. Antibiotics

Antibiotics should be given as soon as sepsis is suspected, since delays in therapy have been associated with increased mortality rates, particularly once hypotension develops. In general, bactericidal antibiotics should be used and given intravenously to ensure therapeutic serum levels. Antibiotics that penetrate the primary site of infection are critical for successful treatment—ie, if the infection originates in the CNS, antibiotics that penetrate the blood–brain barrier should be used (such as third- or fourth- but not first-generation cephalosporins, which penetrate poorly). Because sepsis caused by gram-positive organisms cannot be differentiated on clinical grounds from that due to gram-negative bacteria, initial therapy should include antibiotics active against both types of organisms.

The number of antibiotics necessary remains controversial and depends on the source of bacteremia. Table 35–6 provides a guide for empiric therapy. Although a combination of antibiotics may be recommended in patients who are critically ill and/or at risk for multidrug-resistant organisms, a single-drug regimen (such as a third-generation cephalosporin, piperacillin-tazobactam, or carbapenem) is often appropriate. If multiple drugs are used initially, the regimen should be modified and coverage narrowed based on the results of culture and sensitivity testing. Rapid molecular diagnostic testing on positive blood cultures can decrease time to species identification and detection of resistance mechanisms.

Uncomplicated gram-negative bacteremia (such as a bacteremic urinary tract infection secondary to *E coli*) may be successfully treated with as few as 7 days of antibiotic therapy. In patients with presumed septic shock who respond clinically to antibiotic therapy—but in whom blood cultures remain negative and the source of infection is unclear—consider extending therapy to 10–14 days.

SALMONELLOSIS

Salmonellosis includes infection by any of > 2000 serotypes of salmonellae. Human infections are caused almost exclusively by *S enterica* subsp *enterica*, of which three serotypes—Typhi, Typhimurium, and Enteritidis—are predominantly isolated. Three clinical patterns of infection are recognized: (1) enteric fever, for example, typhoid fever, due to *Salmonella enterica* subsp *enterica* serovars Typhi or Paratyphi; (2) acute enterocolitis, typically caused by nontyphoidal *Salmonella* serotypes; and (3) the "septicemic" type, characterized by bacteremia and focal lesions. All types are acquired via ingestion of the organism, usually from contaminated food or drink.

1. Enteric Fever (Typhoid Fever)

ESSENTIALS OF DIAGNOSIS

- Gradual onset of headache, vomiting, abdominal pain.
- Rose spots, relative bradycardia, splenomegaly, and abdominal distention and tenderness.
- Slow (stepladder) rise of fever to maximum and then slow return to normal.
- Leukopenia; blood, stool, and urine cultures positive for *Salmonella*.

General Considerations

Enteric fever is a clinical syndrome characterized by GI and constitutional symptoms such as fever, malaise, and headache. The infection may have a long incubation period (6–30 days), and the GI symptoms may resolve but then recur. Progressive infection often evolves with delirium. Enteric fever is caused by typhoidal serotypes of *Salmonella*, namely Typhi and, to a lesser extent, Paratyphi (subtypes A, B, and C).

Infection begins when organisms breach the mucosal epithelium of the intestines. Having crossed the epithelial barrier, the organisms invade and replicate in macrophages in Peyer's patches, mesenteric lymph nodes, and the spleen. Bacteremia occurs, and the infection then localizes principally in the lymphoid tissue of the small intestine. Peyer's patches become inflamed and may ulcerate, with greatest involvement during the third week of disease. The organism may disseminate to the lungs, gallbladder, kidneys, or CNS.

Clinical Findings

A. Symptoms and Signs

During the prodromal stage, patients experience increasing malaise, headache, cough, and sore throat, often with abdominal pain and constipation, while their fever ascends in a stepwise fashion. After about 7–10 days, the fever reaches a plateau and the patient is much more ill. Marked constipation, especially early, or "pea soup" diarrhea may develop; abdominal distention occurs as well. If there are no complications, the patient's condition will gradually improve over the next 7–10 days though relapse may occur for up to 2 weeks following defervescence.

There are few physical exam findings during the early prodrome. Later, splenomegaly, abdominal distention and tenderness, relative bradycardia, and occasionally meningismus occur. A rash (known as rose spots) commonly appears during the second week of disease. Rose spots are found principally on the trunk, appear as pink papules 2–3 mm in diameter that fade on pressure, and disappear in 3–4 days.

B. Laboratory Findings

Unlike with other causes of gram-negative bacteremia, most patients with enteric fever do not have leukocytosis; leukopenia may be observed instead. Transaminitis is common; anemia and thrombocytopenia may also occur. Typhoid fever is best diagnosed by blood culture, which may be positive in the first week of illness in approximately 80% of patients who have not taken antimicrobials. The rate of positivity declines thereafter, but one-fourth or more of patients may still have positive blood cultures in the third week. Cultures of bone marrow are occasionally positive when blood cultures are not. Stool cultures are often negative by the time systemic symptoms develop.

Differential Diagnosis

Enteric fever must be distinguished from other GI illnesses and from other infections that have few localizing findings. Examples include tuberculosis, infective endocarditis, brucellosis, lymphoma, and Q fever. Often there is a history of recent travel to endemic areas (such as Eastern or Southern Asia, Africa, the Caribbean, Central or South America, and the Middle East); consider viral hepatitis, malaria, or amebiasis in the differential.

Complications

Complications occur in about 30% of untreated cases and may result in mortality. Intestinal hemorrhage, manifested by a sudden drop in blood pressure and signs of shock followed by dark or fresh blood in the stool, or intestinal perforation, accompanied by abdominal pain and tenderness, are most likely to occur during the third week. Appearance of leukocytosis and tachycardia should suggest these complications. Urinary retention, pneumonia, thrombophlebitis, myocarditis, neurologic complications, cholecystitis, nephritis, osteomyelitis, and meningitis are less often observed.

Prognosis

The mortality rate of typhoid fever is about 2% in treated cases. Older or debilitated patients are likely to have worse outcomes. With complications, the prognosis is poor. Relapses occur in up to 10% of untreated patients. A residual carrier state frequently persists despite therapy.

Prevention

Immunization is not always effective but should be considered for household contacts of a typhoid carrier, for travelers to endemic areas, and during epidemic outbreaks. A multiple-dose oral vaccine and a single-dose intramuscular vaccine are available. Their efficacies are similar, but the oral vaccine causes fewer side effects. Boosters, when indicated, should be given every 5 and 2 years for oral and parenteral preparations, respectively.

Adequate waste disposal and protection of food and water supplies from contamination are important public health measures to prevent salmonellosis. Carriers cannot work as food handlers.

Treatment

A. Specific Measures

Most *S enterica* subsp *enterica* serotypes Typhi and Paratyphi isolates remain susceptible to azithromycin and ceftriaxone. When treating empirically, ceftriaxone (2 g intravenous daily for 7–14 days) or azithromycin (1 g orally once, then 500 mg orally for 5–7 days) are reasonable choices for most patients. Due to high rates of antimicrobial resistance, patients who acquire uncomplicated typhoid fever in Pakistan or Iraq should be treated with either azithromycin (dosages as above) or meropenem (1–2 g given intravenously every 8 hours). Combination therapy (ceftriaxone or meropenem plus azithromycin) should be considered for hospitalized patients. Dexamethasone (3 mg/kg initially, then 1 mg/kg every 6 hours for 48 hours) is indicated in critically ill patients, such as those with shock or encephalopathy. Fluoroquinolones (ciprofloxacin, 500 mg twice daily or levofloxacin 750 mg once daily, given orally or intravenously) can be used when isolates are known or suspected to be susceptible. When an infection is caused by a multidrug-resistant strain, select an antibiotic to which the isolate is susceptible in vitro. There is global resistance to ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole.

B. Treatment of Carriers

Ciprofloxacin, 500–750 mg orally twice a day for 4 weeks, has proved to be highly effective in eradicating the carrier state. When the isolate is susceptible, treatment of carriage with amoxicillin, ampicillin, or trimethoprim-sulfamethoxazole may be successful. *Salmonella* may sequester in the gallbladder; cholecystectomy may be required if prolonged antimicrobial therapy fails.

Marchello CS et al. A systematic review on antimicrobial resistance among *Salmonella* Typhi worldwide. Am J Trop Med Hyg. 2020;103:2518. [PMID: 32996447]

2. *Salmonella* Gastroenteritis

By far the most common form of salmonellosis is acute enterocolitis, which is typically caused by non-typhoidal *Salmonella*. The incubation period is 6–72 hours after ingestion of contaminated food or liquid.

Symptoms and signs consist of fever (often with chills), nausea and vomiting, cramping abdominal pain, and diarrhea, which may be grossly bloody, lasting 4–7 days; the differential diagnosis also includes viral gastroenteritis, food poisoning, shigellosis, amoebic dysentery, and acute ulcerative colitis. The diagnosis is made by culturing the organism from stool. The disease is usually self-limited, but bacteremia with localization in joints or bones may occur, especially in patients with sickle cell disease.

In most cases, treatment of uncomplicated enterocolitis is symptomatic only, since most illnesses are self-limited and antimicrobial treatment may prolong bacterial shedding. However, certain patients—including those who are malnourished or severely ill, have sickle cell disease, or are immunocompromised (including those with advanced HIV)—should be treated with ciprofloxacin, 500 mg orally twice a day or once-daily levofloxacin 500 mg orally by mouth. Alternative options include ceftriaxone, 1 g intravenously once daily; azithromycin 500 mg orally once per day; or twice-daily oral trimethoprim-sulfamethoxazole, 160 mg/80 mg. Duration of therapy depends on severity of disease and the patient's immune status; patients are generally treated for 7–14 days (14 days for immunocompromised patients).

Shane AL et al. 2017 Infectious Diseases Society of America clinical practice guidelines for the diagnosis and management of infectious diarrhea. Clin Infect Dis. 2017;65:1963. [PMID: 29194529]

3. Complications of *Salmonella* Bacteremia

Salmonella infection may be manifested by prolonged or recurrent fevers accompanied by bacteremia and local infection in bone, joints, pleura, pericardium, lungs, or other sites. Mycotic aortic aneurysms may also occur. These complications tend to occur in immunocompromised patients, including those with advanced HIV, or in older adults with preexisting aneurysms or atherosclerotic plaques. Serotypes other than Typhi may be isolated. Treatment requires systemic antimicrobial therapy (duration depends on the site of infection) plus drainage of any abscesses. In patients with HIV infection, relapse is common, and suppressive therapy may be needed until immune reconstitution has been achieved with antiretroviral therapy. If the organism is susceptible, a fluoroquinolone—such as ciprofloxacin, 750 mg orally twice a day—may be effective both for therapy of acute infection and for suppression of recurrence (when needed). Incidence of infections caused by drug-resistant strains may be on the rise.

SHIGELLOSIS

ESSENTIALS OF DIAGNOSIS

- Diarrhea, often with blood and mucus.
- Crampy abdominal pain and systemic toxicity.
- Leukocytes in stool; positive stool culture.

General Considerations

Shigella dysentery is a common disease, often self-limited and mild but occasionally serious. *S sonnei* is the leading cause in the United States, followed by *S flexneri*. *S dysenteriae* causes the most serious form of illness. Shigellae are invasive organisms. The infective dose is low, on the order of 10 to 100 organisms. Shigellosis is highly transmissible via the fecal-oral route including ingestion of contaminated food and water as well as oral–anal sexual contact, particularly in men who have sex with men. There has been a rise in strains resistant to multiple antibiotics.

Clinical Findings

A. Symptoms and Signs

The illness usually starts abruptly, with diarrhea, lower abdominal cramps, and tenesmus. The diarrhea is often mixed with blood and/or mucus and associated with abdominal tenderness. Systemic symptoms include fever, chills, anorexia and malaise, and headache. Sigmoidoscopic examination, if done, reveals an inflamed, engorged mucosa with punctate and sometimes large areas of ulceration.

B. Laboratory Findings

The stool contains many leukocytes and red cells. Stool culture is positive for *Shigella* in most cases, but blood cultures rarely grow the organism (0–7% of cases).

Differential Diagnosis

Dysentery due to *Shigella* must be distinguished from *Salmonella* enterocolitis and from infections due to enterotoxigenic *Escherichia coli*, *Campylobacter*, and *Yersinia enterocolitica*. Amoebic dysentery may have a similar clinical presentation and is diagnosed by finding amoebas in a fresh stool specimen. Ulcerative colitis is another cause of bloody diarrhea.

Complications

Temporary disaccharidase deficiency, resulting in carbohydrate malabsorption and symptoms like irritable bowel syndrome, may follow the diarrhea. Reactive arthritis is an uncommon complication, usually occurring in HLA-B27 positive individuals infected by *Shigella*. Hemolytic-uremic syndrome also occurs rarely. Intestinal complications may include proctitis, intestinal obstruction, and colonic perforation.

Treatment

Antibiotics are not required for uncomplicated, self-resolving gastroenteritis. On the other hand, along with treatment of dehydration and hypotension, antibiotics are recommended in severe cases, and in patients who are immunocompromised. Antimicrobial therapy should ideally be guided by antibiotic susceptibility testing. Options generally include either a fluoroquinolone (oral or intravenous ciprofloxacin, 750 mg once or twice daily, or levofloxacin, 500 mg orally once daily for 3–5 days) or ceftriaxone, 1–2 g intravenously once daily for 5 days. If the isolate is susceptible, trimethoprim-sulfamethoxazole, 160/80 mg orally twice daily for 5 days, or azithromycin, 500 mg orally once daily for 3 days, are also effective. High rates of resistance to amoxicillin and ampicillin make these less effective treatment options. There are also increasing concerns regarding resistance to ceftriaxone, azithromycin, and fluoroquinolones, particularly among men who have sex with men.

Shane AL et al. 2017 Infectious Diseases Society of America clinical practice guidelines for the diagnosis and management of infectious diarrhea. Clin Infect Dis. 2017;65:1963. [PMID: 29194529]

GASTROENTERITIS CAUSED BY *ESCHERICHIA COLI*

E coli causes gastroenteritis by a variety of mechanisms. Enterotoxigenic *E coli* (ETEC) elaborates either a heat-stable or heat-labile toxin that mediates the disease; this pathogen, along with enteroaggregative *E coli* (EAEC), is an important cause of traveler's diarrhea, which is typically watery (see Chapter 35, Traveler's Diarrhea). Enteroinvasive *E coli* (EIEC), which is uncommon in the United States, differs from other *E coli* bowel pathogens in that these strains invade cells, causing bloody diarrhea and dysentery-like infection. Neither ETEC nor EIEC strains are routinely isolated and identified from stool cultures because there is no selective medium, but they can be detected on stool-based multiplex-PCR. Antimicrobial therapy, such as oral azithromycin (either 1000 mg × 1 or 500 mg daily for 3 days), shortens the clinical course, but the disease is usually self-limited.

Shiga-toxin–producing *E coli* (STEC) infection can result in either asymptomatic carriage, diarrhea that may begin as watery, hemorrhagic colitis, hemolytic-uremic syndrome, or thrombotic thrombocytopenic purpura. Although *E coli* O157:H7 is responsible for most cases of STEC infection in the United States, other STEC strains that cause severe disease have been reported. *E coli* O157:H7 has caused several outbreaks of diarrhea and hemolytic-uremic syndrome related to consumption of products including undercooked hamburger, raw flour, unpasteurized apple juice, and spinach. Older individuals and young children are most affected, with hemolytic-uremic syndrome being more common in the latter group. STEC identification can be difficult. The CDC recommends that all stools submitted for routine testing from patients with acute community-acquired diarrhea be simultaneously cultured for *E coli* O157:H7 and tested for Shiga toxins to detect non-O157 STEC. Antimicrobial therapy does not alter the course of the disease and may increase the risk of hemolytic-uremic syndrome. Treatment is primarily supportive. Hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura occurring in association with a diarrheal illness suggests the diagnosis and should prompt evaluation for STEC. Confirmed STEC infections should be reported to public health officials.

Centers for Disease Control and Prevention. *Escherichia coli*, diarrheagenic. CDC Yellow Book 2024. https://wwwnc.cdc.gov/travel/yellowbook/2024/infections-diseases/escherichia-coli-diarrheagenic

Collins JP et al. Preliminary incidence and trends of infections with pathogens transmitted commonly through food—Foodborne Diseases Active Surveillance Network, 10 U.S. Sites, 2016-2021. MMWR Morb Mortal Wkly Rep. 2022;71:1260. [PMID: 36201372]

CHOLERA

ESSENTIALS OF DIAGNOSIS

- History of travel to endemic area or contact with infected person.
- Voluminous diarrhea (up to 1 L/hour).
- Characteristic "rice water stool."
- Rapid development of marked dehydration.
- Positive stool cultures.

General Considerations

Cholera is an acute diarrheal illness caused by certain serotypes of *Vibrio cholerae*. The disease is toxin-mediated, and fever is unusual. The toxin activates adenylyl cyclase in intestinal epithelial cells of the small intestines, producing hypersecretion of water and chloride ion and resulting in significant diarrhea of up to 1 L/hour. The resulting profound hypovolemia can lead to death. Cholera occurs in epidemics, typically under conditions of crowding, war, and famine (eg, in refugee camps) and where sanitation is inadequate. The infection is acquired via ingestion of contaminated food or water.

Clinical Findings

Cholera is characterized by a sudden onset of severe, frequent watery diarrhea (up to 1 L/hour). The liquid stool is gray and turbid, without fecal odor, blood, or pus ("rice water stool"). Dehydration and hypotension develop rapidly. Definitive diagnosis is based on positive stool culture. Rapid stool antigen and PCR-based stool testing are also available.

Treatment

Treatment is primarily via fluid replacement. In mild or moderate illness, oral rehydration is usually adequate. A simple oral replacement fluid can be made from 1/2 teaspoon of table salt and 6 level teaspoons of sugar added to 1 L of water. Intravenous fluids are indicated for patients with signs of severe hypovolemia and those who cannot take adequate fluids orally. Lactated Ringer infusion is satisfactory.

Antimicrobial therapy shortens the course of illness and is indicated for severely ill patients. Antimicrobials active against *V cholerae* include doxycycline (300 mg orally in a single dose), azithromycin (1 g orally in a single dose), or ciprofloxacin (also 1 g orally in a single dose). Multidrug-resistant strains exist, so susceptibility testing, if available, is advisable.

Prevention

Oral cholera vaccines confer some protection and may be required for entry into or re-entry after travel to some countries. One live attenuated oral vaccine is approved for use in the United States for persons traveling to areas of active cholera transmission. Supplies of the oral vaccine have been limited, and in March 2024, the WHO declared that millions of persons were at risk from cholera due to lack of clean water, soap, and toilets, and shortage of the cholera vaccine.

When to Admit

- Severe diarrhea.
- Moderate to severe dehydration in need of parenteral fluid replacement.
- Inability to maintain fluid replacement because there can be rapid development of dehydration.

Collins JP et al. Cholera vaccine: recommendations of the Advisory Committee on Immunization Practices, 2022. MMWR Morb Mortal Wkly Rep. 2022;71:1. [PMID: 36173766]

Kanungo S et al. Cholera. Lancet. 2022;399:1429. [PMID: 35397865]

INFECTIONS CAUSED BY OTHER *VIBRIO* SPECIES

Vibrios other than *V cholerae* that cause human disease are *V parahaemolyticus, V vulnificus*, and *V alginolyticus*. All are halophilic marine organisms. Infection is acquired by exposure to organisms in contaminated, undercooked, or raw crustaceans or shellfish and/or warm (> 15–20°C) ocean waters and estuaries. Infections are more common during the summer months, in regions along the Atlantic coast and the Gulf of Mexico in the United States and from tropical waters around the world. Oysters are implicated in up to 90% of food-related cases.

V parahaemolyticus causes acute watery diarrhea with crampy abdominal pain and fever, typically occurring within 24 hours after ingestion of contaminated shellfish. The disease is self-limited, and antimicrobial therapy is usually not necessary. Patients with chronic liver disease and those who are immunocompromised should be cautioned to avoid eating raw oysters. *V parahaemolyticus* may also cause cellulitis and sepsis, though these findings are more characteristic of *V vulnificus* infection.

V vulnificus and *V alginolyticus* are important causes of cellulitis, wound infections, and primary bacteremia following exposure to sea water or ingestion of contaminated shellfish. Cellulitis with or without sepsis may be accompanied by bulla formation and necrosis with extensive soft tissue destruction, at times requiring debridement or amputation. The infection can be rapidly progressive and is particularly severe in immunocompromised individuals—especially those with cirrhosis or other hepatic disease—with death rates as high as 50%.

For severe disease caused by non-*cholerae Vibrio* species, primary antibiotic regimens include doxycycline 100 mg twice daily, given orally or intravenously, plus intravenous ceftriaxone 2 g daily or ceftazidime 1 g every 8 hours for up to 7–14 days (based on clinical response). Fluoroquinolones also may be effective against non-*cholerae Vibrio* species.

Chuang PY et al. Hepatic disease and the risk of mortality of *Vibrio vulnificus* necrotizing skin and soft tissue infections: a systematic review and meta-analysis. PLoS One. 2019;14:e0223513. [PMID: 31652263]

INFECTIONS CAUSED BY *CAMPYLOBACTER* SPECIES

Campylobacter organisms are microaerophilic, motile, gram-negative rods. *Campylobacter* enteritis is typically caused by either *C jejuni* or *C coli,* both of which cause a gastroenteritis associated with fever, abdominal pain, and diarrhea characterized by loose, watery, or bloody stools. Dairy cattle and poultry are an important reservoir for campylobacters. Outbreaks of enteritis have been associated with consumption of raw milk. The differential diagnosis includes shigellosis, *Salmonella* gastroenteritis, and enteritis caused by *Y enterocolitica* or invasive *E coli*. The disease is self-limited, but its duration can be shortened modestly, by about 1 day, with antimicrobial therapy. Azithromycin (1 g orally as a single dose or 500 mg orally daily for 3 days) is effective therapy for uncomplicated gastroenteritis due to *C jejuni or C coli*. Isolates may be resistant to fluoroquinolones and doxycycline, particularly among strains outside of the United States.

A third species of *Campylobacter*, *C fetus* causes systemic infections that can be fatal, including primary bacteremia, endocarditis, meningitis, and focal abscesses. It infrequently causes gastroenteritis. Patients infected with *C fetus* are often older, debilitated, or immunocompromised. Systemic infections can be treated with intravenous imipenem-cilastatin (500 mg every 6 hours), meropenem (1 g every 8 hours), ertapenem (1 g daily), or ampicillin (100 mg/kg/day, given in divided doses every 6 hours). Meropenem at 2 g intravenously every 8 hours is appropriate for CNS infections due to its ability to penetrate the blood–brain barrier.

PLAGUE

ESSENTIALS OF DIAGNOSIS

- History of exposure to rodents in endemic area.
- Sudden onset of high fever, muscle pains, and prostration.
- Axillary, cervical, or inguinal lymphadenitis (buboes).
- Pustule or ulcer at inoculation site.
- Pneumonia or meningitis may be fatal.
- Positive smear and culture from bubo and positive blood culture.

General Considerations

Plague is a zoonotic infection carried by wild rodents and caused by *Yersinia pestis*, a small gram-negative rod with bipolar staining on Wright, Giemsa, or Wayson stains. Most human cases in the United States occur in California, Arizona, Nevada, Oregon, Colorado, and New Mexico. Countries with the most cases worldwide include the Democratic Republic of the Congo, Madagascar, and Peru. Plague is transmitted among rodents and to humans by the bites of fleas or from contact with infected animals. Following a fleabite, the organisms spread through the lymphatics to the lymph nodes, which become greatly enlarged (buboes). They may then reach the bloodstream and disseminate to involve all organs. When pneumonia or meningitis develops, the outcome may be fatal. Patients with pneumonia can transmit the infection to others via droplets. The incubation period for bubonic plague is 2–8 days. Because of its extreme virulence and potential for dissemination and person-to-person transmission, plague is considered a high-priority agent for bioterrorism.

Clinical Findings

A. Symptoms and Signs

The onset of plague is sudden, with high fever, malaise, tachycardia, intense headache, delirium, and severe myalgias; patients appear profoundly ill and may have a pustule or ulcer at the site of inoculation. Axillary, inguinal, or cervical lymph nodes become enlarged and tender and may suppurate and drain. With hematogenous spread, patients may rapidly become toxic and comatose, with purpuric spots (black plague) appearing on the skin. There may be signs of meningitis.

If pneumonia develops, tachypnea, productive cough, blood-tinged sputum, and cyanosis also occur. Primary pneumonic plague is a fulminant pneumonitis with bloody, frothy sputum and sepsis. It is usually fatal unless treatment is started within a few hours after onset.

B. Laboratory Findings

The plague bacillus may be found in smears from aspirates of buboes examined with Gram staining or other special stains. Cultures from bubo aspirate or pus, blood, CSF, and sputum can be positive, but the organism may grow slowly. Acute and convalescent serum samples can be helpful for making the diagnosis serologically (using agglutination tests). In cases where tissue is available—such as from lymph nodes, lung, liver, or bone marrow—direct detection methods using PCR or direct fluorescent antibody testing also may be helpful.

Differential Diagnosis

The lymphadenitis of plague may be mistaken for the lymphadenitis accompanying either staphylococcal or streptococcal infections of the extremities, sexually transmitted infections such as lymphogranuloma venereum or syphilis, or tularemia. Systemic manifestations resemble those of enteric or rickettsial fevers, malaria, or influenza, while pneumonia and meningeal infections attributable to plague resemble those caused by other bacteria.

Prevention

Avoiding exposure to rodents and fleas in endemic areas is the best prevention strategy. Drug prophylaxis may provide temporary protection for those exposed to plague, particularly via the respiratory route. Doxycycline, 100 mg orally twice daily for 7 days, is effective, as are fluoroquinolones (ciprofloxacin, 500–750 mg orally every 12 hours, levofloxacin, 750 mg orally once daily, or moxifloxacin, 400 mg orally once daily; all are given for 7-day courses). No vaccine is available.

Treatment

Therapy should be started immediately once plague is suspected. Either a fluoroquinolone (ciprofloxacin, 400 mg intravenously every 8 hours, or 750 mg orally every 12 hours; levofloxacin, 750 mg intravenously or orally every 24 hours; or moxifloxacin, 400 mg intravenously or orally every 24 hours) or an aminoglycoside (such as intravenous gentamicin, 5 mg/kg every 24 hours) is effective. The duration of therapy is 10–14 days. Combination therapy with two different classes of antimicrobials is recommended for the initial treatment of patients with severe pneumonic or septicemic plague. Alternative treatment options include doxycycline (200-mg loading dose, then 100 mg every 12 hours intravenously or orally) or trimethoprim-sulfamethoxazole (5 mg/kg of the trimethoprim component, given intravenously or orally every 8 hours). Patients with plague pneumonia are placed in strict respiratory isolation, and prophylactic therapy is given to any person who had contact with the patient.

GONOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS

- Purulent, profuse urethral discharge with dysuria; classically yields positive Gram stain.
- Urethritis, epididymitis, prostatitis, proctitis, pharyngitis.
- Cervicitis with purulent discharge; vaginitis; salpingitis.
- Preferred method of diagnosis at a mucosal site is testing with nucleic acid amplification
- Disseminated disease: fever, rash, tenosynovitis, and arthritis; can also cause bacteremia, septic arthritis, and endocarditis.

General Considerations

Gonorrhea is caused by *Neisseria gonorrhoeae*, a gram-negative diplococcus typically found inside polymorphonuclear cells. It is transmitted during sexual activity and has its greatest incidence in the 15- to 29-year-old age group. The incubation period is usually 2–8 days.

Clinical Findings

A. Urethritis and Cervicitis

1. Penile/urethral infections—Initial symptoms include burning on urination and a serous or milky discharge. One to 3 days later, urethral pain is more pronounced, and the discharge becomes yellow, creamy, and profuse, sometimes blood-tinged. The disorder may regress and become chronic or progress to involve the prostate, epididymis, and periurethral glands with painful inflammation. Chronic infection can lead to prostatitis or urethral strictures. Rectal infection (proctitis) is common in men who have sex with men. Extragenital mucosal sites of primary infection (eg, the pharynx or rectum) must always be considered. Asymptomatic infection can occur in all genders.

2. Cervicovaginal infections—Cervicovaginal gonococcal infections may present with dysuria, urinary frequency, and urgency, and/or a purulent discharge. Vaginitis and cervicitis with inflammation of Bartholin glands are common. Infection may be asymptomatic or present with only slightly increased vaginal discharge and moderate cervicitis on exam. Infection may also persist as chronic cervicitis, serving as an important reservoir for gonococci. Cervicovaginal gonorrhea can progress to involve the uterus and Fallopian tubes with acute and chronic salpingitis, potentially resulting in scarring and infertility. In pelvic inflammatory disease, anaerobes and chlamydia often accompany gonococci. Rectal infection may result from spread of the organism from the genital tract or from receptive anal intercourse.

Nucleic acid amplification tests have excellent sensitivity and specificity; they are the preferred method for diagnosing gonorrhea at all mucosal sites, regardless of gender or sex. In patients with suspected cervicovaginal infections, endocervical or vaginal swabs (clinician- or self-collected) as well as first-catch morning urine samples are options for testing. In people with suspected penile/urethral infections, first-catch AM urine is recommended. Nucleic acid amplification tests are also recommended for gonorrhea screening and testing at pharyngeal and rectal sites. Urine testing does not detect oropharyngeal or rectal gonorrhea unless there is concurrent genital infection. Gram stain of urethral, cervicovaginal, or rectal discharge may show gram-negative diplococci in polymorphonuclear leukocytes. Cultures and antimicrobial susceptibility testing should be obtained to evaluate for antimicrobial resistance whenever there is concern for gonococcal treatment failure at any mucosal site.

B. Disseminated Disease

Disseminated gonococcal infection (DGI) occurs rarely when gonorrhea invades the bloodstream from a mucosal site and travels to distant sites of the body. DGI can present as an arthritis–dermatitis syndrome, with skin lesions, arthralgias, and tenosynovitis. In this syndrome, arthritis and arthralgias can occur in one or more joints and may be migratory. Skin lesions, when present, can range from maculopapular to petechial, pustular, or hemorrhagic; they tend to be few in number and appear most often on the distal extremities (including the palms and soles). Tenosynovitis is often found in the hands and wrists, or the feet and ankles. These unique findings can help distinguish DGI from other infectious syndromes.

DGI can also present as purulent mono- or oligoarticular septic arthritis, or—more rarely—as perihepatitis, bacteremia, meningitis, osteomyelitis, or endocarditis. Although gonococci are isolated by culture from less than half of patients with gonococcal arthritis, antimicrobial susceptibility testing should always be performed whenever the organism grows on culture from a disseminated site (eg, blood, cerebrospinal fluid, synovial fluid). Nucleic acid amplification testing can be performed on synovial fluid (if available) and may be more sensitive for the diagnosis. Host factors that increase the likelihood of DGI include complement deficiencies, systemic lupus erythematosus, and receipt of the monoclonal antibody eculizumab.

C. Conjunctivitis

The most common form of eye involvement is direct inoculation of gonococci into the conjunctival sac. In adults, this occurs by autoinoculation in persons with genital infections. Purulent conjunctivitis may rapidly progress to pan-ophthalmitis and loss of the eye unless treated promptly.

Differential Diagnosis

Gonococcal urethritis and cervicovaginal infections must be differentiated from those caused by other pathogens (many of which are also sexually transmitted) such as *Chlamydia trachomatis* and *Trichomonas vaginalis*. Vaginal discharge can also be caused by non-sexually transmitted pathogens, including *Candida* species and *Gardnerella vaginalis*. Patients with mucosal-site gonococcal infections should be evaluated for any symptoms to suggest complications, such as DGI or pelvic inflammatory disease. They should also be screened for other sexually transmitted infections, including chlamydia, syphilis, and HIV, since coinfections are common. Reactive arthritis (urethritis, conjunctivitis, arthritis) may mimic manifestations of gonorrhea or coexist with it.

Prevention

Prevention is based on education and mechanical or biomedical prophylaxis. Condoms, if properly used, can reduce the risk of infection. Partner notification and referral of sexual contacts for gonorrhea testing and empiric treatment is recommended. In cases where partners are unable or unwilling to come into care for testing and treatment, patient-delivered expedited partner therapy with oral cefixime (800 mg) is a helpful strategy. In terms of biomedical prevention, doxycycline 200 mg taken orally as postexposure prophylaxis preferably taken within 24 (but up to 72) hours after sex has been shown to significantly reduce the incidence of syphilis, chlamydia, and gonorrhea among men who have sex with men and transgender women in clinical trials. This strategy, known as doxy PEP, seems to be reducing the incidence of chlamydia and syphilis in municipalities (such as San Francisco, CA, United States) that quickly adopted the intervention.

Treatment

Gonorrhea has developed resistance to multiple antibiotics, including penicillin, doxycycline, and ciprofloxacin. These antibiotics should not be used for treatment unless antimicrobial susceptibilities are known. Resistance to azithromycin and ceftriaxone also has been reported, although the latter is rare. Patients and their sexual partners should be treated for gonorrhea and tested for other STIs (such as HIV, chlamydia, and syphilis).

A. Uncomplicated Gonorrhea

For uncomplicated gonococcal infections of the cervix, urethra, rectum, and pharynx, the recommended treatment is ceftriaxone (500 mg intramuscularly for patients who weigh < 150 kg and 1 g intramuscularly for patients who weigh 150 kg or more). Cefixime, 800 mg orally as a single dose, can be used for non-pharyngeal infections when an oral cephalosporin is the only option. When chlamydial infection has not been excluded, co-treatment of chlamydia with oral doxycycline, 100 mg twice daily for 7 days, is recommended in nonpregnant patients with gonorrhea. For penicillin-allergic patients, the recommended treatment regimen consists of gentamicin, 240 mg intramuscularly, and azithromycin, 2 g orally.

B. Complicated Gonorrhea

Disseminated gonococcal infection (including arthritis and arthritis-dermatitis syndromes) should be treated with ceftriaxone (1 g intravenously or intramuscularly daily). For the arthritis-dermatitis syndrome, therapy may be switched to an oral regimen, guided by antimicrobial susceptibility testing, within 24–48 hours after substantial clinical improvement, for a total treatment course of at least 7 days. Gonococcal endocarditis should be treated with ceftriaxone (2 g every 24 hours intravenously) for at least 4 weeks.

For patients admitted to the hospital, pelvic inflammatory disease (PID) is initially treated with ceftriaxone (1 g intravenously daily) plus doxycycline (100 mg orally or intravenously twice daily) and metronidazole (500 mg orally or intravenously every 12 hours). Admitted patients can also be treated with cefoxitin (2 g intravenously every 6 hours) or cefotetan (2 g intravenously every 12 hours), both given with doxycycline (100 mg orally or intravenously twice daily). Within 24–48 hours after substantial clinical improvement, patients initially treated with intravenous therapy can be transitioned to intramuscular or oral therapy (often with doxycycline and metronidazole at the doses listed above) to complete a total 14-day course. Outpatients with PID can be treated with a one-time dose of either ceftriaxone (500 mg intravenously) or cefoxitin (2 g intramuscularly, given with a single dose of probenecid 1 g orally), both with doxycycline (100 mg orally twice daily) and metronidazole (500 mg orally twice daily) for a total of 14 days.

CHANCROID

Chancroid is an STI caused by the short gram-negative bacillus *Haemophilus ducreyi*. The incubation period is 4–10 days. A vesico-pustule develops at the site of inoculation; it subsequently breaks down to form a painful, soft ulcer with a necrotic base, surrounding erythema, and undermined edges. There may be multiple lesions due to autoinoculation. Associated lymphadenitis is usually unilateral and consists of tender, matted nodes of moderate size with overlying erythema. The diagnosis is established by culturing a swab of the lesion onto a special medium. In the United States, a probable case of chancroid can be diagnosed if a patient has a consistent ulcer (with or without regional lymphadenopathy) and the alternative, more common diagnoses of syphilis and herpes simplex virus have been ruled out.

Chancroid must be differentiated from other genital ulcers. The chancre of syphilis is clean and classically painless, with a hard base and raised border, whereas the ulcer of chancroid is nonindurated, deep, and painful, with serpiginous borders and often a purulent exudate. Coinfections with other sexually transmitted pathogens (including syphilis, herpes simplex virus, and HIV) are very common, as is super-infection of the chancroid ulcer with other bacteria.

A single dose of either azithromycin, 1 g orally, or ceftriaxone, 250 mg intramuscularly, is recommended to treat chancroid. Effective multidose regimens are erythromycin base, 500 mg orally three times a day for 7 days, or ciprofloxacin, 500 mg orally twice a day for 3 days.

Workowski KA et al. Sexually transmitted infections treatment guidelines, 2021. MMWR Recomm Rep. 2021;70:1. [PMID: 34292926]

MYCOPLASMA GENITALIUM

The gram-negative intracellular pathogen *M genitalium* is a newly emerged sexually transmitted infection. Clinical manifestations include symptomatic urethritis and cervicitis. *M genitalium* is implicated in 15–20% of nongonococcal urethritis and 40% of persistent or recurrent urethritis cases, respectively. Cervical *M genitalium* infections have been associated with PID preterm delivery, spontaneous pregnancy loss, and infertility. Asymptomatic genitourinary and rectal carriage is common, although the clinical implications of colonization are not clearly defined.

Routine screening for *M genitalium* is not recommended, but testing should be performed in people with persistent or recurrent urethritis/cervicitis. The organism is extremely slow growing (with culture requiring up to 6 months); the diagnosis can be made instead using nucleic amplification testing on urine or urethral, penile meatal, endocervical, or vaginal swabs. Molecular tests for markers of macrolide (azithromycin) or quinolone (moxifloxacin) resistance are not widely available in the United States but may be used in other countries.

Antibiotic resistance is common, and treatment requires two different antibiotics used in sequential order. When *M genitalium* resistance testing is not available or the organism is known to be macrolide-resistant, the recommended treatment consists of doxycycline 100 mg orally twice per day for 7 days (to reduce *M genitalium* bacterial load), followed by moxifloxacin 400 mg daily by mouth for another 7 days. If resistance testing is available and the organism retains macrolide sensitivity, treatment can instead be with doxycycline 100 mg orally twice daily for 7 days followed by azithromycin (1 g orally on day 1, followed by 500 mg orally once per day for 3 more days). Sex partners of patients with confirmed *M genitalium* infections should be tested for *M genitalium* and provided treatment if their test results are positive.

Neither doxycycline nor moxifloxacin are recommended for use in pregnant patients, so *M genitalium* treatment decisions in pregnancy are made on a case-by-case basis, considering symptom severity, patient preferences, and risk/benefit discussions. Clinical consultation for complex cases involving sexually transmitted infections is available online at stdccn.org.

Workowski KA et al. Sexually transmitted infections treatment guidelines, 2021. MMWR Recomm Rep. 2021;70:1. [PMID: 34292926]

BARTONELLA SPECIES

Bartonella species are responsible for a wide variety of clinical syndromes. **Bacillary angiomatosis**, an important manifestation of bartonellosis, is discussed in Chapter 36. A variety of atypical infections, including retinitis, encephalitis, osteomyelitis, persistent bacteremia, and endocarditis (especially consider in culture-negative endocarditis), have been described.

1. *Bartonella quintana*—*B quintana* classically causes **trench fever,** a louse-borne relapsing febrile illness. The disease has occurred epidemically in louse-infested troops and civilians during wars and endemically in residents of scattered geographic areas. An urban equivalent of trench fever has been described among people experiencing homelessness. Humans acquire the infection when infected lice feces enter sites of skin breakdown. Symptom onset is abrupt: fever lasts 2–5 days, with relapses, although isolated febrile episodes or prolonged persistent fevers also can occur. Patients may report weakness and headache, with severe pain behind the eyes and in the back and legs (especially shins). Lymphadenopathy, splenomegaly, and a transient maculopapular rash may appear. The differential diagnosis includes other febrile, self-limited illnesses such as dengue, leptospirosis, malaria, relapsing fever, and typhus. Optimal therapy is uncertain, but experts suggest doxycycline, 100 mg orally twice daily for 4 weeks, given with either gentamicin (3 mg/kg intravenously once daily) or rifampin (300 mg orally twice daily) during the first 2 weeks of treatment.

2. *Bartonella henselae*—*B henselae* classically causes **cat-scratch disease,** an acute infection of children and young adults that is transmitted from cats to humans as the result of a scratch or bite, and most commonly presents as a regional lymphadenitis. Within a few days after exposure, a papule or ulcer may develop at the inoculation site. One to 3 weeks later, fever, headache, and malaise occur. Regional lymph nodes become enlarged, often tender, and may suppurate. Lymphadenopathy from cat scratch disease resembles that due to neoplasm, tuberculosis, lymphogranuloma venereum, or bacterial lymphadenitis. The diagnosis is usually made clinically. Serology can confirm the diagnosis, as can PCR or special stains performed on lymph node aspirates or biopsy. Excisional biopsy is rarely necessary, but—if done—reveals a necrotizing granulomatous lymphadenitis (which itself is not specific for cat-scratch disease). Cat-scratch disease is usually self-limited, but treatment for lymphadenitis (eg, with azithromycin, 500 mg orally once, followed by 250 mg orally daily for 4 days) is recommended to shorten the duration of illness and reduce complications. Disseminated cat-scratch disease occurs rarely but can involve either hepatosplenic or neurologic infection (including encephalitis).

Disseminated Forms of *Bartonella* Infection

Other disseminated forms of *Bartonella* infection—such as bacillary angiomatosis, peliosis hepatis, endocarditis, and retinitis—occur most commonly in immunocompromised patients such as those with advanced HIV or solid organ transplants. *B quintana* or *B henselae* are most often involved, although other *Bartonella* species also can cause human disease. In bacillary angiomatosis, histopathologically distinct vasculoproliferative lesions due to *Bartonella* infection develop in the skin or internal organs. In *Bartonella*-associated endocarditis, blood cultures will typically be negative. Due to the fastidious nature of the organism and its special growth requirements, serologic testing (eg, demonstration of a high antibody titer in an indirect immunofluorescence assay) or PCR tests performed on tissue or blood are often required to establish a diagnosis.

Disseminated *Bartonella* infections require prolonged courses of antibiotic therapy. Endocarditis due to *Bartonella* species can be effectively treated with doxycycline (200 mg orally or intravenously in two divided doses per day) plus either rifampin (300 mg orally or intravenously, given twice daily for the first 6 weeks) or 2 weeks of gentamicin (3 mg/kg/day intravenously, if unable to take rifampin), followed by doxycycline monotherapy for a total duration of at least 3 months. Valve surgery, if performed, may change the duration of antibiotic therapy. Relapses may occur.

ANAEROBIC INFECTIONS

Anaerobic infections tend to be polymicrobial, and abscesses are common. Pus and infected tissue often are malodorous. Septic thrombophlebitis and metastatic infection can occur; the latter may require incision and drainage. Cultures, unless carefully collected under anaerobic conditions, may be negative.

Important types of infections caused by anaerobic organisms are listed below. Treatment of these infections may consist of surgical exploration and judicious excision in conjunction with antimicrobial medications.

1. Head & Neck Infections

Prevotella species and anaerobic spirochetes, among other bacteria, are commonly involved in periodontal infections. These organisms, *Fusobacterium* species, and anaerobic streptococci may be implicated in chronic sinusitis, peritonsillar abscess, deep neck space infections, chronic otitis media, and/or mastoiditis. *F necrophorum* has been recognized as a cause of pharyngitis in adolescents and young adults; infection with this organism has also been associated with septic internal jugular thrombophlebitis (Lemierre syndrome), which can cause septic pulmonary embolization. Surgical debridement and drainage are as important as antimicrobials in the treatment of many head and neck infections. Penicillin alone is generally inadequate for oral anaerobes because of penicillin resistance, usually due to β-lactamase production. Ampicillin/sulbactam 3 g intravenously every 6 hours (if parenteral therapy is required), or amoxicillin/clavulanic acid 875 mg/125 mg orally twice daily are often reasonable choices instead. Antibiotics are typically continued for a few days after symptoms and signs of infection have resolved. Indolent, established infections (like mastoiditis or osteomyelitis) may require prolonged courses of therapy, eg, 4–6 weeks or longer, using antimicrobials that penetrate bone.

2. Chest Infections

Often in the setting of poor oral hygiene and periodontal disease, aspiration of saliva may lead to necrotizing pneumonia, lung abscesses, or empyema. Polymicrobial infections are common, and anaerobes—such as *Bacteroides* species, oral gram-negative anaerobes, or anaerobic streptococci—are often among the etiologic agents. Most pulmonary infections respond to antimicrobial therapy alone. Percutaneous chest tube or surgical drainage is indicated for empyema.

Depending on the microbiology, preferred regimens may include ampicillin-sulbactam (3 g intravenously every 6 hours, followed by amoxicillin/clavulanic acid 875/125 mg orally twice daily); ceftriaxone (1–2 g intravenously every 24 hours) given with metronidazole (500 mg intravenously or orally every 6–8 hours); or moxifloxacin (400 mg intravenously or orally once daily). Clindamycin (300–450 mg orally three times daily) may be another option. Because these infections respond slowly, a prolonged course of therapy (eg, 4–6 weeks) may be recommended for complicated infections.

3. Central Nervous System

Anaerobes (especially *Bacteroides* species) are a common cause of brain abscess, subdural empyema, and septic CNS thrombophlebitis. The organisms reach the CNS by direct extension from sinusitis, otitis, or mastoiditis or by hematogenous spread from chronic lung infections. Antimicrobial therapy—eg, ceftriaxone, 2 g intravenously every 12 hours, plus metronidazole, 500 mg intravenously or orally every 8 hours—is an important adjunct to surgical drainage. Duration of therapy is 6–8 weeks but should be based on follow-up imaging. Some small brain abscesses can be treated with antibiotics alone without surgical drainage.

4. Intra-Abdominal Infections

Anaerobes—predominantly *B fragilis*, clostridia, and anaerobic streptococci—constitute > 90% of colonic bacteria. These organisms play a central role in most intra-abdominal abscesses following trauma to the colon, as well as diverticulitis, appendicitis, perirectal abscess, hepatic abscess, and cholecystitis. The bacteriology of such infections typically includes anaerobes as well as other organisms, eg, enteric gram-negative rods and occasionally enterococci. Empiric therapy for intra-abdominal infections should thus be directed against both anaerobes and gram-negative aerobes. Agents that are typically active against *B fragilis* include metronidazole, piperacillin-tazobactam, or carbapenems (eg, ertapenem, imipenem-cilastatin, doripenem, or meropenem); amoxicillin-clavulanate may be an option for milder disease. Resistance to cefoxitin, cefotetan, and clindamycin is increasingly encountered, and most third-generation cephalosporins have poor efficacy. Whenever source control procedures are performed, intra-abdominal fluid cultures should be obtained to further elucidate the microbiology and guide antimicrobial selection.

5. Female Genital Tract & Pelvic Infections

The normal flora of the vagina and cervix includes several species of *Bacteroides*, anaerobic and group B streptococci, lactobacilli, coliform bacteria, and, occasionally, spirochetes and clostridia. These organisms commonly cause genital tract infections and may disseminate from there.

While salpingitis is often caused by gonococci and chlamydiae, tubo-ovarian and pelvic abscesses are also commonly associated with anaerobes. Similarly, while postpartum infections may be caused by aerobic streptococci or staphylococci, anaerobes are also often involved. The most severe cases of postpartum or postabortion sepsis may be associated with clostridia and/or *Bacteroides* species. These infections have a high mortality rate without prompt treatment, generally using antimicrobials directed against both anaerobes and coliforms combined with abscess drainage or early hysterectomy when appropriate. Potential antibiotic options for chorioamnionitis, septic abortion, or postpartum endometritis include intravenous piperacillin-tazobactam (4.5 g as a one-time loading dose, then—starting 4 hours later—3.375 g given every 8 hours) or meropenem (1–2 g as loading dose, then 0.5–1 g every 8 hours).

6. Bacteremia & Endocarditis

Complications of anaerobic infections of the GI tract, female genital tract, oropharynx, or pressure injuries can include bacteremia and endocarditis. Cases of endocarditis due to microaerophilic or anaerobic streptococci may be effectively treated with 12–18 million units of intravenous aqueous crystalline penicillin G given daily for 4–6 weeks, although optimal therapy of anaerobic bacterial endocarditis must often rely on laboratory guidance. *Cutibacterium acnes*, clostridia, *Lactobacillus* species, and *Bacteroides* species also occasionally cause endocarditis.

7. Skin & Soft Tissue Infections

Anaerobic infections of the skin and soft tissue usually follow trauma, ischemia, or surgery and are most common in areas that are contaminated by oral or fecal flora. These infections also occur in persons who inject drugs or have sustained animal bites. There may be progressive tissue necrosis (Figure 38–5) and a putrid odor.

Several terms, such as *bacterial synergistic gangrene*, *synergistic necrotizing cellulitis*, *necrotizing fasciitis* (see above), and *nonclostridial crepitant cellulitis*, have been used to classify these infections. Although there can be some differences in microbiology among them, differentiation on clinical grounds alone is difficult. All are mixed infections caused by aerobic and anaerobic organisms; they require aggressive surgical debridement of necrotic tissue for cure.

Broad-spectrum antibiotics active against both anaerobes and gram-positive and gram-negative aerobes (eg, intravenous vancomycin plus piperacillin-tazobactam with intravenous clindamycin for necrotizing fasciitis) should be instituted empirically and modified by culture results. Antibiotics are given for about a week after progressive tissue destruction has been controlled, and the margins of the wound remain free of inflammation.

ACTINOMYCOSIS

ESSENTIALS OF DIAGNOSIS

- Recent dental infection, abdominal trauma, or intrauterine contraception device placement.
- Chronic pneumonia or indolent cervicofacial or intra-abdominal abscess.
- Sinus tract formation.

General Considerations

Actinomyces israelii and other species of *Actinomyces* occur in the normal flora of the mouth and tonsillar crypts. When introduced into traumatized tissue and associated with other anaerobic bacteria, these actinomycetes become pathogens.

The most common site of infection is the cervicofacial area (about 60% of cases). Infection typically follows extraction of a tooth or other trauma. Lesions may develop in the GI tract or lungs following ingestion or aspiration of the organism from its endogenous source in the mouth.

Clinical Findings

A. Symptoms and Signs

1. Cervicofacial actinomycosis—Cervicofacial actinomycosis develops slowly. The affected area becomes markedly indurated, and the overlying skin becomes reddish or cyanotic. Abscesses eventually draining to the surface persist for long periods. "Sulfur granules"—masses of filamentous organisms—may be found in the pus. There is usually little pain unless there is another secondary infection. Trismus indicates that the muscles of mastication are involved. Radiographs may reveal bony involvement. Cervicofacial or thoracic disease may occasionally involve the CNS, most commonly causing brain abscess or meningitis.

2. Thoracic actinomycosis—Thoracic involvement begins with fever, cough, and sputum production with night sweats and weight loss. Pleuritic pain may be present. Multiple sinus tracts may extend through the chest wall, to the heart, or into the abdominal cavity. Ribs may be involved. Radiography shows areas of consolidation and sometimes pleural effusion.

3. Abdominal and pelvic actinomycosis—Abdominal actinomycosis usually causes pain in the ileocecal region, spiking fever and chills, vomiting, and weight loss; it may be confused with Crohn disease. Irregular abdominal masses may be palpated. PID caused by actinomycetes has been associated with prolonged use of intrauterine contraceptive devices. Sinuses draining to the exterior may develop. CT scanning may reveal an inflammatory mass extending to involve bone.

B. Laboratory Findings

The anaerobic, gram-positive organism may be demonstrated as a granule or as scattered branching gram-positive filaments in pus. Anaerobic culture is necessary to distinguish actinomycetes from *Nocardia* species because treatment differs for the two infections. Histopathologic examination of affected tissue and bone is useful in identifying organisms that are fastidious and slow to culture.

Treatment

Penicillin G is the drug of choice. Ten to 20 million units are given intravenously in divided doses every 4–6 hours, typically for 4–6 weeks, followed by oral penicillin V, 2–4 g per day, divided into four daily doses. Alternatives include intravenous ampicillin (200 mg/kg/day in 3–4 divided doses) or ceftriaxone (2 g daily) for 2–6 weeks, followed by oral amoxicillin or doxycycline. Response to therapy is slow. Therapy should be continued for weeks to months after clinical manifestations have disappeared to ensure cure. Surgical procedures such as drainage and resection may be beneficial. With optimal antimicrobial therapy and surgery, the prognosis is good. However, because actinomycosis is difficult to diagnose, there may be extensive tissue destruction before the diagnosis is confirmed and treatment initiated.

Xu Y et al. Disseminated actinomycosis. N Engl J Med. 2018;379:1071. [PMID: 30207906]

NOCARDIOSIS

ESSENTIALS OF DIAGNOSIS

- Indolent pneumonia with dissemination to CNS, skin, and bone or primary cutaneous disease.
- Suspect in setting of chronic lung disease or immunocompromised person.

General Considerations

Nocardia species are aerobic filamentous soil bacteria that can cause primary cutaneous, lymphocutaneous, pulmonary, and/or systemic nocardiosis. Common *Nocardia* species include members of the *Nocardia nova* complex, *Nocardia farcinica*, *Nocardia cyriacigeorgica*, *Nocardia brasiliensis*, and *Nocardia abscessus*. Bronchopulmonary abnormalities (eg, bronchiectasis) may predispose to colonization, while infection is more likely to occur in patients who are receiving systemic corticosteroids or are otherwise immunosuppressed.

Clinical Findings

Primary cutaneous nocardiosis represents ~20% of nocardia infections; the presentation resembles other forms of bacterial cellulitis, typically occurring after a traumatic injury. In the lymphocutaneous form of the disease, cellulitis is accompanied by ascending regional lymphadenopathy. Pulmonary nocardiosis typically presents with a cough productive of purulent sputum, often associated with malaise, weight loss, fever, and night sweats. Pulmonary infiltrates may become cavitary and may be accompanied by pleural effusions or empyema; they may also invade through the ribs and penetrate exteriorly through the chest wall.

Disseminated nocardiosis can involve any organ, with the CNS being one of the more common sites of dissemination. Even in the absence of clinical symptoms and signs of CNS infection, clinicians should pursue brain imaging in patients diagnosed with nocardiosis to rule out occult CNS abscess.

Diagnostically, *Nocardia* species are usually found as delicate, branching, gram-positive filaments. They may be weakly acid-fast, occasionally causing diagnostic confusion with tuberculosis. Identification is typically made by culture with antimicrobial susceptibility testing to guide treatment options.

Treatment

For isolated primary cutaneous infections or lymphadenitis, therapy is initiated with trimethoprim-sulfamethoxazole orally or intravenously (5–10 mg/kg/day based on trimethoprim, given in 2–4 divided doses). Surgical procedures such as drainage and resection may be needed as adjunctive therapy. For pulmonary or disseminated infections, a higher dose of trimethoprim-sulfamethoxazole (15 mg/kg/day based on trimethoprim) should be used, typically in combination with at least one other antibiotic. Other agents generally active against *Nocardia* species include imipenem-cilastatin (500 mg intravenously every 6 hours); meropenem (2 g intravenously every 8 hours); amikacin (7.5 mg/kg intravenously every 12 hours); linezolid (600 mg intravenously or orally every 12 hours); or (for lymphadenitis and/or skin abscess) minocycline (100–200 mg orally or intravenously twice daily). Consultation with an infectious disease expert is encouraged.

Response to treatment may be slow; therapy should be continued for at least 6–12 months. The prognosis in systemic nocardiosis is poor when diagnosis and therapy are delayed.

INFECTIONS CAUSED BY MYCOBACTERIA

NONTUBERCULOUS MYCOBACTERIAL DISEASES

Nontuberculous mycobacterial infections are among the most common opportunistic infections in advanced HIV but may also cause disease in immunocompetent persons. These organisms occur ubiquitously in the environment, are not communicable from person to person, have distinctive laboratory characteristics, and may be resistant to standard antitubercular drugs.

1. Pulmonary Infections

Mycobacterium avium-intracellulare complex (MAC) causes a chronic, slowly progressive pulmonary infection resembling tuberculosis in immunocompetent patients—classically those with underlying pulmonary disease. Pulmonary disease is often classified as nodular, bronchiectatic, or fibrocavitary. Treatment of pulmonary MAC requires a three-drug regimen, and macrolide susceptibility testing should be performed on all clinical isolates. For nodular or bronchiectatic disease in immunocompetent hosts, treatment may include azithromycin (500 mg), ethambutol (25 mg/kg) and rifampin (600 mg), with all three drugs given orally three times per week. For cavitary disease, treatment may consist of azithromycin (250–500 mg orally per day) plus ethambutol (15 mg/kg/day orally per day) plus rifampin (up to 600 mg orally per day) and amikacin (15–25 mg/kg intravenously or intramuscularly three times weekly for the first 2–3 months). Therapy is continued for at least 12 months after sterilization of sputum cultures.

M kansasii can produce clinical disease resembling tuberculosis, but the illness progresses more slowly. Most pulmonary infections occur in patients with preexisting lung disease. Microbiologically, *M kansasii* is similar to *M tuberculosis* and is sensitive to the same drugs except pyrazinamide, to which it is resistant. Therapy with daily oral azithromycin (250–500 mg, preferred) or isoniazid 300 mg (given with pyridoxine 50 mg), plus ethambutol (15 mg/kg) and rifampin (600 mg), given for at least 12 months, has been successful.

Less common causes of pulmonary disease include *M xenopi*, *M szulgai*, and *M malmoense*. These organisms have variable sensitivities, and treatment is based on results of sensitivity tests. The rapidly growing mycobacteria—*M abscessus*, *M chelonae*, and *M fortuitum*—can also occasionally cause pneumonia.

Daley CL et al. Treatment of nontuberculous mycobacterial pulmonary disease: an official ATS/ERS/ESCMID/IDSA clinical practice guideline. Eur Respir J. 2020;56:2000535. [PMID: 32636299]

Nasiri MJ et al. Antibiotic therapy success rate in pulmonary *Mycobacterium avium* complex: a systematic review and meta-analysis. Expert Rev Anti Infect Ther. 2020;18:263. [PMID: 31986933]

2. Lymphadenitis

Most cases of lymphadenitis (scrofula) in adults are caused by *M tuberculosis* and can be a manifestation of disseminated disease. In children, most cases are due to nontuberculous mycobacterial species. Infection with nontuberculous mycobacteria has been successfully treated by surgical excision with or without anti-tuberculous drugs.

3. Skin & Soft Tissue Infections

Skin and soft tissue infections such as abscesses, septic arthritis, and osteomyelitis can result from direct inoculation, from hematogenous dissemination, or as a complication of surgery.

The rapidly growing nontuberculous mycobacteria (*M abscessus*, *M chelonae*, and *M fortuitum*) may cause these types of infections. Most cases occur on the extremities, initially presenting as nodules that may then ulcerate and form abscesses. These organisms are resistant to the usual antituberculosis drugs but (depending on the species) may have susceptibility to azithromycin, clarithromycin, amikacin, imipenem, cefoxitin, linezolid, tetracyclines, fluoroquinolones, sulfonamides, clofazimine, or bedaquiline, among other agents; antibiotic susceptibility testing is recommended. Treatment often includes surgical debridement along with at least two active antibiotics. Treatment is usually continued for at least 3–6 months, although duration must ultimately be determined based on clinical response.

M marinum infection ("swimming pool" or "fish tank" granuloma) presents as a nodular skin lesion following exposure to nonchlorinated water. Surgical excision may be recommended. Therapy is based on susceptibility testing and often involves 2–3 active agents; isolates may be susceptible to rifampin, ethambutol, and clarithromycin, among other agents.

4. Disseminated *Mycobacterium avium-intracellulare* complex Infection

MAC causes disseminated, multiorgan disease in immunocompromised patients, especially those with HIV who have a CD4 cell count < 50/mcL (see Pulmonary Disease Caused by Nontuberculous Mycobacteria, Chapter 9, for a discussion of the infection in immunocompetent patients). Signs and symptoms are nonspecific, including fever, weight loss, fatigue, night sweats, diarrhea, abdominal pain, hepatosplenomegaly, and/or lymphadenopathy. The organism may be cultured from multiple sites, including blood, lymph nodes, bone marrow, or other normally sterile sites. Blood culture is the preferred means of establishing the diagnosis, with a sensitivity of 98%.

Agents with proven activity against MAC are rifabutin, azithromycin, clarithromycin, and ethambutol. A combination of two or more active agents should be used to prevent rapid emergence of secondary resistance. Clarithromycin, 500 mg orally twice daily, plus ethambutol, 15 mg/kg/day orally, with or without rifabutin, 300 mg/day orally, is the treatment of choice. Azithromycin, 500–600 mg orally once daily, may be used instead of clarithromycin in cases of drug–drug interactions or intolerance. In more severe or refractory cases, a fourth drug—such as a fluoroquinolone, injectable aminoglycoside, bedaquiline, linezolid, tedizolid, or omadacycline—may be considered. MAC therapy is usually continued for at least 12 months, although shorter durations may be possible in patients who have a high degree of immune recovery following the initiation of antiretroviral therapy. CD4 counts should exceed 100/mcL (0.1 × 10^9/L) for ≥ 6 months while receiving antiretroviral therapy before stopping MAC treatment.

Antimicrobial prophylaxis of MAC prevents disseminated disease and prolongs survival in certain patients with HIV. Prophylaxis is recommended for patients with HIV who have CD4 counts of ≤ 50/mcL (0.05 × 10^9/L) and are not on antiretroviral therapy, remain viremic despite antiretroviral therapy, or do not have options for a fully suppressive HIV regimen. MAC Prophylaxis is no longer recommended in patients with HIV who immediately initiate ART or are on a fully suppressive ART regimen. In contrast to active infection, single-drug oral regimens of clarithromycin (500 mg twice daily), azithromycin (either 1200 mg once weekly or 600 mg twice weekly), or rifabutin (300 mg once daily) are appropriate for MAC prevention. Clarithromycin and azithromycin are preferred, as they are more effective and better tolerated. When previously initiated, primary prophylaxis for MAC infection can be stopped in adult and adolescent patients who are continuing fully suppressive ART.

Panel on Opportunistic Infections in Adults and Adolescents with HIV. MYCOBACTERIUM TUBERCULOSIS INFECTIONS

Tuberculosis is discussed in Chapter 9. Further information and expert consultation can be obtained from the Curry International Tuberculosis Center at the website www.currytbcenter.ucsf.edu or by telephone, (877) 390-6682.

TUBERCULOUS MENINGITIS

ESSENTIALS OF DIAGNOSIS

- Gradual onset of listlessness and anorexia.
- Headache, vomiting, and seizures common.
- Cranial nerve abnormalities typical.
- Tuberculosis focus may be evident elsewhere.
- CSF shows several hundred lymphocytes, low glucose, and high protein.

General Considerations

Tuberculous meningitis is often basilar-predominant. It may result from rupture of a meningeal tuberculoma (itself the result of earlier hematogenous seeding of tubercle bacilli from a primary pulmonary focus), or it may be a consequence of miliary spread.

Clinical Findings

A. Symptoms and Signs

The onset is usually gradual, with listlessness, irritability, anorexia, and fever, followed by headache, vomiting, convulsions, and coma. In older patients, headache and behavioral changes are prominent early symptoms. Nuchal rigidity and cranial nerve palsies occur as the meningitis progresses. Evidence of active tuberculosis elsewhere or a history of prior tuberculosis are often present.

B. Laboratory Findings

The spinal fluid is frequently yellowish, with increased opening pressure, cell count 100–500/mcL (0.1–0.5 × 10^9/L) (predominantly lymphocytes, though neutrophils may be present early during infection), increased protein, and decreased glucose. Acid-fast stains of CSF are often negative, and cultures also may be negative (sensitivity up to 50–60%). Nucleic acid amplification tests are valuable tools that allow for rapid diagnosis when positive. CXRs often reveal abnormalities compatible with tuberculosis but may instead be normal. Tuberculin skin testing and interferon γ release assays do not distinguish between active and latent tuberculosis and may be negative in the presence of CNS infection.

Differential Diagnosis

Tuberculous meningitis may be confused with any other type of meningitis, but the gradual onset, predominantly lymphocytic pleocytosis of the spinal fluid, and evidence of tuberculosis elsewhere often point to the diagnosis. Fungal and other granulomatous meningitides, syphilis, and carcinomatous meningitis are in the differential diagnosis.

Complications

Complications of tuberculous meningitis include seizures, cranial nerve palsies, stroke, and obstructive hydrocephalus with impaired cognitive function. These result from inflammatory exudate primarily affecting the basilar meninges and arteries.

Treatment

Presumptive diagnosis followed by early, empiric antituberculous therapy is essential for survival and to minimize sequelae. Even if CSF cultures are negative, a full course of therapy is warranted if the clinical scenario is suggestive of tuberculous meningitis.

Regimens that are effective for pulmonary tuberculosis are effective also for tuberculous meningitis. The current standard of care regimen for tuberculous meningitis includes isoniazid and rifampin with ethambutol and pyrazinamide (the latter two drugs given only for the first 2 months; total treatment duration 9–12 months). Some experts may opt to treat tuberculous meningitis with higher doses of rifampin (up to 20 mg/kg/day) for better blood–brain barrier penetration, and/or may opt to use other antibiotics (such as levofloxacin) in place of ethambutol. Expert consultation is strongly advised when treating tuberculous meningitis.

Many authorities recommend the addition of corticosteroids as adjunctive therapy, as this has been shown to reduce mortality from tuberculous meningitis. Dexamethasone (0.4 mg/kg/day intravenously for week 1, then 0.3 mg/kg/day for week 2, then 0.2 mg/kg/day for week 3, then 0.1 mg/kg/day for week 4, and then tapered over 3–4 more weeks) may be used for this purpose.

Nahid P et al. Official American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America clinical practice guidelines: treatment of drug-susceptible tuberculosis. Clin Infect Dis. 2016;63:e147. [PMID: 27516382]

LEPROSY (Hansen Disease)

ESSENTIALS OF DIAGNOSIS

- Pale, anesthetic macular—or nodular and erythematous—skin lesions.
- Superficial nerve thickening with resultant anesthesia.
- History of residence in endemic area in childhood.
- Acid-fast bacilli in skin lesions or nasal scrapings, or characteristic histologic nerve changes.

General Considerations

Hansen disease (leprosy) is a chronic infectious disease caused by the acid-fast atypical mycobacteria *M leprae* and *M lepromatosis*. The primary mode of transmission is likely respiratory (versus zoonotic, associated with armadillos) and involves prolonged exposures. The disease is endemic in tropical and subtropical Asia, Africa, South America, and the Pacific regions, and seen sporadically in the United States, particularly in the south and southeast. There have been reports of leprosy occurring in Florida and Georgia without traditional risk factors, raising concerns for endemicity in the soil.

Clinical Findings

A. Symptoms and Signs

The onset is insidious, and the lesions involve cooler body tissues: skin, superficial nerves, nose, pharynx, larynx, eyes, and testicles. Skin lesions may occur as pale, anesthetic macular lesions; discrete erythematous, infiltrated nodules; or diffuse skin infiltration. Neurologic disturbances are caused by nerve infiltration and thickening, with resultant anesthesia and motor abnormalities. Bilateral ulnar neuropathy is highly suggestive. In untreated cases, disfigurement due to skin infiltration and nerve involvement may be extreme, leading to trophic ulcers, bone resorption, and loss of digits.

Hansen disease is divided clinically and by laboratory tests into two distinct types: lepromatous and tuberculoid. The **multibacillary type** (also referred to as lepromatous leprosy) typically occurs in patients with defective cellular immunity. The course is progressive, with diffuse skin involvement that may become nodular, slow and symmetric nerve involvement, abundant acid-fast bacilli in the skin lesions, and a negative lepromin skin test. In the **paucibacillary type** (tuberculoid leprosy), cellular immunity is intact. The course is more benign and less progressive, with macular skin lesions, sudden-onset severe and asymmetric nerve involvement, few bacilli present in the lesions, and a positive lepromin skin test. Intermediate ("borderline") cases are frequent. Eye involvement (keratitis and iridocyclitis), nasal ulcers, epistaxis, anemia, and lymphadenopathy may occur.

B. Laboratory Findings

Laboratory confirmation of leprosy requires the demonstration of acid-fast bacilli in a skin biopsy. Skin or nerve biopsies may also show a typical histologic picture. *M leprae* does not grow in artificial media but does grow in the foot pads of armadillos.

Differential Diagnosis

The skin lesions of leprosy often resemble those of SLE, sarcoidosis, syphilis, erythema nodosum, erythema multiforme, cutaneous tuberculosis, and vitiligo.

Complications

Kidney failure and hepatomegaly from secondary amyloidosis may occur with long-standing disease.

Treatment

Combination therapy is recommended for treatment of all types of leprosy. Single-drug treatment promotes the development of resistance, and primary resistance to dapsone also occurs. For multibacillary cases, the WHO recommends a triple oral drug regimen of rifampin, 600 mg once a month; dapsone, 100 mg daily; and clofazimine, 300 mg once a month and 50 mg daily for 12 months, although longer courses may be needed for patients with a high burden of disease. For paucibacillary disease, the duration of therapy may be shorter (on the order of 6 months). The US National Hansen's Disease Program has slightly different treatment recommendations and is available for consultation at 1-800-642-2477.

INFECTIONS CAUSED BY CHLAMYDIAE

CHLAMYDIA TRACHOMATIS INFECTIONS

1. Lymphogranuloma Venereum

ESSENTIALS OF DIAGNOSIS

- Evanescent primary genital lesion.
- Inguinal buboes with suppuration and draining sinuses.
- Proctitis or proctocolitis, with risk of colorectal strictures and fistulae.
- Diagnosis supported by positive nucleic amplification test for *C trachomatis* in right clinical context.

General Considerations

Lymphogranuloma venereum (LGV) is an acute and chronic sexually transmitted infection caused by *C trachomatis* serovars L1–L3. The disease is acquired during intercourse or through contact with contaminated exudate from active lesions. The incubation period is between 3–30 days. A self-limited ulcer or papule may form at the initial site of inoculation. After the genital lesion disappears, the infection spreads to the lymph nodes of the genital and rectal areas.

Clinical Findings

A. Symptoms and Signs

The initial papule or ulcerative lesion (usually on the external genitalia) is evanescent and often goes unnoticed. Patients may present instead with tender inguinal or femoral lymphadenopathy or buboes, which appear 1–4 weeks after exposure, are typically unilateral, and tend to fuse, soften, and break down to form multiple draining sinuses with extensive scarring. In people engaging in receptive anal sex, LGV most commonly presents with symptoms of proctocolitis. Early anorectal manifestations include proctitis with tenesmus and bloody purulent discharge; late manifestations include chronic cicatrizing inflammation of the rectal and perirectal tissue. These changes can lead to obstipation, rectal stricture and, occasionally, rectovaginal and perianal fistulas.

B. Laboratory Findings

A diagnosis of LGV can be confirmed only with LGV-specific molecular tests (ie, polymerase chain reaction), which can differentiate LGV from non-LGV *C trachomatis* infections. These LGV-specific tests, however, are not widely available, and can have prolonged turnaround times. Instead, the diagnosis of LGV can be made when a patient has a positive nucleic amplification test for chlamydia at a symptomatic site (frequently the rectum) in the appropriate clinical context. Chlamydia serology (complement fixation or microimmunofluorescence) should not be used routinely but may be helpful in cases of isolated inguinal or femoral lymphadenopathy when nucleic amplification testing is unable to be obtained.

Differential Diagnosis

Early LGV lesions must be differentiated from ulcers caused by syphilis, genital herpes, or chancroid; lymph node involvement must be distinguished from that due to tularemia, tuberculosis, plague, neoplasm, or pyogenic infection. Rectal strictures attributable to LGV must be distinguished from those due to malignancy or IBD.

Treatment

If diagnostic testing for LGV is not available, patients with a clinical presentation suggestive of LGV should be treated empirically. The antibiotic of choice (for nonpregnant patients only) is doxycycline, 100 mg orally twice daily for 21 days. Erythromycin, 500 mg orally four times a day for 21 days, is an alternative treatment. Azithromycin, 1 g orally once weekly for 3 weeks, also may be effective.

De Vries HJC et al. 2019 European guideline on the management of lymphogranuloma venereum. J Eur Acad Dermatol Venereol. 2019;33:1821. [PMID: 31243838]

Workowski KA et al. Sexually transmitted infections treatment guidelines, 2021. MMWR Recomm Rep. 2021;70:1. [PMID: 34292926]

2. Chlamydial Urethritis & Cervicitis

ESSENTIALS OF DIAGNOSIS

- *C trachomatis*: common cause of nongonococcal urethritis and cervicitis.
- Diagnosis made by nucleic acid amplification testing from a mucosal site (ie, urine sample or swab from the rectum, pharynx, cervix, or vagina).

General Considerations

C trachomatis serotypes D–K are a common cause of nongonococcal urethritis and cervicitis. *Mycoplasma genitalium* is another potential cause of these syndromes. Co-infections with other sexually transmitted pathogens, including gonorrhea, are common. *C trachomatis* infections can occasionally cause epididymitis, prostatitis, or proctitis; sequalae following cervicovaginal infections can include PID, ectopic pregnancy, and infertility.

Clinical Findings

A. Symptoms and Signs

Urethral or cervical discharge due to *C trachomatis* tends to be less painful, less purulent, and more watery than that due to *N gonorrhoeae*. Cervicovaginal chlamydial infections may be asymptomatic or may present with signs and symptoms of cervicitis, salpingitis, or pelvic inflammatory disease. Long-term sequelae may include ectopic pregnancy and infertility.

B. Laboratory Findings

Patients with signs and symptoms of urethritis or cervicitis are assumed to have chlamydial infection until proven otherwise. The diagnosis should be confirmed, whenever possible, by FDA-approved, highly sensitive nucleic acid amplification tests performed on urine, or urethral, cervical or vaginal swabs. A negative urogenital nucleic acid amplification test can reliably exclude the diagnosis of chlamydial urethritis or cervicitis. Urogenital testing does not exclude infection at other sites, such as the rectum or pharynx.

C. Screening

Screening for chlamydial infection is recommended for certain populations: all sexually active women age ≥ 25 years; women age > 25 years with risk factors for sexually transmitted infections; pregnant persons age < 25 or at increased vulnerability to sexually transmitted infections; patients with HIV; and men with risk factors for sexually acquired infections, such as men who have sex with men.

Treatment

Doxycycline, 100 mg orally twice daily for 7 days, is the preferred regimen for urogenital, rectal, and pharyngeal chlamydial infections in nonpregnant people. A single oral 1-g dose of azithromycin (alternative regimen, preferred in pregnancy), or 500 mg of levofloxacin once daily for 7 days, can alternatively be used. Empiric chlamydia treatment may be indicated for some patients, such as: (1) people with gonococcal infections in whom no chlamydial testing was performed, or a test other than a nucleic acid amplification test was used to exclude the diagnosis, or (2) people with pending chlamydia test results who are considered unlikely to follow up. Sex partners of patients with confirmed chlamydial infections also should be tested and treated empirically for chlamydia. Screening for HIV, gonorrhea, and syphilis should also be performed in all patients with an STI diagnosis.

Centers for Disease Control and Prevention. STI screening recommendations and considerations referenced in treatment guidelines and original sources. https://www.cdc.gov/std/treatment-guidelines/screening-recommendations.htm

Workowski KA et al. Sexually transmitted infections treatment guidelines, 2021. MMWR Recomm Rep. 2021;70:1. [PMID: 34292926]

CHLAMYDIA PSITTACI & PSITTACOSIS (Ornithosis)

ESSENTIALS OF DIAGNOSIS

- Fever, chills, and cough; headache common.
- Atypical pneumonia with slightly delayed appearance of signs of pneumonitis.
- Contact with infected bird (psittacine, pigeons, many others) 5–14 days previously.
- Isolation of chlamydiae or rising antibody titers.

General Considerations

Psittacosis is acquired from contact with infected birds (parrots, parakeets, pigeons, chickens, ducks, and many others), which may or may not be ill.

Clinical Findings

Most patients with psittacosis experience a mild illness, similar to other respiratory illnesses, with onset 5–14 days after exposure. Symptoms include fever, chills, myalgia, dry cough, and headache. Signs include relative bradycardia (temperature-pulse dissociation), dullness to percussion, and rales. Pulmonary findings may be absent early in the clinical course. Dyspnea and cyanosis may occur later. Culture-negative endocarditis may occasionally occur. Rarely, patients may experience fulminant disease with multiorgan failure. The radiographic findings in psittacosis are usually those of atypical pneumonia—which tends to be interstitial and diffuse in appearance—although consolidation also can occur. Psittacosis is thus indistinguishable from other bacterial or viral pneumonias by radiography.

The organism is rarely isolated from respiratory cultures. Instead, the diagnosis is usually made serologically by either complement fixation or microimmunofluorescence and can be supported by a fourfold or greater rise in antibody titers between acute and convalescent samples (collected 2 weeks apart, to a titer of ≥ 1:32) or a single IgM titer of ≥ 1:16 (by microimmunofluorescence). If available, polymerase chain reaction testing of lower respiratory tract, sputum, nasopharyngeal, or stool samples may provide a more rapid diagnosis.

Differential Diagnosis

The illness is indistinguishable from viral, mycoplasma, or other atypical pneumonias except for the history of contact with birds. Psittacosis is on the differential diagnosis for culture-negative endocarditis.

Treatment

Treatment is with doxycycline 100 mg orally twice daily for 7–10 days. Azithromycin, 500 mg orally on day 1, and then 250 mg once daily for 4 days, may be effective as well.

Centers for Disease Control and Prevention. About psittacosis. https://www.cdc.gov/psittacosis/about/

CHLAMYDOPHILA PNEUMONIAE INFECTION

C pneumoniae causes pneumonia, pharyngitis, sinusitis, and bronchitis. The organism may be the second most common cause of atypical pneumonia (after mycoplasma) and presents similarly, with fever and nonproductive cough. When a diagnosis of pneumonia due to *C pneumoniae* is confirmed, recommended treatments include doxycycline (100 mg twice daily, given orally or intravenously for 14 days) or azithromycin (500 mg on day 1, then 250 mg daily for 4 more days, given orally or intravenously).

Metlay JP et al. Diagnosis and treatment of adults with community-acquired pneumonia. An official clinical practice guideline of the American Thoracic Society and Infectious Diseases Society of America. Am J Respir Crit Care Med. 2019;200:e45. [PMID: 31573350]

Spirochetal Infections

39

Ina Park, MD, MS

SYPHILIS

NATURAL HISTORY & PRINCIPLES OF DIAGNOSIS & TREATMENT

Syphilis is a complex infectious disease caused by *Treponema pallidum*, a spirochete capable of infecting almost any organ or tissue in the body and causing protean clinical manifestations. Transmission occurs most frequently during sexual contact or via the placenta from mother to fetus (congenital syphilis). The risk of acquiring syphilis after unprotected sex with an individual with infectious syphilis is approximately 30–50%. Rarely, it can also be transmitted through nonsexual contact or blood transfusion. The natural history of acquired syphilis is generally divided into two major groups: early syphilis, which is < 1 year in duration and infectious, and late syphilis, which is present for > 1 year and not infectious. Ocular, otosyphilis and neurosyphilis can occur at any stage and may occur alone or concurrently with other symptoms.

1. Early syphilis (primary, secondary, and early latent)— *The hallmark of the lesions of primary and secondary syphilis is an abundance of spirochetes*; tissue reaction is usually minimal (Table 39–1).

Primary syphilis lesions include a chancre (usually solitary but multiple lesions can occur) and regional lymphadenopathy.

Secondary syphilis lesions commonly involve the skin (rash) and mucous membranes—and occasionally bone, CNS, or liver, when dissemination of *T pallidum* produces systemic signs.

Early latent disease is without signs or symptoms, although relapsing symptoms/lesions may occur.

Congenital syphilis findings (eg, rhinitis, osteitis, skin lesions) are categorized as early disease.

The progression of syphilis without treatment is from the primary stage (chancre at the site of inoculation) to resolution of the lesion(s), and a period of latency. Secondary lesions can arise as the treponemes disseminate; these also can resolve without treatment, and this stage is called early latent syphilis if it has been < 1 year since infection. Thus, there are two distinct periods of early latent syphilis, one after the primary lesion resolves and another after the secondary lesions resolve. During the early latent period after secondary syphilis, there can be a relapse back into secondary signs and symptoms.

Whether an infection is less than a year old (and therefore early syphilis) may be determined by the patient recalling primary or secondary lesions—or, more commonly, by confirming the date of the patient's last known negative syphilis serology.

2. Late syphilis (late latent and tertiary)—Late latent disease is infection acquired > 1 year prior without active lesions, while tertiary disease is characterized by gummatous lesions involving skin, bones, and viscera; CVD (principally aortitis); and CNS and ocular syndromes (Table 39–1). These late forms of syphilis are not contagious. The lesions contain few demonstrable spirochetes, but tissue reactivity (vasculitis, necrosis) is severe and suggestive of hypersensitivity phenomena.

3. Syphilis data and statistics—Public health efforts to control syphilis focus on the diagnosis and treatment of early infectious cases and their sexual partners.

In 2023, one-third of cases of primary and secondary syphilis in the United States occurred in men who have sex with men (MSM). Globally, the WHO estimates 8 million total incident syphilis infections occurred in 2022, with country-specific prevalence ranging from 0 to 10% among pregnant women attending antenatal clinics. Preventing congenital syphilis is a major public health goal for both the CDC and WHO.

COURSE & PROGNOSIS

The lesions associated with primary and secondary syphilis are self-limiting, even without treatment, and resolve with few or no residua. Ocular and otologic syphilis have been associated with permanent vision and hearing loss. Tertiary and congenital syphilis may be highly destructive and permanently disabling and may lead to death. While infection is rarely eradicated completely in the absence of treatment, most infections likely remain latent without sequelae, and only a small number of latent infections progress to further disease.

Table 39–1. Stages of syphilis and common clinical manifestations.

Stage	Manifestations
Early (infectious) syphilis	
Primary	Chancre: painless ulcer with clean base and firm indurated borders, can present with multiple or painful lesions Regional lymphadenopathy
Secondary	Skin and mucous membranes Rash: diffuse (may include palms and soles), macular, papular, pustular, and combinations Condylomata lata Mucous patches: painless, silvery ulcerations of mucous membrane with surrounding erythema Generalized lymphadenopathy Constitutional symptoms Fever, usually low-grade Malaise, anorexia Arthralgias and myalgias CNS Asymptomatic Symptomatic Meningitis Cranial neuropathies (II–VIII) Other Ocular: iritis, iridocyclitis Renal: glomerulonephritis, nephrotic syndrome Hepatitis Musculoskeletal: arthritis, periostitis
Early latent	No signs or symptoms
Late (noninfectious) syphilis	
Late latent	No signs or symptoms
Tertiary	Late benign (gummatous): granulomatous lesion usually involving skin, mucous membranes, and bones but any organ can be involved Cardiovascular Aortic regurgitation Coronary ostial stenosis Aortic aneurysm Neurosyphilis Asymptomatic Meningovascular Tabes dorsalis General paresis

Note: CNS involvement may occur at any stage.

CLINICAL STAGES OF SYPHILIS

1. Primary Syphilis

ESSENTIALS OF DIAGNOSIS

- Painless ulcer on genitalia, perianal area, rectum, pharynx, tongue, lip, or elsewhere.
- Fluid expressed from ulcer contains *T pallidum* by immunofluorescence or darkfield microscopy.
- Nontender enlargement of regional lymph nodes.
- Serologic nontreponemal and treponemal tests may be positive.

Clinical Findings

A. Symptoms and Signs

The typical lesion is the chancre at the site or sites of inoculation, most frequently located on the penis (Figure 39–1), labia, cervix, or anorectal region. Anorectal lesions are especially common among MSM. Chancres also occur occasionally in the oropharynx (lip, tongue, or tonsil) and rarely on the breast or finger or elsewhere. An initial small erosion appears 10–90 days (average, 3–4 weeks) after inoculation and rapidly develops into a single, painless, superficial ulcer with a clean base and firm, indurated margins. Although the "classic" ulcer of syphilis has been described as nontender, nonpurulent, and indurated, only 31% of patients have this triad. Bacterial superinfection of the chancre may occur and may be painful. Healing of the chancre occurs without treatment, but a scar may form, especially with secondary bacterial infection. Multiple chancres may be present, particularly in patients with HIV. At the primary stage there is often enlargement of regional lymph nodes, which are rubbery, discrete, and nontender.

B. Laboratory Findings

1. Microscopic examination—In early syphilis, darkfield microscopic examination by a skilled observer of fresh exudate from moist lesions or material aspirated from regional lymph nodes is up to 90% sensitive for diagnosis but is usually only available in select sexual health clinics.

An immunofluorescent staining technique for demonstrating *T pallidum* in dried smears of fluid taken from early syphilitic lesions is performed in only a few laboratories.

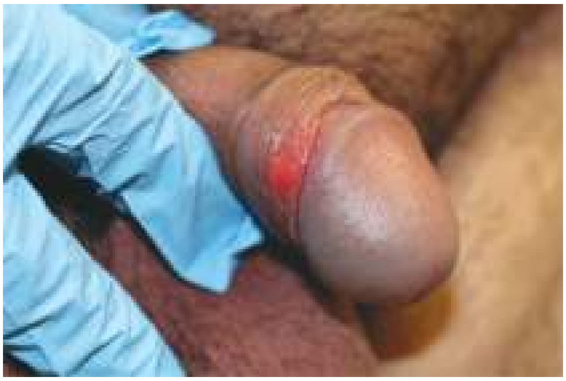

Figure 39–1. Chancre from primary syphilis. Used with permission from Christopher Ried, MD, Orange County Public Health.

Table 39–2. Percentage of patients with positive serologic tests for syphilis.[1]

Test	Stage		
	Primary	Secondary	Tertiary
VDRL or RPR	63–78%	100%	47–64%
FTA-ABS, TPPA	78–100%	100%	94–98%
MHA-TP	46–89%	90–100%	NA
EIA or CIA	54–100%	100%	NA

[1] Based on untreated cases.

CIA, chemiluminescence immunoassay; EIA, enzyme immunoassay; FTA-ABS, fluorescent treponemal antibody absorption assay; MHA-TP, microhemagglutination assay for *T pallidum*; RPR, rapid plasma reagin test; TPPA, *T pallidum* particle agglutination; VDRL, Venereal Disease Research Laboratory test.

2. Serologic tests for syphilis—Serologic tests for antibodies (the mainstay of syphilis diagnosis) fall into two general categories: (1) **Nontreponemal** tests detect antibodies to lipoidal antigens present in both the host cell membrane as well as *T pallidum*; and (2) **Treponemal** tests use live or killed *T pallidum* as antigen to detect antibodies specific for pathogenic treponemes (Table 39–2).

A. Nontreponemal antibody tests—The most commonly used nontreponemal antibody tests are the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests. A patient infected with syphilis produces antibodies that react with lipoidal antigens such as cardiolipin and lecithin; the VDRL and RPR tests detect these antibodies. The traditional term *nontreponemal* is a misnomer because the RPR detects antibodies against antigens in both the host and *T pallidum*.

Nontreponemal tests generally become positive 4–6 weeks after infection or 1–3 weeks after the appearance of a primary lesion; they are almost always positive in the secondary stage.

(1) False-positive nontreponemal tests—False-positive serologic reactions are encountered in many conditions, including infection with non–sexually transmitted treponematoses, autoimmune diseases, infectious mononucleosis, malaria, febrile diseases, leprosy, injection drug use, infective endocarditis, advanced age, and hepatitis C infection, and with the use of COVID-19 mRNA vaccines. False-positive nontreponemal tests are usually of low titer and may be distinguished from true-positive results by correlating with clinical findings and performing a treponemal-specific antibody test.

(2) False-negative nontreponemal tests—False-negative results can occur in very early infection or paradoxically, when high antibody titers are present ("prozone phenomenon"). If syphilis is strongly suspected and the nontreponemal test is negative, the laboratory should be instructed to dilute the specimen to detect a positive reaction.

Nontreponemal antibody titers are used to monitor the response to therapy and should decline over time. When these tests are used to follow disease activity, the same testing method should be used, preferably at the same laboratory. The rate of decline depends on various factors. In general, persons with repeat infections, higher initial titers, more advanced stages of disease, or uncontrolled HIV infection at the time of treatment have a slower seroconversion rate and are more likely to remain serofast (ie, titers decline but do not become nonreactive).

B. Treponemal antibody tests—These tests measure antibodies that react with *T pallidum* antigens. The *T pallidum* particle agglutination (TPPA) test and the fluorescent treponemal antibody absorption test (FTA-ABS) are two of the most commonly used treponemal tests. Other treponemal tests include the enzyme immunoassay (EIA) and chemiluminescence immunoassay (CIA).

In the traditional screening algorithm, the treponemal tests are used to confirm a positive nontreponemal test. Because of their sensitivity, particularly in the late stages of the disease, treponemal tests are also of value when there is clinical evidence of syphilis, but the nontreponemal serologic test for syphilis is negative. Treponemal tests are reactive in many patients with primary syphilis and in almost all patients with secondary syphilis (Table 39–2). Although a reactive treponemal-specific serologic test remains reactive throughout a patient's life in most cases, it may (like nontreponemal antibody tests) revert to negative with adequate therapy. Final decisions about the significance of the results of serologic tests for syphilis must be based on a clinical appraisal and may require expert consultation. The CDC provides consultation services through the STD Clinical Consultation Network (https://stdccn.org).

C. Enzyme immunoassay (EIA)- or chemiluminescence immunoassay (CIA)-based screening algorithms—Newer screening algorithms reverse the traditional test order and begin with an automated treponemal antibody test (eg, EIA or CIA) followed by a nontreponemal test (RPR or VDRL) if the treponemal test is positive. This is faster and decreases labor costs to laboratories when compared with traditional screening. The EIA and CIA tests generally have high sensitivity and specificity (95–100%), though lower specificity has been reported in some studies.

The reverse algorithms can cause challenges in clinical management. A positive treponemal test with a negative RPR or VDRL may represent prior treated syphilis, untreated latent syphilis, or a false-positive treponemal test. Such results should be evaluated with a second, different treponemal test as a "tiebreaker." Both traditional and reverse algorithms are recognized by the CDC and several international organizations including the International Union Against Sexually Transmitted Infections.

D. Rapid treponemal tests—Both a treponemal and a dual HIV/treponemal rapid point of care test are approved for use in the United States. Numerous other tests are available internationally and are commonly used in limited-resource settings. Sensitivity ranges widely from 60% to 100% in most published studies, with specificity typically ranging from 90% to 100% when using combined RPR and VDRL plus a treponemal test as the reference standard.

3. PCR—In the United States, there are no commercially available, FDA-approved *T pallidum* PCR test kits. However, kits are available as a laboratory-developed test in selected research, referral, and public health laboratories and have the highest yield in primary and secondary lesions. There are no standards for these tests, but PCR has many advantages as a tool for direct detection, including high sensitivity and ability to use a wide range of clinical specimen types, including CSF. PCR testing of blood has low sensitivity and is not recommended.

4. CSF examination—See Neurosyphilis, below.

Differential Diagnosis

The syphilitic chancre may be confused with genital herpes, chancroid (usually painful and uncommon in the United States), lymphogranuloma venereum, or neoplasm. Simultaneous evaluation for herpes simplex virus types 1 and 2 using PCR or culture should also be done in these cases.

Prevention & Screening

Avoidance of sexual contact is the only completely reliable method of prevention but is an impractical public health measure. Latex or polyurethane condoms are effective only if all infectious lesions are covered. MSM should be screened every 6–12 months, and as often as every 3 months for those who have multiple partners, those on HIV PrEP, or those who have sex in conjunction with the use of drugs. Because of epidemic increases in congenital syphilis, the CDC recommends universal screening among 15- to 44-year-olds in counties with high syphilis morbidity among women of reproductive age (> 4.6 cases per 100,000). The American College of Obstetrics and Gynecology recommends screening three times during pregnancy: at the first prenatal visit, during the third trimester, and at delivery. Additional screening can be considered based on risk factors: new partner(s), history of incarceration, transactional sex work, illicit drug use, or history of STIs. Patients treated for other STIs should also be tested for syphilis, and persons who have known or suspected sexual contact with patients who have syphilis should be evaluated and presumptively treated to abort development of infectious syphilis (see Treating Syphilis Contacts, below).

Treatment

A. Antibiotic Therapy

Penicillin remains the preferred treatment for syphilis, since there have been no documented cases of penicillin-resistant *T pallidum* (Table 39–3). In pregnancy, penicillin is the only option that reliably treats the fetus.

The most commonly used alternatives to penicillin for nonpregnant patients include doxycycline and ceftriaxone (although optimum dose and duration for ceftriaxone are not well defined). Azithromycin is effective in some parts of the world but should be used with caution; it should not be used at all in MSM due to demonstrated resistance. All patients treated with a non-penicillin regimen must have close clinical and serologic follow-up.

B. Managing Jarisch–Herxheimer Reaction

The Jarisch–Herxheimer reaction, manifested by fever, headache, myalgia, and tachycardia in the hours following treatment, is a cytokine-mediated immunologic reaction to endotoxins released from the killed bacteria. This reaction is most common in early syphilis, particularly secondary syphilis, where it can occur in 66% of cases.

The Jarisch–Herxheimer reaction may be blunted by simultaneous administration of antipyretics, although no proven method of prevention exists. In cases with increased risk of morbidity due to the reaction (including CNS or cardiac involvement and pregnancy), consultation with an infectious disease expert is recommended. Patients should be reminded that the reaction does not signify an allergy to penicillin.

C. Local Measures (Mucocutaneous Lesions)

Local treatment is usually not necessary. No local antiseptics or topical antibiotics should be applied to a lesion until specimens for microscopy have been obtained.

D. Public Health Measures

Counsel patients with infectious syphilis of > 1 year duration to abstain from sexual activity for 7 days after treatment. All cases of syphilis must be reported to the appropriate local public health agency to identify and treat sexual contacts of early cases. In addition, all patients with syphilis who are not known to be living with HIV should have an HIV test at the time of diagnosis. Those with a negative HIV test should be offered HIV preexposure prophylaxis (HIV PrEP) because syphilis is associated with an increased risk of future HIV acquisition.

E. Treating Syphilis Contacts

Patients who have been sexually exposed to infectious syphilis within the preceding 3 months may be infected but seronegative and, thus, should be treated for early syphilis even if serologic tests are negative. Persons exposed > 3 months previously should be treated based on serologic results; however, if patient follow-up is unreliable, empiric therapy is indicated. Sexual contacts of the persons with syphilis should be evaluated for HIV PrEP.

Follow-Up Care

Because treatment failures and reinfection may occur, patients treated for syphilis should be monitored clinically and serologically with nontreponemal titers (RPR or VDRL) at 6 and 12 months. In primary and secondary syphilis, titers are expected to decrease fourfold by 12 months; however, titers in up to 20% of patients may not decrease. Optimal management of these patients is unclear, but at a minimum, close clinical and serologic follow-up is indicated. In patients without HIV, an HIV test should be repeated; a thorough neurologic history and examination should be performed and lumbar puncture considered because unrecognized neurosyphilis can be a cause of treatment failure. If symptoms or signs persist or recur after initial therapy or there is a fourfold or greater

Table 39–3. Recommended treatment for syphilis.[1]

Stage of Syphilis	Treatment	Alternative[2]	Comment
Early syphilis			
Primary, secondary, or early latent	Benzathine penicillin G 2.4 million units intramuscularly once	Doxycycline 100 mg orally twice daily for 14 days or Tetracycline 500 mg orally four times daily for 14 days or Ceftriaxone 1 g intramuscularly or intravenously daily for 10 days[3]	HIV testing is recommended at diagnosis or treatment
Late syphilis			
Late latent or uncertain duration	Benzathine penicillin G 2.4 million units intramuscularly weekly for 3 weeks	Doxycycline 100 mg orally twice daily for 28 days or Tetracycline 500 mg orally four times daily for 28 days	No routine CSF evaluation is needed unless there are neurologic symptoms Obtain an HIV test
Tertiary without neurosyphilis	Benzathine penicillin G 2.4 million units intramuscularly weekly for 3 weeks	Consult with an infectious disease specialist	CSF evaluation and an HIV test are recommended in all patients
Neurosyphilis	Aqueous penicillin G 18–24 million units intravenously daily, given every 3–4 hours or as continuous infusion for 10–14 days[4]	Procaine penicillin, 2.4 million units intramuscularly daily with probenecid 500 mg orally four times daily for 10–14 days or Ceftriaxone 2 g intramuscularly or intravenously daily for 10–14 days	Follow treatment with benzathine penicillin G 2.4 million units intramuscularly weekly for 1–3 weeks Obtain an HIV test

[1] Penicillin is the only documented effective treatment in pregnancy; pregnant patients with true allergy should be desensitized and treated with penicillin according to stage of disease as above.
[2] Patients treated with alternative therapies require close clinical and serologic monitoring.
[3] Fewer data for ceftriaxone treatment; optimal dose or duration not known.
[4] Because the 10- to 14-day treatment course for neurosyphilis is less than the 21 days recommended for treatment of late syphilis, CDC guidelines state that clinicians may consider giving an additional 2.4 million units of benzathine penicillin G intramuscularly once weekly for 1–3 weeks at the conclusion of the intravenous treatment.

increase in nontreponemal titers, the patient has reinfection (more likely) or the therapy failed (if a non-penicillin regimen was used). In those individuals, an HIV test should be performed, a lumbar puncture done (unless reinfection is a certainty), and re-treatment given as indicated above.

Papp JR, Park IU et al. CDC laboratory recommendations for syphilis testing, United States, 2024. MMWR Recomm Rep 2024;73:1. [PMID: 38319847]

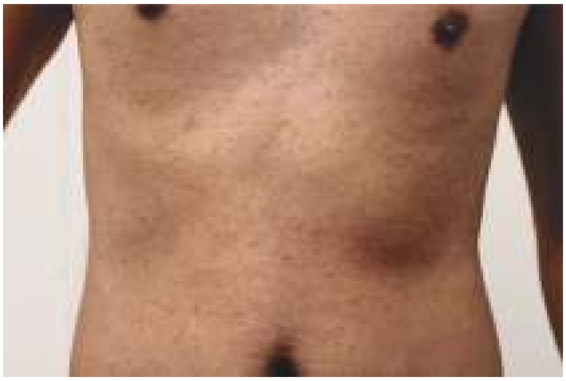
2. Secondary Syphilis

ESSENTIALS OF DIAGNOSIS

- Generalized maculopapular rash; condylomata lata may appear in moist anogenital skin.
- Mucous membrane lesions (eg, white patches in oral cavity).
- Generalized nontender lymphadenopathy.
- Fever may be present.
- Meningitis, hepatitis, osteitis, arthritis, iritis.
- Many treponemes in moist lesions by immunofluorescence or darkfield microscopy.
- Positive serologic tests for syphilis.

Clinical Findings

The secondary stage of syphilis usually appears a few weeks (or up to 6 months) after development of the chancre, when dissemination of *T pallidum* produces systemic signs (fever, lymphadenopathy) or infectious lesions at sites distant from the site of inoculation. The most common manifestations are skin and mucosal lesions. The skin lesions are nonpruritic, macular, papular, pustular, or follicular (or combinations of any of these types, but generally *not* vesicular) and generalized (Figure 39–2) (Figure 39–3); involvement of the palms and soles occurs in 80% of cases. Annular lesions simulating ringworm may be observed. Transillumination may help identify faint rashes, or rashes

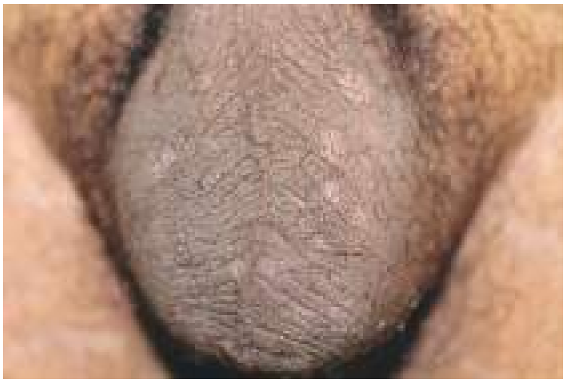


▲ **Figure 39–2. Maculopapular rash on torso from secondary syphilis.** Used with permission from Christopher Ried, MD, Orange County Public Health.

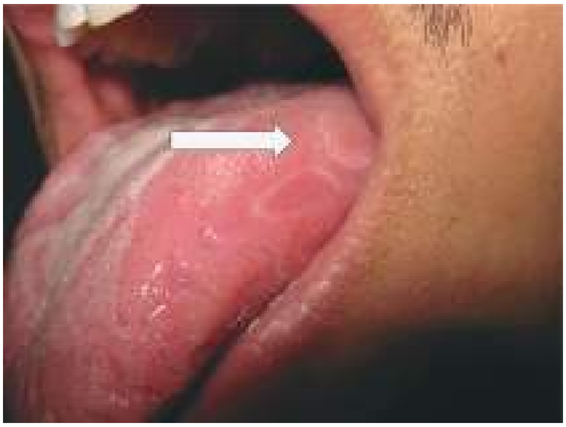
in persons with darker skin color. Mucous membrane lesions may include mucous patches (Figure 39–4), which can be found on the lips, mouth, throat, genitalia, and anus. Condylomata lata, which are fused, weeping papules on the moist skin areas and mucous membranes, are sometimes mistaken for genital warts (Figure 39–5) Unlike the dry rashes, the mucous membrane lesions are highly infectious.

Meningeal (aseptic meningitis or acute basilar meningitis), hepatic, renal, bone, and joint invasion may occur, with resulting cranial nerve palsies, jaundice, nephrotic syndrome, and periostitis. Alopecia (moth-eaten appearance) (Figure 39–6) and uveitis also may occur.

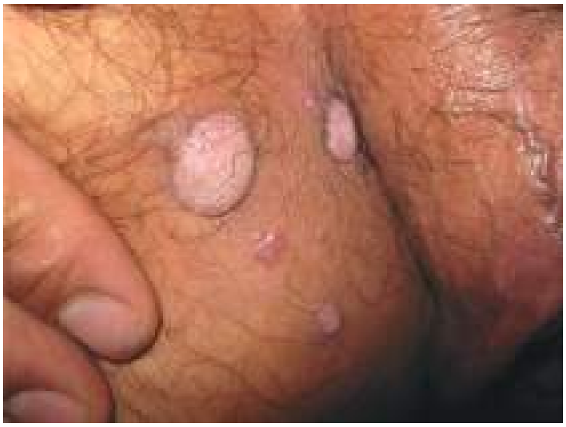
Serologic tests for syphilis are almost always positive (see Primary Syphilis, below, and Table 39–2). The moist cutaneous and mucous membrane lesions often show *T pallidum* on darkfield microscopic examination. A transient CSF lymphocytic pleocytosis (cell count usually $< 50–100$/mcL [$0.05–0.1 \times 10^9$/L]) is seen in 40% of patients with secondary syphilis. There may be evidence of hepatitis or immune complex nephritis as circulating immune complexes are deposited in blood vessel walls.



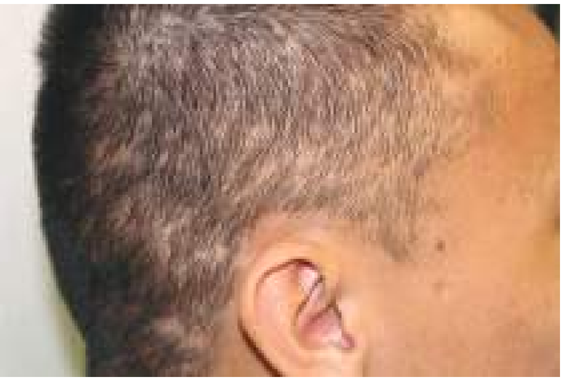
▲ **Figure 39–3. Scrotal rash from secondary syphilis.** Used with permission from Christopher Ried, MD, Orange County Public Health.



▲ **Figure 39–4. Mucous patches on the tongue from secondary syphilis.** Used with permission from Christopher Ried, MD, Orange County Public Health.



▲ **Figure 39–5. Condyloma lata from secondary syphilis.** Used with permission from Christopher Ried, MD, Orange County Public Health.



▲ **Figure 39–6. Patchy alopecia from secondary syphilis.** Used with permission from Christopher Ried, MD, Orange County Public Health.

Skin lesions may be confused with the infectious exanthems, pityriasis rosea, and drug eruptions. Visceral lesions may suggest nephritis or hepatitis due to other causes.

Treatment

Treatment is as for primary syphilis unless CNS or ocular disease or neurologic signs or symptoms are present, in which case a lumbar puncture should be performed. If examination of the fluid is positive (see Spinal fluid examination for Neurosyphilis, below), treatment for neurosyphilis should be given (Table 39–3). See Primary Syphilis, above, for follow-up care and treatment of contacts.

3. Latent Syphilis

ESSENTIALS OF DIAGNOSIS

- **Early latent syphilis:** infection ≤ 1 year.
- **Late latent syphilis:** infection > 1 year.
- No physical signs.
- May have history of syphilis with inadequate treatment.
- Positive serologic tests for syphilis.

General Considerations

Latent syphilis is the clinically quiescent phase in the absence of lesions; the diagnosis is made by positive serologic tests.

1. Early latent syphilis—Defined as the first year after primary infection, early latent syphilis may relapse to secondary syphilis if undiagnosed or inadequately treated. Relapse is almost always accompanied by a rising titer in quantitative serologic tests; indeed, a rising titer may be the first or only evidence of relapse. About 90% of relapses occur during the first year after infection. Early latent infection can be diagnosed if there was documented seroconversion or a fourfold increase in nontreponemal titers in the past 12 months; the patient can recall symptoms of primary or secondary syphilis; or the patient had a sex partner with documented primary, secondary, or early latent syphilis.

2. Late latent stage—After the first year of latent syphilis, the patient is said to be in the late latent stage and noninfectious to sex partners. Transplacental transmission to a fetus, however, is possible in any phase. A diagnosis of late latent syphilis is justified only when the history and physical examination show no evidence of tertiary disease or neurosyphilis. The latent stage may last from months to decades.

Treatment

Treatment of early latent syphilis and follow-up are the same as for primary syphilis unless CNS disease is present (Table 39–3). Treatment of late latent syphilis is intended to prevent late sequelae (Table 39–3). If there is evidence of CNS involvement, a lumbar puncture should be performed and, if positive, the patient should receive treatment for neurosyphilis (see Spinal fluid examination for Neurosyphilis, below). Titers may not decline as rapidly following treatment compared to early syphilis. Nontreponemal serologic tests should be repeated at 6, 12, and 24 months. If titers increase fourfold or if initially high titers (1:32 or higher) fail to decrease fourfold by 24 months or if symptoms or signs consistent with syphilis develop, an HIV test should be repeated in patients not known to have HIV, lumbar puncture should be performed, and re-treatment given according to the stage of the disease.

4. Tertiary (Late Symptomatic) Syphilis

ESSENTIALS OF DIAGNOSIS

- Infiltrative tumors of skin, bones, liver (gummas).
- Aortitis, aortic aneurysms, aortic regurgitation.
- CNS disorders: meningovascular and degenerative changes, paresthesias, shooting pains, abnormal reflexes, dementia, or psychosis.

General Considerations

This stage may occur at any time after secondary syphilis, even after years of latency, and is rarely seen in developed countries in the modern antibiotic era. Late lesions are thought to represent an immunologic reaction to the organism and are usually divided into two types: (1) a localized hyperproliferative gummatous reaction with a relatively rapid onset and generally prompt response to therapy and (2) diffuse inflammation of a more insidious onset that characteristically involves the CNS and large arteries, may not improve despite treatment, and is often fatal if untreated. Gummas may involve any area or organ of the body but most often affect the skin or long bones. CVD is usually manifested by aortic aneurysm, aortic regurgitation, or aortitis. Various forms of diffuse or localized CNS involvement may occur.

Late syphilis must be differentiated from neoplasms of the skin, liver, lung, stomach, or brain; other forms of meningitis; and primary neurologic lesions.

Although almost any tissue and organ may be involved in late syphilis, the following are the most common sites of involvement: skin, mucous membranes, skeletal system, eyes, respiratory system, GI system, cardiovascular system, and nervous system.

Clinical Findings

A. Symptoms and Signs

1. Skin—Cutaneous lesions of late syphilis are of two varieties: (1) multiple nodular lesions that eventually ulcerate (lues maligna) or resolve by forming atrophic, pigmented scars; and (2) solitary gummas that start as painless subcutaneous nodules, then enlarge, attach to the overlying skin, and eventually ulcerate.

2. Mucous membranes—Late lesions of the mucous membranes are nodular gummas or leukoplakia, highly destructive to the involved tissue.

3. Skeletal system—Bone lesions are destructive, causing periostitis, osteitis, and arthritis with little or no associated redness or swelling but often marked myalgia and myositis of the neighboring muscles.

4. Eyes—Late ocular lesions are gummatous iritis, chorioretinitis, optic atrophy, and cranial nerve palsies, in addition to the lesions of CNS syphilis.

5. Respiratory system—Respiratory involvement is caused by gummatous infiltrates into the larynx, trachea, and pulmonary parenchyma, producing discrete pulmonary densities. There may be hoarseness, respiratory distress, and wheezing secondary to the gummatous lesion itself or to subsequent stenosis occurring with healing.

6. GI system—Gummas involving the liver may be benign but can cause cirrhosis. Gastric involvement can consist of diffuse infiltration into the stomach wall or focal lesions that endoscopically and microscopically can be confused with lymphoma or carcinoma. Epigastric pain, early satiety, regurgitation, belching, and weight loss are common symptoms.

7. Cardiovascular system—Cardiovascular lesions (10–15% of tertiary syphilitic lesions) are often progressive, disabling, and life-threatening. CNS lesions are often present concomitantly. Involvement usually starts as an arteritis in the supracardiac portion of the aorta and progresses to one or more of the following: (1) narrowing of the coronary ostia, with resulting decreased coronary circulation, angina, and acute MI; (2) scarring of the aortic valves, producing aortic regurgitation, and eventually HF; and (3) weakness of the wall of the aorta, with saccular aneurysm formation and associated pressure symptoms of dysphagia, hoarseness, brassy cough, back pain (vertebral erosion), and occasionally rupture of the aneurysm. Recurrent respiratory infections are common as a result of pressure on the trachea and bronchi.

8. Nervous system (neurosyphilis)—See next section.

Treatment

Treatment of tertiary syphilis (excluding neurosyphilis) is the same as late latent syphilis (Table 39–3); symptoms may not resolve after treatment. Positive serologic tests do not usually become negative.

The pretreatment clinical and laboratory evaluation should include neurologic, ocular, cardiovascular, psychiatric, and CSF examinations. *In the presence of definite CSF or neurologic abnormalities, treat for neurosyphilis.*

5. Neurosyphilis

ESSENTIALS OF DIAGNOSIS

- Can occur at any stage of disease.
- Consider both clinical presentation and laboratory data.
- Perform neurologic examination on all patients; consider CSF evaluation for atypical symptoms or lack of decrease in nontreponemal serology titers.

General Considerations

Neurosyphilis can occur at any stage of disease and can be a progressive, disabling, and life-threatening complication. Asymptomatic CSF abnormalities and meningovascular syphilis occur earlier (months to years after infection, sometimes coexisting with primary and secondary syphilis) than tabes dorsalis and general paresis (2–50 years after infection).

Clinical Findings

A. Classification

1. Asymptomatic neuroinvasion—This form has been reported in up to 40% of patients with early syphilis and is characterized by spinal fluid abnormalities (positive CSF serology [VDRL], lymphocytic pleocytosis, occasionally increased protein) without symptoms or signs of neurologic involvement. There are no clear data to support that these asymptomatic CSF abnormalities have clinical significance.

2. Meningovascular syphilis—This form is characterized by meningeal involvement or changes in the vascular structures of the brain (or both), producing symptoms of acute or chronic meningitis (headache, irritability); cranial nerve palsies (basilar meningitis); unequal reflexes; irregular pupils with poor light and accommodation reflexes; and when large vessels are involved, cerebrovascular accidents. The CSF shows lymphocytic pleocytosis (cell count of 100–1000/mcL [$0.1–1.0 \times 10^9$/L]) and elevated protein and may have a positive serology (CSF VDRL). The symptoms of acute meningitis are rare in late syphilis.

3. Ocular syphilis and otosyphilis—Changes in vision or hearing may occur with or without meningitis. In cases of isolated ocular symptoms or signs (without cranial nerve deficits or other neurologic symptoms), CSF examination is not necessary before treatment. In cases of isolated auditory symptoms, the CDC recommends against performing CSF examination before treatment as CSF is likely to be normal. Patients with ocular or otic syphilis should be treated with the same regimen as for neurosyphilis.

4. Tabes dorsalis—This is a chronic progressive degeneration of the parenchyma of the posterior columns of the spinal cord and of the posterior sensory ganglia and nerve roots. The symptoms and signs are impairment of proprioception and vibration sense, Argyll Robertson pupils (which react poorly to light but accommodate for near focus), and muscular hypotonia and hyporeflexia. Impaired proprioception results in a wide-based gait and inability to walk in the dark. Paresthesias, analgesia, or sharp recurrent pains in the muscles of the leg ("shooting" or "lightning" pains) may occur. Joint damage may occur because of lack of sensory innervation (Charcot joint). The CSF may have a normal or increased lymphocytic cell count, elevated protein, and variable results of serologic tests.

5. General paresis—This is generalized involvement of the cerebral cortex with insidious onset of symptoms. There is usually a decrease in concentrating power, memory loss, dysarthria, tremor of the fingers and lips, irritability, and mild headaches. Most striking is the change of personality; the patient may become slovenly, irresponsible, confused, and psychotic. The CSF findings resemble those of tabes dorsalis. Combinations of the various forms of neurosyphilis (especially tabes and paresis) are not uncommon.

B. Laboratory Findings

See Serologic Tests for Syphilis, above, and Table 39–2; these tests should also be performed in cases of suspected neurosyphilis.

1. Indications for a lumbar puncture—In early syphilis (primary and secondary syphilis and early latent syphilis), invasion of the CNS by *T pallidum* with CSF abnormalities occurs commonly, but clinical neurosyphilis rarely develops in patients who have received standard therapy. Thus, unless clinical symptoms or signs of neurosyphilis or ocular involvement (uveitis, neuroretinitis, optic neuritis, iritis) are present, a lumbar puncture is not routinely recommended. CSF evaluation is recommended, however, if neurologic or ophthalmologic symptoms or signs are present, if there is evidence of treatment failure (see earlier discussion), or if there is evidence of active tertiary syphilis (eg, aortitis, iritis, optic atrophy, the presence of a gumma).

2. Spinal fluid examination—CSF findings in neurosyphilis are variable. In "classic" cases, there is an elevation of total protein above 46 mg/dL, lymphocytic pleocytosis with a cell count of 5–100/mcL (0.005–0.1 × 10^9/L), and a positive CSF nontreponemal test. VDRL is more sensitive and preferred over RPR. The serum nontreponemal titers will be reactive in most cases. Because the CSF VDRL may be negative in 30–70% of cases of neurosyphilis, *a negative test does not exclude neurosyphilis*, while a positive test confirms the diagnosis. The CSF FTA-ABS is sometimes used; it is a highly sensitive test but lacks specificity. A negative FTA-ABS can help rule out a diagnosis of neurosyphilis.

▶ Treatment

Neurosyphilis is treated with high doses of aqueous penicillin to achieve better penetration and higher drug levels in the CSF than is possible with benzathine penicillin G (Table 39–3). There are some observational data that support using ceftriaxone (with close follow-up) to treat neurosyphilis, but in some cases, patients with a history of an IgE-mediated reaction to penicillin may require skin testing for allergy to penicillin and, if positive, should be desensitized.

All patients treated for neurosyphilis should have nontreponemal serologic tests done every 3–6 months. CDC guidelines recommend that for patients with HIV who are taking antiretroviral therapy and those without HIV, clinical response and serum nontreponemal titers can be followed in lieu of repeated CSF examinations. If symptoms persist or titers do not normalize, consider repeating the CSF analysis; expert consultation may be helpful in this scenario.

6. Syphilis in Patients with HIV

Syphilis is common among individuals with HIV. Some data suggest that syphilis coinfection is associated with an increase in HIV viral load and a decrease in CD4 count that normalizes with therapy; other studies have not found an association with HIV disease progression. For optimal patient care as well as prevention of transmission to partners, guidelines for the primary care of patients with HIV recommend syphilis screening at least annually.

Interpretation of serologic tests should be the same for persons with or without HIV. If the diagnosis of syphilis is suspected on clinical grounds but nontreponemal antibody tests are negative, consider the prozone effect caused by high titers (see Nontreponemal Antibody Tests, above), or try direct examination of primary or secondary lesions for spirochetes.

Patients with HIV and with primary and secondary syphilis should have careful clinical and serologic follow-up at 3-month intervals. The use of antiretroviral therapy has been associated with reduced serologic failure rates after syphilis treatment.

The diagnosis of neurosyphilis in patients with HIV is complicated because mild CSF abnormalities may be found in HIV infection alone. Evaluate patients for visual and hearing changes, since ocular and auditory syphilis may not result in CSF abnormalities. As in patients without HIV, routine lumbar puncture is not recommended in asymptomatic patients; it should be reserved for cases in which neurologic symptoms or signs are present or there is concern for treatment failure. Following treatment, CSF WBC counts should normalize within 12 months regardless of HIV status, while the CSF VDRL may take longer. As discussed above, the same criteria for failure apply to patients with and without HIV, and re-treatment regimens are the same.

For all stages and sites of syphilitic infection, treatment does not differ by HIV infection status.

7. Syphilis in Pregnancy

All pregnant persons should have a nontreponemal serologic test for syphilis at the time of the first prenatal visit (see Chapter 22). The American College of Obstetrics and Gynecology recommends screening three times during pregnancy: at the first prenatal visit, during the third trimester (eg, 28 weeks), and at delivery. The serologic status of mother and infant should be confirmed before discharge from the hospital. Patients who are seropositive should be considered infected and should be treated unless adequate prior treatment and serologic response are documented.

The only recommended treatment for syphilis in pregnancy is penicillin in dosage schedules appropriate for the stage of disease (Table 39–3). Penicillin prevents congenital syphilis in 90% of cases, even when treatment is given late in pregnancy. Patients with a history of penicillin allergy should be skin tested and desensitized if necessary. *Tetracycline and doxycycline are not recommended in pregnancy.*

The infant should be evaluated immediately at birth, and, depending on the likelihood of infection, monitored for clinical and serologic manifestations in the first year of life.

8. Congenital Syphilis

Prevention of Syphilis

A study of doxycycline postexposure prophylaxis (PEP) for bacterial STIs among MSM in France resulted in a 73% reduction in syphilis and 70% reduction in chlamydia. A subsequent trial among MSM and transgender women in Seattle and San Francisco demonstrated a 77–87% reduction in syphilis, a 74–88% reduction in chlamydia, and a 55–57% reduction in gonorrhea. The CDC released guidelines for the use of doxycycline as PEP in 2024 (https://www.cdc.gov/mmwr/volumes/73/rr/rr7302a1.htm).

When to Refer

- Consultation with the local public health department may help obtain all prior positive syphilis serologic results and may be helpful in complicated or atypical cases.
- Early (infectious) syphilis cases may be contacted for partner notification and treatment by local public health authorities.

When to Admit

- Pregnant women with syphilis and true penicillin allergy should be admitted for desensitization and treatment.
- Women in late pregnancy treated for early syphilis should have close outpatient monitoring or be admitted because the Jarisch–Herxheimer reaction can induce premature labor.
- Patients with neurosyphilis usually require admission for treatment with aqueous penicillin.

Bachmann LH et al. CDC clinical guidelines on the use of doxycycline postexposure prophylaxis for bacterial sexually transmitted infection prevention, United States, 2024. MMWR Recomm Rep. 2024;73:1. [PMID: 38833414]

SELECTED SPIROCHETAL DISEASES

RELAPSING FEVER

The infectious organisms in relapsing fever are spirochetes of the genus *Borrelia*. The infection has two forms: tick-borne and louse-borne.

A. Tick-Borne Relapsing Fever

Rodents serve as the main reservoir of infection for ticks. Tick-borne relapsing fever may also be transmitted transovarially from one generation of ticks to the next. Humans can be infected by tick bites or by rubbing crushed tick tissues or feces into the bite wound. Tick-borne relapsing fever is endemic but is not transmitted from person to person. In the United States, infected ticks are found throughout the western states, but clinical cases are uncommon in humans.

B. Louse-Borne Relapsing Fever

The louse-borne form is primarily seen in the developing world, and humans are the only reservoir. Large epidemics may occur in louse-infested populations, and transmission is favored by crowding, malnutrition, and cold climate.

Clinical Findings

A. Symptoms and Signs

For both tick-borne and louse-borne relapsing fever, an abrupt onset of fever, chills, tachycardia, nausea and vomiting, arthralgia, and severe headache may occur as soon as 3 days after infection. A large analysis of US surveillance data found the most common symptoms of tick-borne disease were fever (89%), fatigue (75%), headache (72%), chills (68%), and arthralgia (55%). In both tick-borne and louse-borne relapsing fever, hepatomegaly and splenomegaly may develop, as well as various types of rashes (macular, papular, petechial) that usually occur at the end of a febrile episode. Delirium occurs with high fever, and there may be various neurologic and psychological abnormalities. The attack terminates, usually abruptly, after 3–10 days. After an interval of 1–2 weeks, relapse occurs, but often it is somewhat milder. Before recovery in tick-borne disease, 3–10 relapses may occur; louse-borne disease is associated with only 1 or 2 relapses.

B. Laboratory Findings

During episodes of fever, large spirochetes are seen in thick and thin blood smears stained with Wright or Giemsa stain. The organisms can be cultured in special media but rapidly lose pathogenicity. The spirochetes can multiply in injected rats or mice and can be seen in their blood.

A variety of anti-*Borrelia* antibodies develop during the illness; sometimes the Weil–Felix test for rickettsioses and nontreponemal serologic tests for syphilis may be falsely positive. Infection can cause false-positive indirect fluorescent antibody and Western blot tests for *Borrelia burgdorferi*, causing some cases to be misdiagnosed as Lyme disease. PCR assays can be performed on blood, CSF, and tissue but are not always available in endemic regions. CSF abnormalities occur in patients with meningeal involvement. Mild anemia and thrombocytopenia are common. Leukopenia is less common and reported in 37% of patients with tick-borne relapsing fever.

Differential Diagnosis

The manifestations of relapsing fever may be confused with malaria, leptospirosis, meningococcemia, yellow fever, typhus, or rat-bite fever.

Prevention

Prevention of tick bites (as described for rickettsial diseases) and delousing procedures applicable to large groups can prevent illness. There are no vaccines for relapsing fever.

Postexposure prophylaxis with doxycycline 200 mg orally on day 1 and 100 mg daily for 4 days has been shown to prevent relapsing fever following tick bites in highly endemic areas.

Treatment

A. Tick-Borne Relapsing Fever

Treatment begins with penicillin G, 3 million units intravenously every 4 hours, or ceftriaxone, 1 g intravenously daily; with clinical improvement, a 10-day course can be completed with 0.5 g of tetracycline or erythromycin given orally four times daily. If CNS invasion is suspected, intravenous penicillin G or ceftriaxone should be continued for 10–14 days. Jarisch–Herxheimer reactions occur commonly following treatment and may be life-threatening, so patients should be closely monitored (see Syphilis, above). In louse-borne relapsing fever, administration of anti-TNF antibodies prior to antibiotic therapy can be effective in preventing the reaction. All pregnant women with tick-borne disease should be treated for 14 days, ideally with intravenous penicillin or ceftriaxone.

B. Louse-Borne Relapsing Fevers

A single dose of tetracycline or erythromycin, 0.5 g orally, or a single dose of procaine penicillin G, 600,000–800,000 units intramuscularly likely constitutes adequate treatment for this infection; however, some experts advocate for longer courses of treatment to prevent persistent infection.

Prognosis

The mortality rate without treatment ranges from 5% to as high as 50–70%. Fatalities are most common in older, debilitated, or very young patients. Treatment shortens the initial attack and often prevents relapses. The Jarisch–Herxheimer reaction is more common in louse-borne relapsing fever (55.8%) compared with tick-borne relapsing fever (19.3%).

Jakab Á et al. Tick borne relapsing fever: a systematic review and analysis of the literature. PLoS Negl Trop Dis. 2022;16:e0010212. [PMID: 35171908]

RAT-BITE FEVER

Rat-bite fever is an uncommon acute infectious disease caused by the treponeme *Spirillum minus* (Asia) or the bacteria *Streptobacillus notomytis* (Asia) or *Streptobacillus moniliformis* (North America). Because this disease is transmitted to humans from rat bites and from ingesting rat feces, inhabitants of rat-infested dwellings, owners of pet rats, and laboratory workers are at greatest risk.

Clinical Findings

A. Symptoms and Signs

In *Spirillum* infections, the original rat bite, unless secondarily infected, heals promptly. However, one to several weeks later, the site becomes swollen, indurated, and painful; it assumes a dusky purplish hue and may ulcerate. Regional lymphangitis and lymphadenitis, fever, chills, malaise, myalgia, arthralgia, and headache are present. Splenomegaly may occur. A sparse, dusky-red maculopapular rash appears on the trunk and extremities in many cases, and there may be frank arthritis.

After a few days, both the local and systemic symptoms subside, only to reappear several days later. This relapsing pattern of fever for 3–4 days alternating with afebrile periods lasting 3–9 days may persist for weeks. The other features, however, usually recur only during the first few relapses.

S moniliformis infections have similar clinical features as *Spirillum* infections but have a shorter incubation period of up to 7 days and a diffuse rash. Endocarditis, osteomyelitis, meningitis, and sepsis are rare complications.

B. Laboratory Findings

Leukocytosis is often present, and the nontreponemal test for syphilis (eg, RPR) is often falsely positive. *S minus* may be identified in darkfield examination of the ulcer exudate or aspirated lymph node material. *S minus* has not been cultured in artificial media.

Differential Diagnosis

Clinically, the severe arthritis and myalgias seen in streptobacillary disease are rarely seen in disease caused by *S minus*. Reliable differentiation requires an increasing titer of agglutinins against *S moniliformis* or isolation of the causative organism. Other diseases in the differential include tularemia, rickettsial disease, *Pasteurella multocida* infections, and relapsing fever.

Treatment

In acute illness in adults, intravenous penicillin, 1–2 million units every 4–6 hours, is given initially; ceftriaxone 1 g intravenously daily is another option; higher doses are used for rare severe complications including endocarditis. Once improvement has occurred, therapy may be switched to oral penicillin V 500 mg four times daily, or amoxicillin 500 mg three times daily, to complete 10–14 days of therapy. For the penicillin-allergic patient, tetracycline 500 mg orally four times daily or doxycycline 100 mg twice a day can be used.

Prognosis

The reported mortality rate of about 10% should be markedly reduced by prompt diagnosis and antimicrobial treatment.

LEPTOSPIROSIS

ESSENTIALS OF DIAGNOSIS

- Clinical illness can vary from asymptomatic to fatal liver and kidney failure.
- **Anicteric leptospirosis:** more common and milder form of the disease.
- **Icteric leptospirosis (Weil syndrome):** impaired kidney and liver function, abnormal mental status, hemorrhagic pneumonia; 5–40% mortality rate.

General Considerations

Leptospirosis is an acute and sometimes severe treponemal infection that is caused by several species within the genus *Leptospira.* This worldwide disease is among the most common zoonotic infections. The leptospires enter through minor skin lesions and probably via the conjunctiva. Cases have occurred in international travelers after swimming or rafting in contaminated water, and occupational cases occur among sewer workers, rice planters, abattoir workers, and farmers. Sporadic urban cases have been seen in unhoused persons exposed to rat urine.

Clinical Findings

A. Symptoms and Signs

1. Anicteric leptospirosis—The more common and milder form of the disease, anicteric leptospirosis is often biphasic. After an incubation period of 2–20 days, the initial or acute phase begins with abrupt fever to 39–40°C, chills, abdominal pain, severe headache, and myalgias, especially of the calf muscles. There may be marked conjunctival suffusion. Leptospires can be isolated from blood, CSF, and tissues. Following a 1- to 3-day period of improvement in symptoms and absence of fever, the second or "immune" phase begins; however, in severe disease the phases may appear indistinct. Leptospires are absent from blood and CSF but are still present in the kidney, and specific antibodies appear. Aseptic meningitis often occurs; uveitis, rash, nausea, vomiting, diarrhea, and adenopathy may also occur. A rare but severe manifestation is hemorrhagic pneumonia. The illness is usually self-limited, lasting 4–30 days, and complete recovery is the rule.

2. Icteric leptospirosis (Weil syndrome)—The more severe form of the disease, icteric leptospirosis is characterized by fever, impaired kidney and liver function including jaundice, abnormal mental status, hemorrhagic pneumonia, hypotension, and a 5–40% mortality rate. Symptoms and signs often are continuous and not biphasic.

Leptospirosis with jaundice must be distinguished from hepatitis, yellow fever, rickettsial disease, and relapsing fever.

B. Laboratory Findings

1. Nonicteric leptospirosis—The leukocyte count may be normal, low, or high with neutrophils predominating. The urine may contain bile, protein, casts, and red cells. Oliguria is common, and in severe cases uremia may occur. In acute infection, leptospires can be identified by nucleic acid amplification tests (NAATs) or by culture. Blood cultures are most often positive within the first week if obtained before antibiotics are given. Aseptic meningitis in the immune phase is characterized by pleocytosis and elevated protein.

2. Icteric leptospirosis—Features may initially overlap with nonicteric disease. Elevated bilirubin and aminotransferases are seen in 75%, and elevated serum creatinine (> 1.5 mg/dL) (132.6 mcmol/L) is seen in 50% of cases. Serum creatine kinase is usually elevated in persons with leptospirosis and normal in persons with hepatitis. Pulmonary hemorrhage is associated with laboratory findings of disseminated intravascular coagulation; elevated PT, PTT, and D-dimer and low fibrinogen.

3. Both icteric and nonicteric leptospirosis—In both types of disease, diagnosis is usually made by serologic tests, including the microscopic agglutination test and ELISA. PCR molecular diagnostics appear to be sensitive, specific, positive early in disease, and able to detect leptospiral DNA in blood, urine, CSF, and aqueous humor.

Complications

Myocarditis, aseptic meningitis, AKI, and pulmonary infiltrates with hemorrhage are not common but are the usual causes of death. Iridocyclitis may occur.

Prevention

The mainstay of prevention is avoidance of potentially contaminated food and water.

A 2024 meta-analysis did not find that pre- or postexposure prophylaxis reduced infection or all-cause mortality.

Prophylaxis with doxycycline (200 mg orally once a week) can be considered if a person is at high risk due to being in an area or season (eg, monsoon flooding) when exposure would be more likely. Human vaccine is used in some limited settings but is not widely available.

Treatment

Many cases are self-limited without specific treatment. Although therapy for mild disease is controversial, most clinicians treat for 7 days with doxycycline (100 mg orally twice daily) or amoxicillin (50 mg/kg, divided into three doses daily); azithromycin (500 mg once daily) for 3 days also may be used. For severe disease, treatment options include 7 days of doxycycline (100 mg every 12 hours orally or intravenously), penicillin (eg, 1.5 million units every 6 hours intravenously), cefotaxime (1 g every 6 hours intravenously), or ceftriaxone (1 g daily intravenously). A 2024 meta-analysis did not demonstrate a clear survival benefit for any antibiotic. Jarisch–Herxheimer reactions may occur (see Syphilis, above).

Prognosis

Without jaundice, the disease is almost never fatal. With jaundice, the mortality rate is 5% for those under age 30 years and 40% for those over age 60 years.

When to Admit

Patients with jaundice or other evidence of severe disease should be admitted for close monitoring and may require admission to an ICU.

LYME DISEASE (Lyme Borreliosis)

ESSENTIALS OF DIAGNOSIS

- Erythema migrans: a flat or slightly raised red lesion that expands with central clearing.
- Headache or stiff neck.
- Arthralgias, arthritis, and myalgias; arthritis is often chronic and recurrent.

General Considerations

This illness, named after the town of Old Lyme, Connecticut, is the most common tick-borne disease in the United States and Europe. Most US cases are reported from the mid-Atlantic, northeastern, and north central regions of the country. The true incidence of Lyme disease is not known for several reasons: (1) serologic tests are not standardized (see Laboratory Findings, below); (2) clinical manifestations are nonspecific; and (3) even with reliable testing, serology is insensitive in early disease.

The tick vector of Lyme disease varies geographically and is *Ixodes scapularis* in the northeastern, north central, and mid-Atlantic regions of the United States; *Ixodes pacificus* on the West Coast; *Ixodes ricinus* in Europe; and *Ixodes persulcatus* in Asia. The disease also occurs in Australia. Mice and deer make up the major animal reservoir of *B burgdorferi*, but other rodents and birds may also be infected. Domestic animals such as dogs, cattle, and horses can also develop clinical illness, usually arthritis.

Under experimental conditions, ticks must feed for 24–36 hours or longer to transmit infections. Most cases are reported in the spring and summer months. In addition, the percentage of ticks infected varies on a regional and local basis. The description of exposure is important; a history of brushing a tick off the skin (ie, the tick was not feeding) or removing a tick on the same day as exposure (ie, the tick did not feed long enough) decreases the likelihood that infection will develop.

Because the *Ixodes* tick is so small, the bite is usually painless and goes unnoticed. After feeding, the tick drops off in 2–4 days. If a tick is found, it should be removed immediately. The best way to accomplish this is to use fine-tipped tweezers to pull firmly and repeatedly on the tick's mouth part—not the tick's body—until the tick releases its hold. Saving the tick in a bottle of alcohol for future identification may be useful, especially if symptoms develop.

Clinical Findings

The three stages of Lyme disease are classified based on early or late manifestations of the disease and whether it is localized or disseminated.

A. Symptoms and Signs

1. Stage 1, early localized infection—Stage 1 infection is characterized by erythema migrans (see Figure 6–18). About 1 week after the tick bite (range, 3–30 days; median, 7–10 days), a flat or slightly raised red lesion appears at the bite site, which is commonly seen in areas of tight clothing such as the groin, thigh, or axilla. This lesion expands over several days. Although originally described as a lesion that progresses with central clearing ("bulls-eye" lesion), often there is a more homogeneous appearance or even central intensification. About 10–20% of patients either do not have typical skin lesions or the lesions go unnoticed, which may lead to misdiagnosis. Vesicular, urticarial, and evanescent erythema migrans have all been reported. Most patients with erythema migrans will have a concomitant viral-like illness (the "summer flu") characterized by myalgias, arthralgias, headache, and fatigue. Fever may or may not be present. Even without treatment, the symptoms and signs of erythema migrans resolve in 3–4 weeks.

Completely asymptomatic disease, without erythema migrans or flu-like symptoms, can occur but is uncommon in the United States.

2. Stage 2, early disseminated infection—Up to 50–60% of patients with erythema migrans are bacteremic, and within days to weeks of the original infection, secondary skin lesions develop in about 50% of patients. These lesions are similar in appearance to the primary lesion but are usually smaller. Malaise, fatigue, fever, headache (sometimes severe), neck pain, and generalized achiness are common with the skin lesions. Most symptoms are transient. After hematogenous spread, some patients experience cardiac (4–10% of patients) or neurologic (10–15% of patients) manifestations, including myopericarditis, with atrial or ventricular arrhythmias and heart block. Neurologic manifestations include both the central and peripheral nervous systems. The most common CNS manifestation is aseptic meningitis with mild headache and neck stiffness. The most common peripheral manifestation is a cranial nerve VII neuropathy, ie, facial palsy (usually unilateral but can be bilateral, see Figure 27–1). A sensory or motor radiculopathy and mononeuritis multiplex occur less frequently. Conjunctivitis, keratitis, and, rarely, panophthalmitis can also occur. Rarely, a cutaneous hypopigmented skin lesion called a borrelial lymphocytoma develops.

3. Stage 3, late persistent infection—Stage 3 infection occurs months to years after the initial infection and again primarily manifests itself as musculoskeletal, neurologic, and skin disease. In early reports, musculoskeletal complaints developed in up to 60% of patients, but with early recognition and treatment of disease, this has decreased to < 10%. The classic manifestation of late disease is a monoarticular or oligoarticular arthritis most commonly affecting the knee or other large weight bearing joints. While these joints may be quite swollen, these patients generally report less pain compared to patients with bacterial septic arthritis. Even if untreated, the arthritis is self-limited, resolving in a few weeks to months. Multiple recurrences are common but are usually less severe. Joint fluid reflects an inflammatory arthritis with a mean WBC count of 25,000/mcL (25×10^9/L) with a predominance of neutrophils. Chronic arthritis can develop in about 10% of patients; this pathogenesis may be an immunologic phenomenon rather than persistence of infection.

Rarely, the nervous system (both central and peripheral) can be involved in late Lyme disease. In the United States, a subacute encephalopathy, characterized by memory loss, mood changes, and sleep disturbance, is seen. In Europe, a more severe encephalomyelitis caused by *B garinii* occurs and presents with cognitive dysfunction, spastic paraparesis, ataxia, and bladder dysfunction. Peripheral nervous system involvement includes intermittent paresthesias, often in a stocking glove distribution, or radicular pain.

The cutaneous manifestation of late infection, which can occur up to 10 years after infection, is acrodermatitis chronicum atrophicans. It has been described mainly in Europe after infection with *B afzelii*. There is usually bluish-red discoloration of a distal extremity with associated swelling. These lesions become atrophic and sclerotic with time and eventually resemble localized scleroderma. Cases of diffuse fasciitis with eosinophilia, an entity that resembles scleroderma, have been rarely associated with infection with *B burgdorferi*.

B. Laboratory Findings

The diagnosis of Lyme disease is based on both clinical manifestations and laboratory findings. The US Surveillance Case Definition specifies a person with exposure to a potential tick habitat (within the 30 days prior to developing erythema migrans) with (1) erythema migrans diagnosed by a clinician or (2) at least one late manifestation of the disease and (3) laboratory confirmation as fulfilling the criteria for Lyme disease.

Nonspecific laboratory abnormalities can occur, particularly in early disease. The most common are an elevated ESR of > 20 mm/hour seen in 50% of cases and mildly abnormal liver biochemical tests in 30% of cases (these are usually transient and return to normal within a few weeks of treatment). The CBC is usually normal. Mild anemia, leukocytosis (11,000–18,000/mcL [$11–18 \times 10^9$/L]), and microscopic hematuria have been reported in 10% or less of patients.

Laboratory confirmation requires serologic tests to detect specific antibodies to *B burgdorferi* in serum, preferably by ELISA and not by indirect immunofluorescence assay (IFA), which is less sensitive and specific and can cause misdiagnosis. A two-test approach is recommended for the diagnosis of active Lyme disease, with all specimens positive or equivocal by ELISA then confirmed with either a Western immunoblot assay that can detect both IgM and IgG antibodies or with a different ELISA. A negative Western immunoblot following an initial positive ELISA indicates a false-positive ELISA; the patient does not have evidence of exposure to *B burgdorferi*. A positive immunoblot requires that antibodies are detected against two (for IgM) or five (for IgG) specific protein antigens from *B burgdorferi*.

If a patient with suspected early Lyme disease has negative serologic studies, acute and convalescent titers should be obtained since up to 50% of patients with early disease can be antibody negative in the first several weeks of illness. A fourfold rise in antibody titer would be diagnostic of recent infection. Antibiotic therapy early in disease can abort subsequent seroconversion.

The diagnosis of late nervous system Lyme disease is often difficult since clinical manifestations, such as subtle memory impairment, may be difficult to document. Patients with late disease and peripheral neuropathy almost always have positive serum antibody tests, usually have abnormal neurophysiology tests, and may have abnormal nerve biopsies showing perivascular collections of lymphocytes; however, the CSF is usually normal and does not demonstrate local antibody production.

Caution should be exercised in interpreting serologic tests because they are not subject to national standards, and inter-laboratory variation is a major problem. In addition, some laboratories perform tests that are entirely unreliable and should never be used to support the diagnosis of Lyme disease (including Lyme urinary antigen tests or PCR on inappropriate specimens such as blood or urine). Finally, testing is often done in patients with nonspecific symptoms such as headache, arthralgia, myalgia, fatigue, and palpitations. For these reasons, the CDC and Infectious Diseases

Society of America have guidelines for laboratory evaluation of suspected Lyme disease:

1. The diagnosis of early Lyme disease is clinical (ie, exposure in an endemic area, with clinician-documented erythema migrans) and does *not* require laboratory confirmation. (Tests are often negative at this stage.) If lesions are atypical, serology performed on acute and convalescent sera (collected 14–21 days later) can help confirm the diagnosis.
2. Late disease requires objective evidence of clinical manifestations (recurrent brief attacks of monoarticular or oligoarticular arthritis of the large joints; lymphocytic meningitis, cranial neuritis [facial palsy]; peripheral neuropathy or, rarely, encephalomyelitis—but *not* headache, fatigue, paresthesias, or stiff neck alone; atrioventricular conduction defects with or without myocarditis) and laboratory evidence of disease (two-stage testing with ELISA or IFA followed by Western blot or a second ELISA, as described above).
3. Patients with nonspecific symptoms without objective signs of Lyme disease should *not* have serologic testing done. False-positive tests occur more commonly than true-positive tests in this setting.
4. When assessing for CNS Lyme disease in an appropriate clinical syndrome, serum antibody testing is recommended over CSF serology or PCR.
5. Serum antibody testing is recommended to diagnose Lyme arthritis; PCR can be done on synovial fluid or tissue if needed to confirm the diagnosis and guide treatment.

Erythema migrans is a clinical diagnosis; cultures and PCR of the lesions for *B burgdorferi* are not recommended.

Complications

B burgdorferi infection in pregnant women has *not* been associated with congenital syndromes, unlike other spirochetal illnesses such as syphilis.

Some patients and advocacy groups have claimed either a post–Lyme disease syndrome (in the presence of positive laboratory tests and after appropriate treatment) or "chronic Lyme disease" in which tests may all be negative. Both entities include nonspecific symptoms such as fatigue, myalgias, and cognitive difficulties (see Prognosis, below). Expert groups agree that there are no data to support that ongoing infection is the cause of either syndrome.

Differential Diagnosis

Chemical reactions to tick and spider bites (these usually recede in 24–48 hours, whereas erythema migrans increases in size during this period), drug eruptions, urticaria, and staphylococcal and streptococcal cellulitis have been mistaken for erythema migrans. Southern tick–associated rash illness (STARI) is transmitted by the tick bite of *Amblyomma americanum*. The bite may present with flu-like symptoms and a rash similar to that of erythema migrans or tick-associated rashes, but these bites generally occur in the southern United States only. It is uncertain what borrelial species, if any, is transmitted by the *A americanum*, but STARI is distinct from Lyme disease.

Lyme arthritis may resemble bacterial arthritis, although the former is usually less painful. Lyme carditis presenting as atrioventricular heart block may resemble infectious bacterial endocarditis or noninfectious autoimmune disease. Lyme meningitis must be distinguished from other causes of aseptic meningitis, such as viral meningitis. In early disseminated or late Lyme disease, clinical findings such as erythema migrans and positive serologic tests help confirm the diagnosis.

Prevention

There is no human vaccine available. Measures such as avoiding tick-infested areas, covering exposed skin with long-sleeved shirts, tucking long trousers into socks, wearing light-colored clothing, using repellents, and inspecting for ticks after exposure reduce the risk of tick bites.

Prophylactic antibiotic treatment following tick bites is recommended in certain high-risk situations if all of the following criteria are met: (1) a tick identified as an adult or nymphal *I scapularis* has been attached for at least 36 hours; (2) prophylaxis can be started within 72 hours of the time the tick was removed; (3) more than 20% of ticks in the area are known to be infected with *B burgdorferi*; and (4) there is no contraindication to the use of doxycycline (not pregnant, age > 8 years, not allergic). The medication of choice for prophylaxis is a single 200-mg dose of doxycycline. If doxycycline is contraindicated, no prophylaxis should be given since short-course prophylactic therapy with other agents has not been studied. The patient should be closely monitored for early disease, and if early disease does develop, appropriate therapy is effective in preventing long-term sequelae. Individuals who have removed ticks (including those who have had prophylaxis) should be monitored carefully for 30 days for possible coinfections.

Coinfections

Lyme disease, babesiosis (see Chapter 40), and human granulocytic anaplasmosis (see Chapter 37) are endemic in similar regions and are transmitted by the same tick, *I scapularis*. Coinfection with two or all three of these organisms can occur, causing a clinical picture that is not "classic" for any of these diseases. The presence of erythema migrans is highly suggestive of Lyme disease, whereas flu-like symptoms without rash are more suggestive of babesiosis or anaplasmosis. *Coinfection should be considered and excluded in patients who have persistent high fevers 48 hours after starting appropriate therapy for Lyme disease; in patients with persistent symptoms despite resolution of rash; and in those with anemia, leukopenia, or thrombocytopenia.*

Treatment

Recommendations for therapy are outlined in Table 39–4. For erythema migrans, antibiotic therapy shortens the duration of rash and prevents late sequelae. Doxycycline is most commonly used and has the advantage of being active against anaplasmosis, a common coinfection; it has proven effective in shorter courses of 7–10 days compared with

Table 39–4. Treatment of Lyme disease.

Manifestations	Medication and Dosage
Tick bite	No treatment in most circumstances (see text); observe
Erythema migrans	Doxycycline, 100 mg orally twice daily for 7–10 days, or amoxicillin, 500 mg orally three times daily for 14 days, or cefuroxime axetil, 500 mg orally twice daily for 14 days An alternative is azithromycin, 500 mg orally daily for 7 days with monitoring for resolution
Neurologic disease	
Facial palsy (without meningitis)	Doxycycline, 100 mg orally twice daily, or amoxicillin, 500 mg orally three times daily, or cefuroxime axetil, 500 mg orally twice daily—all for 14–21 days
Meningitis (without parenchymal disease of brain or spinal cord)	Ceftriaxone, 2 g intravenously once daily, or cefotaxime, 2 g intravenously every 8 hours, or penicillin G, 18–24 million units daily intravenously in six divided doses—all for 14–21 days or doxycycline, 100 mg orally twice daily for 14–21 days
Parenchymal brain or spinal cord disease	Ceftriaxone, 2 g intravenously once daily, or cefotaxime, 2 g intravenously every 8 hours, or penicillin G, 18–24 million units daily intravenously in six divided doses—all for 14–28 days
Cardiac disease	
Atrioventricular block and myopericarditis[1]	
Outpatient	Doxycycline, 100 mg orally twice daily, or amoxicillin, 500 mg orally three times daily, or cefuroxime axetil, 500 mg orally twice daily—all for 14–21 days
Inpatient	Ceftriaxone, 2 g intravenously once daily; patients can be switched to an oral agent (doxycycline is first-line therapy) to complete 14–21 days of total antibiotic treatment if clinically improving
Arthritis	Doxycycline, 100 mg orally twice daily, or amoxicillin, 500 mg orally three times daily, or cefuroxime axetil, 500 mg orally twice daily—all for 28 days. An oral agent is preferred as initial treatment and can be repeated if needed. If no response to initial treatment or worsening after initial treatment, ceftriaxone, 2 g intravenously once daily, can be given for 14–28 days (see text)
Acrodermatitis chronicum atrophicans	Doxycycline, amoxicillin, or cefuroxime axetil as above for 21–28 days
"Chronic Lyme disease" or "post–Lyme disease syndrome"	Symptomatic therapy; prolonged antibiotics are *not* recommended

[1] Symptomatic patients, those with second- or third-degree block, and those with first-degree block with a PR interval ≥ 300 milliseconds should be hospitalized for observation.

other regimens. The Infectious Diseases Society of America guidelines recommend 10 days of doxycycline treatment while a European study demonstrated efficacy with 7 days of treatment. Amoxicillin is also effective and is recommended for pregnant or lactating women and for those who cannot tolerate doxycycline.

Isolated facial palsy (without meningitis or peripheral neuropathy) can be treated with doxycycline, amoxicillin, or cefuroxime axetil for 14–21 days. Therapy does not affect the rate of resolution of the cranial neuropathy, but it does prevent development of late disease manifestations.

Some clinicians perform lumbar puncture on all patients with facial palsy and others only if there are symptoms or signs of meningitis. If meningitis is present, either parenteral therapy with ceftriaxone, cefotaxime, or penicillin G or oral doxycycline is recommended. The best initial agent will depend on the clinical scenario; patients who initially receive parenteral therapy can be switched to oral therapy to complete 14–21 total days of treatment. Patients with parenchymal brain or spinal cord disease should be treated with intravenous antibiotics for 14–28 days.

Atrioventricular block or myopericarditis (or both) can be treated with either oral or parenteral agents for 14–21 days. Hospitalization is indicated for symptomatic patients, those with second- or third-degree block, and those with first-degree block with a PR interval of 300 milliseconds or more. Once stabilized, hospitalized patients can be transitioned to one of the oral regimens to complete therapy.

Therapy of arthritis is difficult because some patients do not respond to any therapy, and those who do respond may do so slowly. Oral agents (doxycycline, amoxicillin, or cefuroxime axetil) are as effective as intravenous regimens (ceftriaxone, cefotaxime, or penicillin). A reasonable approach to the patient with Lyme arthritis is to start with oral therapy for 28 days. If there is partial resolution, retreat with an additional 28 days of the same oral regimen. However, if there has been no response or worsening with initial oral therapy, switch to intravenous ceftriaxone for 14–28 days. If arthritis persists after re-treatment, symptomatic therapy with NSAIDs is recommended. For severe refractory pain, synovectomy may be required.

Acrodermatitis chronicum atrophicans can be treated with oral doxycycline, amoxicillin, or cefuroxime axetil for 21–28 days.

Based on limited data, therapy of Lyme disease in pregnancy should be the same as therapy in other patients, with the exception that doxycycline should not be used.

Clinicians may encounter patients with nonspecific symptoms (such as fatigue and myalgias) and positive serologic tests for Lyme disease who request therapy for their illness. When treating these patients, clinicians must remember (1) that nonspecific symptoms alone are not diagnostic; (2) that serologic tests are fraught with difficulty (as noted above), and in areas where disease prevalence is low, false-positive serologic tests are much more common than true-positive tests; and (3) that parenteral therapy with ceftriaxone for 2–4 weeks can cause significant adverse effects, including cholelithiasis and *Clostridioides difficile* colitis, and is costly. Parenteral therapy should be reserved for those most likely to benefit, ie, those with characteristic cutaneous, neurologic, cardiac, or rheumatic manifestations of Lyme disease.

Prognosis

Most patients respond to appropriate therapy with prompt resolution of symptoms within 4 weeks. True treatment failures are uncommon, and in most cases, re-treatment or prolonged treatment of Lyme disease is instituted because of misdiagnosis or misinterpretation of serologic results (both IgG and IgM antibodies can persist for prolonged periods despite adequate therapy) rather than inadequate therapy or response. Prolonged courses of antibiotic therapy for nonspecific symptoms that persist after completion of appropriate assessment (and treatment, if necessary) for Lyme disease are not recommended.

The long-term outcome of adult patients with Lyme disease is generally favorable, but some patients have chronic complaints. Joint pain, memory impairment, and poor functional status because of pain are common subjective complaints, but physical examination and neurocognitive testing fail to document the presence of these symptoms as objective sequelae.

Immunity is not complete after Lyme disease. Reinfection, although uncommon, is predominantly seen in patients successfully treated for early disease (erythema migrans) in whom antibody titers do not develop. Clinical manifestations and serologic response are similar to an initial infection.

When to Refer

Consultation with an infectious diseases specialist experienced in Lyme disease can be helpful in atypical or prolonged cases.

When to Admit

Admission for parenteral antibiotics is indicated for symptomatic CNS or cardiac disease, second- or third-degree atrioventricular block, or first-degree block with a PR interval of 300 milliseconds or more.

Protozoal & Helminthic Infections

Philip J. Rosenthal, MD

PROTOZOAL INFECTIONS

AFRICAN TRYPANOSOMIASIS (Sleeping Sickness)

ESSENTIALS OF DIAGNOSIS

- Exposure to tsetse flies; chancre at bite site uncommon.
- **Hemolymphatic disease:** Irregular fever, headache, joint pain, rash, edema, lymphadenopathy.
- **Meningoencephalitic disease:** Somnolence, severe headache, progressing to coma.
- Trypanosomes in blood or lymph node aspirates; positive serologic tests.
- Trypanosomes and increased white cells and protein in CSF.

General Considerations

African trypanosomiasis is caused by the hemoflagellates *Trypanosoma brucei rhodesiense* and *Trypanosoma brucei gambiense*. The organisms are transmitted by bites of tsetse flies (genus *Glossina*), which inhabit shaded areas along streams and rivers. Trypanosomes ingested in a blood meal develop over 18–35 days in the fly; when the fly feeds again on a mammalian host, the infective stage is injected. Human disease occurs in rural areas of sub-Saharan Africa from south of the Sahara to about 30 degrees south latitude. *T b gambiense* causes West African trypanosomiasis and is transmitted in the moist sub-Saharan savannas and forests of west and central Africa. *T b rhodesiense* causes East African trypanosomiasis and is transmitted in the savannas of east and southeast Africa.

T b rhodesiense infection is primarily a zoonosis of game animals and cattle; humans are infected sporadically. Humans are the principal mammalian host for *T b gambiense*, but domestic animals can be infected. After major decreases in incidence, < 1000 cases have been reported annually in recent years, mostly due to *T b gambiense*, with the largest number in the Democratic Republic of the Congo. Infections are rare among travelers, including visitors to game parks.

Clinical Findings

A. Symptoms and Signs

1. West African trypanosomiasis (*T b gambiense*)— Chancres at the site of the bite are uncommon. After an asymptomatic period that may last for months, hemolymphatic disease presents with fever, headache, myalgias, arthralgias, weight loss, and lymphadenopathy, with discrete, nontender, rubbery nodes, referred to as Winterbottom sign when in a posterior cervical distribution. Other common signs are mild splenomegaly, transient edema, and a pruritic erythematous rash. Febrile episodes may be broken by afebrile periods of up to several weeks. The hemolymphatic stage progresses over months to meningoencephalitic disease, with somnolence, irritability, personality changes, severe headache, and parkinsonian symptoms progressing to coma and death.

2. East African trypanosomiasis (*T b rhodesiense*)— Chancres at the bite site are more commonly recognized with this infection, with a painful lesion of 3–10 cm and regional lymphadenopathy that appears about 48 hours after the tsetse fly bite and lasts 2–4 weeks. East African disease follows a much more acute course, with the onset of symptoms usually within a few days of the insect bite. The hemolymphatic stage includes intermittent fever and rash, but lymphadenopathy is less common than with West African disease. Myocarditis can cause tachycardia and death due to arrhythmias or heart failure. If untreated, East African trypanosomiasis progresses over weeks to months to meningoencephalitic disease, somnolence, coma, and death.

B. Laboratory Findings

Diagnosis can be difficult, and definitive diagnosis requires identification of trypanosomes. Microscopic examination of fluid expressed from a chancre or lymph node may show motile trypanosomes or, in fixed specimens, parasites stained with Giemsa. During the hemolymphatic stage, detection of parasites in Giemsa-stained blood smears is common in East African disease but difficult in West African disease. Serial specimens should be examined, since parasitemias vary greatly over time. Meningoencephalic disease is defined by the WHO as CSF showing at least five mononuclear cells per microliter, elevated protein, or presence of trypanosomes. Concentration techniques can aid identification of parasites in blood or CSF. Serologic tests are also available. The card agglutination test for trypanosomes (CATT) has excellent sensitivity and specificity for West African disease and can be performed in the field, but the diagnosis should be confirmed by identification of the parasites. Field-applicable immunochromatographic lateral flow rapid diagnostic tests that cost less than CATT and are simpler to perform are available.

Treatment

Detection of trypanosomes is a prerequisite for treatment of African trypanosomiasis because of the significant toxicity of therapies. Treatment recommendations depend on the type of trypanosomiasis (Table 40–1), which is determined by geography, and stage of disease. Fexinidazole is recommended by the WHO as first-line therapy and is FDA-approved for treatment of early (no CNS disease) and advanced (CNS) West African disease. Acoziborole has demonstrated effective and simpler single-dose oral therapy for West African disease, is now under study for treatment of children, and may soon be available. Suramin, eflornithine, and melarsoprol are available in the United States from the CDC Drug Service (www.cdc.gov/laboratory/drugservice).

A. West African Trypanosomiasis

Fexinidazole is effective and safe when administered orally to persons older than 6 years of age (for weight > 35 kg, give 1800 mg once daily for 4 days, followed by 1200 mg once daily for 6 days). It is recommended for persons with a CSF leukocyte count < 100/mcL (0.1×10^9/L). Evaluation of the CSF can be avoided if there is no suspicion of severe CNS disease. Fexinidazole greatly simplifies therapy compared with parenteral regimens, but relapse and death after treatment may be more common than after treatment with eflornithine plus nifurtimox. Side effects from fexinidazole include headache, nausea, vomiting, insomnia, anxiety, weakness, tremor, and decreased appetite. For advanced CNS disease (CNS leukocytes > 100/mcL [0.1×10^9/L]), a combination of intravenous eflornithine (400 mg/kg/day in two doses for 7 days) and oral nifurtimox (15 mg/kg/day in three doses for 10 days) is recommended. Eflornithine, although less toxic than older trypanocidal drugs, can cause GI symptoms, bone marrow suppression, seizures, and alopecia. Alternative therapies include pentamidine and suramin for early disease and melarsoprol for CNS disease, all with serious toxicity concerns.

B. East African Trypanosomiasis

Fexinidazole has replaced suramin and melarsoprol (previously first-line for early and CNS disease, respectively) for individuals > 6 years of age with body weight ≥ 20 kg. As the drug is effective for all disease stages, lumbar punctures are no longer routinely required. For younger children, recommendations remain to treat early disease with suramin and CNS disease with melarsoprol. Suramin toxicities include vomiting and, rarely, seizures and shock during infusions as well as subsequent fever, rash, headache, neuropathy, and kidney and bone marrow dysfunction.

Immediate side effects of melarsoprol include fever and GI symptoms. The most important side effect is a reactive encephalopathy that can progress to seizures, coma, and death. To help avoid this side effect, corticosteroids are coadministered. Increasing resistance to melarsoprol is a serious concern.

Prevention & Control

Individual prevention in endemic areas should include neutral-colored clothes (eg, long sleeve shirts and pants), insect repellents, and mosquito nets. Control programs focusing on vector elimination and treatment of infected persons and animals have shown good success in many areas but suffer from limited resources.

Table 40–1. Treatment of African trypanosomiasis.

		Treatment	
Disease	Stage	First Line	Alternative
West African	Early[1]	Fexinidazole	Pentamidine Suramin Eflornithine
	CNS involvement		Melarsoprol
	< 100 leukocytes/mcL (0.1×10^9/L) in CSF	Fexinidazole	
	> 100 leukocytes/mcL (0.1×10^9/L) in CSF	Eflornithine + nifurtimox	
East African	Early[1]	Suramin	Pentamidine
	CNS involvement	Melarsoprol	

[1] Early stage is without CNS involvement.

AMERICAN TRYPANOSOMIASIS (Chagas Disease)

ESSENTIALS OF DIAGNOSIS

Acute stage

- Inflammatory lesion at inoculation site.
- Fever.
- Hepatosplenomegaly; lymphadenopathy.
- Myocarditis.
- Parasites in blood are diagnostic.

Chronic stage

- Heart failure, cardiac arrhythmias.
- Thromboembolism.
- Megaesophagus; megacolon.
- Serologic tests are usually diagnostic.

General Considerations

Chagas disease is caused by *Trypanosoma cruzi*, a protozoan parasite found only in the Americas; it infects wild animals and, to a lesser extent, humans from southern South America to the southern United States. An estimated 6–7 million persons are infected, mostly in rural areas, with the highest national prevalence in Bolivia, Argentina, Paraguay, Ecuador, El Salvador, and Guatemala. An estimated 288,000 infected persons live in the United States. Control efforts in endemic countries have decreased disease incidence to about 30,000 new infections and 12,000 deaths per year. The disease is often acquired in childhood. In many countries in South America, Chagas disease is the most important cause of heart disease. The vector is endemic in the southern United States where some animals are infected, and a few instances of local transmission have been reported.

T cruzi is transmitted by reduviid (triatomine) bugs infected by ingesting blood from animals or humans who have circulating trypanosomes. Multiplication occurs in the digestive tract of the bug and infective forms are eliminated in feces. Infection in humans occurs when the parasite penetrates the skin through the bite wound, mucous membranes, or the conjunctiva. Transmission can also occur by blood transfusion, organ or bone marrow transplantation, congenital transfer, or ingestion of food contaminated with vector feces. From the bloodstream, *T cruzi* invades many cell types but has a predilection for myocardium, smooth muscle, and CNS glial cells. Multiplication causes cellular destruction, inflammation, and fibrosis, with progressive disease over decades.

Clinical Findings

A. Symptoms and Signs

As many as 70% of infected persons remain asymptomatic.

1. Acute infection—This stage is seen principally in children and lasts 1–2 months. The earliest findings are at the site of inoculation either in the eye—Romaña sign (unilateral edema, conjunctivitis, and lymphadenopathy)—or in the skin—a chagoma (swelling with local lymphadenopathy). Subsequent findings include fever, malaise, headache, mild hepatosplenomegaly, and generalized lymphadenopathy. Acute myocarditis and meningoencephalitis are rare but can be fatal.

2. Asymptomatic latent period—This indeterminate phase may last for life, but symptomatic disease develops in 10–30% of infected individuals, commonly many years after infection.

3. Chronic Chagas disease—Chronic disease generally manifests as abnormalities in cardiac and smooth muscle. Cardiac disease includes arrhythmias, heart failure, and embolic disease. Smooth muscle abnormalities lead to megaesophagus and megacolon, with dysphagia, regurgitation, aspiration, constipation, and abdominal pain. These findings can be complicated by superinfections. In immunosuppressed persons, including patients with AIDS and transplant recipients, latent Chagas disease may reactivate; findings have included brain abscesses and meningoencephalitis.

B. Diagnostic Testing

1. Acute infection—The diagnosis is made by detecting parasites in persons with suggestive findings who have resided in an endemic area. Evaluation of fresh blood or buffy coats may show motile trypanosomes, and fixed preparations may show Giemsa-stained parasites. Concentration methods increase diagnostic yields. Trypanosomes may be identified in lymph nodes, bone marrow, or pericardial or spinal fluid. Molecular tests are highly sensitive and can be used to detect parasites in organ transplant recipients or after accidental exposure. When initial tests are unrevealing, xenodiagnosis using laboratory vectors, laboratory culture, or animal inoculation may provide a diagnosis, but these methods are expensive and slow.

2. Chronic Chagas disease—This is usually diagnosed serologically. Many serologic assays, including rapid diagnostic tests, are available, but sensitivity and specificity are not ideal; confirmatory assays are advised after an initial positive test, as is standard for blood bank testing in South America. The diagnosis of chronic disease with PCR remains suboptimal.

Treatment

Treatment is inadequate because the two drugs used, benznidazole and nifurtimox, often cause severe side effects, must be used for long periods, and are ineffective against chronic infection. In acute and congenital infections, the drugs can reduce the duration and severity of infection, and apparent cure is achieved in about 70–90% of patients. During the chronic phase of infection, although parasitemia may disappear in up to 70% of patients, treatment does not clearly alter the progression of Chagas disease. Nevertheless, there is general consensus that treatment should be considered in all persons infected with *T cruzi* regardless of clinical status or time since infection. In particular, treatment is recommended for acute, congenital, and reactivated infections and for children and young adults with chronic disease.

Both benznidazole and nifurtimox are FDA-approved for the treatment of Chagas disease. Benznidazole is generally preferred to nifurtimox due to better efficacy and safety profiles. The dose is 5 mg/kg/day orally in two divided doses for 60 days; shorter (2–4 week) regimens offer good efficacy. Its side effects include granulocytopenia, rash, and peripheral neuropathy. The dose of nifurtimox is 8–10 mg/kg orally in four divided doses after meals for 90–120 days. Side effects include GI (anorexia, vomiting) and neurologic (headaches, ataxia, insomnia, seizures) symptoms, which appear to be reversible and to lessen with dosage reduction. For both drugs, some recommendations suggest higher dosing for acute infections. Patients with chronic Chagas disease may benefit from antiarrhythmic therapy, standard therapy for heart failure, and conservative and surgical management of megaesophagus and megacolon.

Prevention & Control

In South America, a major eradication program based on improved housing, use of residual pyrethroid insecticides and pyrethroid-impregnated bed curtains, and screening of blood donors has achieved striking reductions in new infections. In endemic areas and ideally in donors from endemic areas, blood should not be used for transfusion unless at least two serologic tests are negative.

LEISHMANIASIS

ESSENTIALS OF DIAGNOSIS

- Sand fly bite in an endemic area.
- **Visceral leishmaniasis:** irregular fever, progressive hepatosplenomegaly, pancytopenia, wasting.
- **Cutaneous leishmaniasis:** chronic, painless, moist ulcers or dry nodules.
- **Mucocutaneous leishmaniasis:** destructive nasopharyngeal lesions.
- Amastigotes in macrophages in aspirates, touch preparations, or biopsies.
- Positive culture, serologic tests, PCR, or skin test.

General Considerations

Leishmaniasis is a zoonosis transmitted by bites of sand flies of the genus *Lutzomyia* in the Americas and *Phlebotomus* elsewhere. When sand flies feed on an infected host, the parasitized cells are ingested with the blood meal. Leishmaniasis is caused by about 20 species of *Leishmania;* taxonomy is complex. Clinical syndromes are generally dictated by the infecting species, but some species can cause more than one syndrome.

The estimated annual incidence of disease has been decreasing, with estimates of 600,000 to 1 million annual cases of cutaneous disease and 50,000–90,000 cases of visceral disease. Progress against visceral disease has been greatest on the Indian subcontinent.

1. Visceral leishmaniasis (kala azar)—More than 90% of cases occur in seven countries: Brazil, Ethiopia, India, Kenya, Somalia, South Sudan, and Sudan. In each locale, the disease has particular clinical and epidemiologic features. The incubation period is usually 4–6 months (range: 10 days to 24 months). Without treatment, the fatality rate reaches 90%. Early diagnosis and treatment reduce mortality to 2–5%.

2. Cutaneous leishmaniasis—About 90% of cases occur in Afghanistan, Pakistan, Syria, Saudi Arabia, Algeria, Iran, Brazil, and Peru. Mucocutaneous leishmaniasis (espundia) occurs in lowland forest areas of the Americas and is caused by *Leishmania braziliensis*, *Leishmania panamensis*, and *Leishmania peruviana*.

Clinical Findings

A. Symptoms and Signs

1. Visceral leishmaniasis (kala azar)—Most infections are subclinical, but a small number progress to full-blown disease. A local nonulcerating nodule at the site of the sand fly bite may precede systemic manifestations but usually is inapparent. The onset of illness may be acute, within 2 weeks of infection, or insidious. Symptoms and signs include fever, chills, sweats, weakness, anorexia, weight loss, cough, and diarrhea. The spleen progressively becomes greatly enlarged, firm, and nontender. The liver is somewhat enlarged, and generalized lymphadenopathy may occur. Hyperpigmentation of skin can be seen, leading to the name kala azar (“black fever”). Other signs include skin lesions, petechiae, gingival bleeding, jaundice, edema, and ascites. As the disease progresses, severe wasting and malnutrition are seen; death eventually occurs, often due to secondary infections, within months to a few years. Post–kala azar dermal leishmaniasis may appear after apparent cure in the Indian subcontinent and Sudan. It may simulate leprosy, with hypopigmented macules or nodules developing on

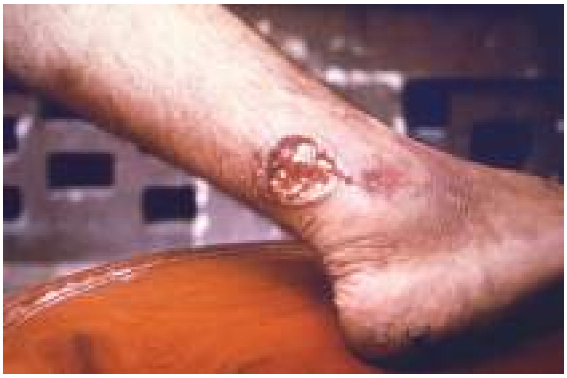

Figure 40–1. Skin ulcer due to cutaneous leishmaniasis. Note the classic morphologic characteristics of this wound with its erythematous, nodular interior, surrounded by a raised border. (From Dr. Mae Melvin, Public Health Image Library, CDC.)

preexisting lesions. Viscerotropic leishmaniasis entails a relatively mild systemic febrile illness, mostly after *L tropica* infections.

2. Old World and New World cutaneous leishmaniasis—Cutaneous swellings appear 1 week to several months after sand fly bites and can be single or multiple. Characteristics of lesions and courses of disease vary depending on the leishmanial species and host immune response. Lesions begin as small papules and develop into nonulcerated dry plaques or large encrusted ulcers with well-demarcated raised and indurated margins (Figure 40–1). Satellite lesions may be present. The lesions are painless unless secondarily infected. Local lymph nodes may be enlarged. Systemic symptoms are uncommon, but fever, constitutional symptoms, and regional lymphadenopathy may be seen. For most species, healing occurs spontaneously in months to a few years, but scarring is common.

Leishmaniasis recidivans is a relapsing form of *L tropica* infection associated with hypersensitivity, in which the primary lesion heals centrally, but spreads laterally, with extensive scarring. Diffuse cutaneous leishmaniasis involves spread from a primary lesion, with local dissemination of nodules and a protracted course. Disseminated cutaneous leishmaniasis involves multiple nodular or ulcerated lesions, often with mucosal involvement.

3. Mucocutaneous leishmaniasis (espundia)—In Latin America, mucosal lesions develop in a small percentage of persons infected with *L braziliensis* and some other species, usually months to years after resolution of a cutaneous lesion. Nasal congestion is followed by ulceration of the nasal mucosa and septum, progressing to involvement of the mouth, lips, palate, pharynx, and larynx. Extensive destruction can occur, and secondary bacterial infection is common.

4. Infections in patients with AIDS—Leishmaniasis is an opportunistic infection in persons with AIDS. Visceral leishmaniasis can present late in the course of HIV infection, with fever, hepatosplenomegaly, and pancytopenia. The GI tract, respiratory tract, and skin may also be involved.

B. Laboratory Findings

Identifying amastigotes within macrophages in tissue samples provides a definitive diagnosis.

1. Visceral leishmaniasis—Fine-needle aspiration of the spleen for culture and tissue evaluation is generally safe and yields a diagnosis in > 95% of cases. Bone marrow aspiration is less sensitive but safer and diagnostic in most cases, and Giemsa-stained buffy coat of peripheral blood may occasionally show organisms. Cultures with media available from the CDC will grow promastigotes within a few days to weeks. Molecular assays can be diagnostic. Immunochromatographic strip assays using the rK39 antigen have shown good sensitivity and specificity; one such test is approved by the FDA.

2. Cutaneous leishmaniasis—Biopsies should be taken from the raised border of a skin lesion, with samples for histopathology, touch preparation, and culture. The histopathology shows inflammation with mononuclear cells. Macrophages filled with amastigotes may be present, especially early in infection. An intradermal leishmanin (Montenegro) skin test is positive in most individuals with cutaneous disease but negative in those with progressive visceral or diffuse cutaneous disease; this test is not approved in the United States.

3. Mucocutaneous leishmaniasis—Diagnosis is established by detecting amastigotes in scrapings, biopsy preparations, or aspirated tissue fluid, but organisms may be rare. Cultures from these samples may grow organisms. Serologic studies are often negative, but the leishmanin skin test is usually positive.

Treatment

A. Visceral Leishmaniasis

1. Amphotericin B—The treatment of choice for visceral leishmaniasis on the Indian subcontinent is liposomal amphotericin B (approved by the FDA), which is generally effective and well tolerated but expensive. Standard dosing is 3 mg/kg/day intravenously on days 1–5, 14, and 21. Simpler regimens that have shown good efficacy in India include four doses of 5 mg/kg over 4–10 days and a single dose of 15 mg/kg, but efficacies of shorter regimens have been lower outside India. A single infusion of an amphotericin B lipid emulsion, which is more affordable than liposomal preparations, showed excellent efficacy, albeit lower than that of the liposomal formulation. Conventional amphotericin B deoxycholate, which is much less expensive, is also highly effective but with more toxicity. It is administered as a slow intravenous infusion of 1 mg/kg/day for 15–20 days or 0.5–1 mg/kg every second day for up to 8 weeks. Infusion-related side effects with conventional or liposomal amphotericin B include GI symptoms, fever, chills, dyspnea, hypotension, and hepatic and renal toxicity.

2. Pentavalent antimonials—These agents remain the most commonly used drugs to treat leishmaniasis in most areas outside India, where resistance is a major problem. Two preparations are available: meglumine antimonate in Latin America and francophone countries and sodium stibogluconate in many other areas. The compounds appear to have comparable activities. Sodium stibogluconate is no longer available in the United States. Standard dosing for either antimonial is 20 mg/kg once daily intravenously (preferred) or intramuscularly for 20 days for cutaneous leishmaniasis and 28 days for visceral or mucocutaneous disease. Toxicity increases over time, with development of GI symptoms, fever, headache, myalgias, arthralgias, pancreatitis, and rash. Intramuscular injections can cause sterile abscesses. Monitoring should include serial ECGs, and changes are indications for discontinuation to avoid progression to serious arrhythmias.

3. Miltefosine—This is the first oral drug for the treatment of leishmaniasis, and it is registered in India for this indication, though efficacy is decreasing due to drug resistance. The daily oral dose is 2.5 mg/kg in two divided doses for 28 days. This same 28-day course of miltefosine is also effective for the treatment of New World cutaneous leishmaniasis. Vomiting, diarrhea, and elevations in transaminases and kidney function studies are common, but generally short-lived, side effects.

4. Paromomycin—Paromomycin (11 mg/kg/day intramuscularly for 21 days) was shown to be similarly efficacious to amphotericin B for the treatment of visceral disease in India, where it is approved for this indication. It is much less expensive than liposomal amphotericin B or miltefosine. The drug is well tolerated; side effects include ototoxicity and reversible elevations in liver enzymes.

5. Combination therapy—The use of drug combinations can improve treatment efficacy, shorten treatment courses, and reduce the selection of resistant parasites.

a. India—In India, compared with a standard 30-day (treatment on alternate days) course of amphotericin, noninferior efficacy and decreased adverse events were seen with a single dose of liposomal amphotericin plus a 14-day course of miltefosine, a single dose of liposomal amphotericin plus a 10-day course of paromomycin (15 mg/kg/day intramuscularly), or a 10-day course of miltefosine plus paromomycin.

b. East africa—In East Africa, the efficacy of amphotericin B is lower than in Asia, and the standard treatment is a combination of sodium stibogluconate (20 mg/kg/day intravenously) plus paromomycin (15 mg/kg/day intramuscularly) for 17 days, with demonstrated excellent efficacy; paromomycin plus miltefosine, a simpler regimen, has demonstrated equivalent efficacy. Liposomal amphotericin B may be considered in older adults or pregnant persons due to toxicity concerns.

B. Cutaneous Leishmaniasis

In the Old World, cutaneous leishmaniasis is generally self-healing over some months and does not metastasize to the mucosa, so it may be justified to withhold treatment in regions without mucocutaneous disease if lesions are small and cosmetically unimportant. Lesions on the face or hands are generally treated. New World leishmaniasis has a greater risk of progression to mucocutaneous disease, so treatment is more often warranted, but choice of therapy is complex. Standard therapy has been with pentavalent antimonials for 20 days, as described above. Two alternatives are increasingly used: miltefosine, which benefits from oral dosing and relatively little toxicity; and amphotericin B, which is fairly toxic, but highly effective. Topical therapy has included intralesional antimony, intralesional pentamidine, paromomycin ointment, cryotherapy, local heat, and surgical removal. In Brazil, intralesional meglumine antimoniate was as effective and better tolerated than systemic therapy with the drug. Diffuse cutaneous leishmaniasis and related chronic skin processes generally respond poorly to therapy.

C. Mucocutaneous Leishmaniasis

Cutaneous infections from regions where parasites include those that cause mucocutaneous disease (eg, *L braziliensis* in parts of Latin America) should all be treated to help prevent disease progression. Treatment of mucocutaneous disease with antimonials (eg, meglumine antimoniate) is disappointing, with responses in only about 60% in Brazil. Other therapies listed above for visceral leishmaniasis may also be used, although they have not been well studied for this indication.

Prevention & Control

Personal protection measures for avoidance of sand fly bites include use of insect repellants, fine-mesh insect netting, long sleeves and pants, and avoidance of warm shaded areas where flies are common. Disease control measures include destruction of animal reservoir hosts, mass treatment of humans in disease-prevalent areas, residual insecticide spraying in dwellings, limiting contact with dogs and other domesticated animals, and use of permethrin-impregnated collars for dogs.

MALARIA

ESSENTIALS OF DIAGNOSIS

- Exposure to anopheline mosquitoes in a malaria-endemic area.
- Intermittent attacks of chills, fever, and sweating.
- Headache, myalgia, vomiting, splenomegaly; anemia, thrombocytopenia.
- Intraerythrocytic parasites identified in thick or thin blood smears or positive rapid diagnostic tests.
- **Falciparum malaria complications:** cerebral malaria, severe anemia, hypotension, pulmonary edema, AKI, hypoglycemia, acidosis, and hemolysis.

General Considerations

Malaria is the most important parasitic disease of humans, causing hundreds of millions of illnesses and hundreds of thousands of deaths each year. The disease is endemic in most of the tropics, including much of South and Central America, Africa, the Middle East, the Indian subcontinent, Southeast Asia, and Oceania; transmission, morbidity, and mortality are greatest in Africa, where most deaths are in young children. Malaria is also common in travelers from nonendemic areas to the tropics. Although the disease remains a major problem, impressive advances have been made in many regions. However, after marked gains, progress has stalled, particularly in Africa, where about 95% of cases occur. The WHO estimated that 263 million cases of malaria occurred in 2023, with 597,000 deaths.

Five species of the genus *Plasmodium* classically cause human malaria:

1. *Plasmodium falciparum* is responsible for nearly all severe disease, since it uniquely infects erythrocytes of all ages and mediates the sequestration of infected erythrocytes in small blood vessels, thereby evading clearance by the spleen. *P falciparum* is endemic in most malarious areas and is by far the predominant species in Africa.
2. *Plasmodium vivax* is about as common as *P falciparum* outside of Africa. *P vivax* uncommonly causes severe disease, although this outcome may be more common than previously appreciated.
3. *Plasmodium ovale* (composed of *P ovale curtisi* and *P ovale wallikeri*) is a much less common cause of disease and generally does not cause severe illness.
4. *Plasmodium malariae* is a relatively uncommon cause of disease and usually does not cause severe illness.
5. *Plasmodium knowlesi*, a parasite of macaque monkeys, causes illnesses in humans, including some severe disease, in Southeast Asia.

Malaria is transmitted by the bite of infected female anopheline mosquitoes. During feeding, mosquitoes inject sporozoites, which circulate to the liver, and rapidly infect hepatocytes, causing asymptomatic liver infection.

Merozoites are subsequently released from the liver, and they rapidly infect erythrocytes to begin the asexual erythrocytic stage of infection that is responsible for human disease. Multiple cycles of erythrocytic development, with production of merozoites that invade additional erythrocytes, lead to large numbers of circulating parasites and clinical illness. Some erythrocytic parasites develop into sexual gametocytes, which are infectious to mosquitoes, allowing completion of the life cycle and infection of others.

Malaria may uncommonly be transmitted from mother to infant (congenital malaria), by blood transfusion, and in nonendemic areas by mosquitoes infected after biting infected immigrants or travelers. In *P vivax* and *P ovale*, parasites also form dormant liver hypnozoites, which are not killed by most drugs, allowing subsequent relapses of illness after initial elimination of erythrocytic infections. For all plasmodial species, parasites may recrudesce following initial clinical improvement after suboptimal therapy.

In highly endemic regions, where persons are infected repeatedly, antimalarial immunity prevents severe disease in most older children and adults. However, relatively nonimmune young children are at high risk for severe disease from *P falciparum* infection, and this population is responsible for most deaths from malaria. Pregnant persons are also at increased risk for severe falciparum malaria. In areas with lower endemicity, individuals of all ages commonly present with uncomplicated or severe malaria. Travelers, who are generally nonimmune, are at high risk for severe disease from falciparum malaria at any age.

Clinical Findings

A. Symptoms and Signs

An acute attack of malaria typically begins with a prodrome of headache and fatigue, followed by fever. A classic malarial paroxysm includes chills, high fever, and then sweats. Patients may appear to be remarkably well between febrile episodes. Fevers are usually irregular, especially early in the illness, but without therapy may become regular, with 48-hour (*P vivax* and *P ovale*) or 72-hour (*P malariae*) cycles, especially with non-falciparum disease. Headache, malaise, myalgias, arthralgias, cough, chest pain, abdominal pain, anorexia, nausea, vomiting, and diarrhea are common. Seizures may represent simple febrile convulsions or evidence of severe neurologic disease. Physical findings may be absent or include signs of anemia, jaundice, splenomegaly, and mild hepatomegaly. Rash and lymphadenopathy are not typical in malaria, and thus suggestive of another cause of fever.

In the developed world, it is imperative that all persons with suggestive symptoms, in particular fever, who have traveled in an endemic area be evaluated for malaria. The risk for falciparum malaria is greatest within 2 months of return from travel; other species may cause disease many months—and occasionally > 1 year—after return from an endemic area.

Severe malaria is principally a result of *P falciparum* infection. It is characterized by signs of severe illness, organ dysfunction, or a high parasite load (peripheral parasitemia > 5% or > 200,000 parasites/mcL). Severe falciparum malaria can include dysfunction of any organ system, including neurologic abnormalities progressing to alterations in consciousness, repeated seizures, and coma (cerebral malaria); severe anemia; hypotension and shock; noncardiogenic pulmonary edema and acute respiratory distress syndrome; AKI due to ATN or, less commonly, severe hemolysis; hypoglycemia; acidosis; hemolysis with jaundice; hepatic dysfunction; retinal hemorrhages and other fundoscopic abnormalities; bleeding abnormalities, including disseminated intravascular coagulation; and secondary bacterial infections, including pneumonia and *Salmonella* bacteremia. In the developing world, severe malaria and deaths from the disease are mostly in young children, in particular from cerebral malaria and severe anemia. Cerebral malaria is a consequence of a single severe infection, while severe anemia follows multiple malarial infections, intestinal helminths, and nutritional deficiencies.

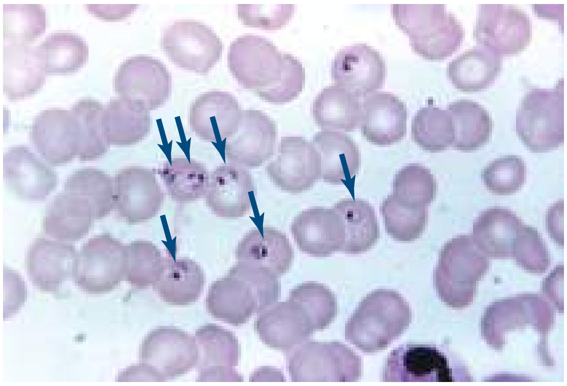
Uncommon disorders resulting from immunologic responses to chronic infection are massive splenomegaly and, with *P malariae* infection, immune complex glomerulopathy with nephrotic syndrome. Patients with HIV are at increased risk for malaria and for severe disease, in particular with advanced immunodeficiency.

B. Laboratory Findings

Giemsa-stained blood smears remain the mainstay of diagnosis. Thick smears provide efficient evaluation of large volumes of blood, but thin smears are simpler for inexperienced personnel and better for discrimination of parasite species (Figure 40–2). Single smears are usually positive in infected individuals, although parasitemias may be low in nonimmune individuals. If illness is suspected, repeating smears at 8- to 24-hour intervals is appropriate. The severity of malaria correlates only loosely with the quantity of infecting parasites, but high parasitemias (especially > 10–20% of erythrocytes infected or > 200,000–500,000 parasites/mcL) or the presence of malarial pigment (a breakdown product of hemoglobin) in > 5% of neutrophils is associated with a particularly poor prognosis.

A second means of diagnosis is rapid diagnostic tests to identify circulating plasmodial antigens. These tests offer sensitivity and specificity near that of high-quality blood smear analysis and are simpler to perform. However, *P falciparum* that is lacking the most common rapid diagnostic test antigen, histidine-rich protein 2 (HRP2), has been identified in some areas (especially parts of South America and the Horn of Africa), so HRP2-based tests may miss some cases of falciparum malaria.

Serologic tests indicate history of disease but are not useful for diagnosis of acute infection. PCR and related molecular tests (eg, LAMP) are highly sensitive but are not available for routine diagnosis. In immune populations, highly sensitive molecular tests, such as PCR, have limited value because subclinical infections, which are not routinely treated, are common.



▲ **Figure 40–2.** Thin film Giemsa-stained micrograph with *Plasmodium falciparum* ring forms. (From Steven Glenn, Laboratory & Consultation Division, Public Health Image Library, CDC.)

Other diagnostic findings with uncomplicated malaria include thrombocytopenia, anemia, leukocytosis or leukopenia, liver function abnormalities, and hepatosplenomegaly. Severe malaria can present with the laboratory abnormalities expected for the advanced organ dysfunction discussed above.

Treatment

Malaria is the most common cause of fever in much of the tropics and in travelers seeking medical attention after return from endemic areas. Fevers are often treated presumptively in endemic areas, but treatment should follow definitive diagnosis, especially in nonimmune individuals. Symptomatic malaria is caused only by the erythrocytic stage of infection. Most antimalarial drugs act against this stage, except for primaquine and tafenoquine, which act principally against hepatic parasites.

A. Non-Falciparum Malaria

The first-line drug for non-falciparum malaria from most areas remains chloroquine (Table 40–2).

1. *P vivax*—Due to increasing resistance of *P vivax*, alternative therapies to chloroquine are recommended when resistance is suspected, particularly for infections acquired in Indonesia, Oceania, and South America. These infections can be treated with artemisinin-based combination therapies (ACTs) or other first-line regimens for *P falciparum* infections (as discussed below) plus primaquine.

2. *P vivax* or *P ovale*—For these species, eradication of erythrocytic parasites with chloroquine should be accompanied by treatment with primaquine or tafenoquine (after evaluating for glucose-6-phosphate dehydrogenase [G6PD] deficiency; see below) to eradicate dormant liver stages (hypnozoites), which may lead to relapses with recurrent erythrocytic infection and malaria symptoms after weeks to months if left untreated.

3. *P malariae* and *P knowlesi*—Infections caused by these species need only be treated with chloroquine.

B. Uncomplicated Falciparum Malaria

P falciparum is resistant to chloroquine and sulfadoxine-pyrimethamine in most areas, and falciparum malaria should not be treated with these older drugs. ACTs, all including a short-acting artemisinin and longer-acting partner drug, are first-line therapies in nearly all endemic countries. The WHO recommends six ACTs to treat falciparum malaria (Table 40–3). Triple ACTs, including an artemisinin plus two partner drugs, have shown excellent treatment efficacy, and their use may delay the spread of resistance. In developed countries, malaria is an uncommon but potentially life-threatening infection of travelers and immigrants. Nonimmune individuals with falciparum

Table 40–2. Treatment of malaria.

Clinical Setting	Drug Therapy[1]	Alternative Drugs
Chloroquine-sensitive *Plasmodium falciparum* and *Plasmodium malariae* infections	Chloroquine phosphate, 1 g at 0 hours, then 500 mg at 6, 24, and 48 hours or Chloroquine phosphate, 1 g at 0 hours and 24 hours, then 0.5 g at 48 hours	
Plasmodium vivax and *Plasmodium ovale* infections	Chloroquine (as above), then (if G6PD normal) primaquine, 30-mg base daily for 14 days or tafenoquine 300 mg once	For infections from Indonesia, Papua New Guinea, and other areas with suspected resistance: therapies listed for uncomplicated chloroquine-resistant *P falciparum* plus primaquine
Uncomplicated infections with chloroquine-resistant *P falciparum*	Coartem (artemether 20 mg, lumefantrine 120 mg), four tablets twice daily for 3 days or Malarone, four tablets (total of 1 g of atovaquone, 400 mg of proguanil) daily for 3 days or Quinine sulfate, 650 mg three times daily for 3–7 days plus One of the following (when quinine given for < 7 days) Doxycycline, 100 mg twice daily for 7 days or Clindamycin, 600 mg twice daily for 7 days	Mefloquine, 15 mg/kg once or 750 mg, then 500 mg in 6–8 hours or Dihydroartemisinin-piperaquine[2] (dihydroartemisinin 40 mg, piperaquine 320 mg), four tablets daily for 3 days or ASAQ[2] (artesunate 100 mg, amodiaquine 270 mg), two tablets daily for 3 days
Severe or complicated infections with *P falciparum*	Artesunate 2.4 mg/kg intravenously every 12 hours for 1 day, then daily[3]	Quinidine gluconate,[4,5] 10 mg/kg intravenously over 1–2 hours, then 0.02 mg/kg intravenously/min or Quinidine gluconate,[4,5] 15 mg/kg intravenously over 4 hours, then 7.5 mg/kg intravenously over 4 hours every 8 hours or Quinine dihydrochloride,[2,4,5] 20 mg/kg intravenously over 4 hours, then 10 mg/kg intravenously every 8 hours or Artemether,[2,3] 3.2 mg/kg intramuscularly, then 1.6 mg/kg/day intramuscularly

[1] All dosages are oral and refer to salts unless otherwise indicated. See text for additional information on all agents, including toxicities and cautions. See CDC guidelines (phone: 877-FYI-TRIP; http://www.cdc.gov/malaria/) for additional information and pediatric dosing.
[2] Not available in the United States.
[3] With all parenteral regimens, change to an oral regimen as soon as the patient can tolerate it.
[4] Cardiac monitoring should be in place during intravenous administration of quinidine or quinine.
[5] Avoid loading doses in persons who have received quinine, quinidine, or mefloquine in the prior 24 hours.
G6PD, glucose-6-phosphate dehydrogenase.

malaria should generally be admitted to the hospital due to risks of rapid progression of disease. Several options are available for the treatment of uncomplicated falciparum malaria in the United States (Table 40–2).

C. Severe Falciparum Malaria

Severe malaria is a medical emergency. Parenteral treatment is indicated for severe malaria, as defined above, and with inability to take oral drugs. With appropriate prompt therapy and supportive care, rapid recoveries may be seen even in very ill individuals.

Intravenous artesunate is FDA-approved and the standard of care for severe malaria. It has superior efficacy and better tolerability than quinine (Table 40–2). If artesunate cannot be obtained promptly, severe malaria should be treated with intravenous quinine (available in most countries but not the United States), intravenous quinidine (not available in the United States), or an oral agent until intravenous artesunate is available. In endemic regions, if parenteral therapy is not available, intrarectal administration of artemether or artesunate is also effective. Patients receiving intravenous quinine or quinidine should receive continuous cardiac monitoring; if QTc prolongation exceeds 25% of baseline, the infusion rate should be reduced. Blood glucose should be monitored every 4–6 hours, and 5–10% dextrose may be coadministered to decrease the likelihood of hypoglycemia.

Appropriate care of severe malaria includes maintenance of fluids and electrolytes; respiratory and hemodynamic support; and consideration of blood transfusions,

Table 40–3. WHO recommendations for the treatment of uncomplicated falciparum malaria.

Regimen	Notes
Artemether-lumefantrine (Coartem, Riamet)	Coformulated, first-line therapy in many countries. Approved in the United States.
Artesunate-amodiaquine (ASAQ)	Coformulated, first-line therapy in multiple African countries.
Artesunate-mefloquine	First-line therapy in parts of Southeast Asia and South America but efficacy decreasing in parts of Thailand.
Artesunate-pyronaridine	Coformulated. Most recently approved regimen; used in some Southeast Asian countries.
Artesunate-sulfadoxine-pyrimethamine	First-line in some countries, but efficacy lower than other regimens in most areas.
Dihydroartemisinin-piperaquine	Coformulated. First-line in some countries, but efficacy decreasing in parts of Southeast Asia.

From World Health Organization: Guidelines for Malaria. https://www.who.int/publications/i/item/guidelines-for-malaria.

anticonvulsants, antibiotics for bacterial infections, and hemofiltration or hemodialysis. Exchange transfusion is sometimes used for those with high parasitemia (> 5–10%), but beneficial effects have not clearly been demonstrated.

D. Antimalarial Drugs

1. Chloroquine—Chloroquine is the drug of choice for the treatment of non-falciparum and sensitive falciparum malaria (Table 40–2). Chloroquine is active against erythrocytic parasites of all human malaria species. It does not eradicate hepatic stages. Chloroquine-resistant *P falciparum* is widespread in nearly all areas of the world with falciparum malaria, with the exceptions of Central America west of the Panama Canal and Hispaniola. Chloroquine-resistant *P vivax* has been reported most notably from Southeast Asia and Oceania.

Chloroquine rapidly terminates fever (in 24–48 hours) and clears parasitemia (in 48–72 hours) caused by sensitive parasites. It is the preferred chemoprophylactic agent in malarious regions without resistant falciparum malaria.

Chloroquine is usually well tolerated, even with prolonged use. Pruritus is common, primarily in patients from sub-Saharan Africa. Nausea, vomiting, abdominal pain, headache, malaise, blurring of vision, and urticaria are uncommon. Dosing after meals may reduce side effects.

2. Amodiaquine, piperaquine, and pyronaridine—Amodiaquine is a 4-aminoquinoline that is closely related to chloroquine. Amodiaquine has been widely used to treat malaria because of its low cost, limited toxicity, and, in some areas, effectiveness against chloroquine-resistant strains of *P falciparum*. Use of amodiaquine decreased after recognition of rare but serious side effects, notably agranulocytosis, aplastic anemia, and hepatotoxicity. However, serious side effects are rare with short-term use, and artesunate-amodiaquine is one of the standard ACTs recommended to treat falciparum malaria (Table 40–3). Chemoprophylaxis with amodiaquine should be avoided because of increased toxicity with long-term use.

Piperaquine is another 4-aminoquinoline that has been coformulated with dihydroartemisinin in an ACT. Piperaquine is well tolerated, and in combination with dihydroartemisinin offers a highly efficacious therapy for falciparum and vivax malaria. Due to the long half-life of piperaquine (~3 weeks), dihydroartemisinin-piperaquine offers the longest period of posttreatment prophylaxis of available ACTs. However, resistance to piperaquine, with consequent treatment failures of dihydroartemisinin-piperaquine, has emerged in Southeast Asia.

Pyronaridine is a benzonaphthyridine active against many drug-resistant strains of *P falciparum*. The combination of artesunate plus pyronaridine has shown excellent efficacy against falciparum and vivax malaria and has been well tolerated, although elevated transaminases can be seen.

3. Mefloquine—Mefloquine is effective against many chloroquine-resistant strains of *P falciparum* and against other malarial species. Although toxicity is a concern, mefloquine is also a recommended chemoprophylactic drug. Resistance to mefloquine has been reported sporadically from many areas, but it appears to be uncommon except in regions of Southeast Asia with high rates of multidrug resistance (especially border areas of Thailand). For uncomplicated malaria, mefloquine can be given as a single dose or in two doses over 1 day (Table 40–2). It is used in combination with artesunate for falciparum malaria, although resistance limits efficacy in Southeast Asia. It should be taken with meals and swallowed with a large amount of water. Mefloquine is recommended by the CDC for chemoprophylaxis in all malarious areas except those with no chloroquine resistance (where chloroquine is preferred) and some rural areas of Southeast Asia with a high prevalence of mefloquine resistance.

Side effects with weekly dosing of mefloquine for chemoprophylaxis include nausea, vomiting, dizziness, sleep and behavioral disturbances, epigastric pain, diarrhea, abdominal pain, headache, rash and, uncommonly, seizures and psychosis. There is an FDA black box warning about neuropsychiatric toxicity, possibly including rare, irreversible effects. Mefloquine should be avoided in persons with histories of psychiatric disease or seizures.

Side effects are more common (up to 50% of treatments) with the higher dosages of mefloquine required for treatment. These effects may be lessened by splitting administration into two doses separated by 6–8 hours. Serious neuropsychiatric toxicities (depression, confusion, acute psychosis, or seizures) have been reported in < 1 in 1000 treatments, but some authorities believe that these are more common. Mefloquine can also alter cardiac conduction, and so it should not be coadministered with quinine. Mefloquine is generally considered safe in young children and pregnant persons.

4. Quinine and quinidine—While artesunate is the standard of care for severe falciparum malaria, quinine dihydrochloride and quinidine gluconate are effective therapies for severe disease, although toxicity concerns complicate therapy (Table 40–2).

Resistance of *P falciparum* to quinine is common in some areas of Southeast Asia, where the drug may fail if used alone to treat falciparum malaria. However, quinine still provides at least a partial therapeutic effect in most patients.

Quinine and quinidine can be administered in divided doses or by continuous intravenous infusion; treatment should begin with a loading dose to rapidly achieve effective plasma concentrations and include cardiac monitoring. Therapy should be changed to an oral agent as soon as the patient has improved and can tolerate oral medications.

In areas without newer combination regimens, oral quinine sulfate is an alternative first-line therapy for uncomplicated falciparum malaria, although poor tolerance may limit compliance. Quinine is commonly used with a second drug (most often doxycycline) to shorten the duration of use (to 3 days) and limit toxicity. Therapeutic dosages of quinine and quinidine commonly cause tinnitus, headache, nausea, dizziness, flushing, and visual disturbances. Hematologic abnormalities include hemolysis (especially with G6PD deficiency), leukopenia, agranulocytosis, and thrombocytopenia. Therapeutic doses may cause hypoglycemia through stimulation of insulin release; this is a particular problem in severe infections and in pregnant patients, who have increased sensitivity to insulin. Overly rapid infusions can cause severe hypotension. ECG abnormalities (QT prolongation) are common, but dangerous arrhythmias are uncommon when the drugs are administered appropriately. Quinine should not be given concurrently with mefloquine and should be used with caution in a patient who has previously received mefloquine.

5. Primaquine and tafenoquine—Primaquine phosphate, a synthetic 8-aminoquinoline, is the drug of choice for the eradication of dormant liver forms of *P vivax* and *P ovale* (Table 40–2). Primaquine is active against hepatic stages of all human malaria parasites. This action is optimal soon after therapy with chloroquine or other agents. Primaquine also acts against erythrocytic stage parasites, although this activity is too weak for the treatment of active disease, and against gametocytes. The addition of a single low dose of primaquine to treatment of falciparum malaria with an ACT is a strategy to lower transmission to mosquitoes.

For *P vivax* and *P ovale* infections, chloroquine or other drugs are used to eradicate erythrocytic forms, and if the G6PD level is normal, a 14-day course of primaquine is initiated to eradicate liver hypnozoites and prevent a subsequent relapse; a 7-day course at twice the daily dose was equally effective, but with somewhat higher risk of toxicity. Some strains of *P vivax*, particularly in New Guinea and Southeast Asia, are relatively resistant to primaquine, and the drug may fail to eradicate liver forms.

Standard chemoprophylaxis does not prevent a relapse of *P vivax* or *P ovale* infections, since liver hypnozoites are not eradicated by chloroquine or other standard treatments. To diminish the likelihood of relapse, some authorities advocate the use of a treatment course of primaquine after the completion of travel to an endemic area. Primaquine can also be used for chemoprophylaxis to prevent *P falciparum* and *P vivax* infection in persons with normal levels of G6PD.

Primaquine in recommended doses is generally well tolerated. It infrequently causes nausea, epigastric pain, abdominal cramps, and headache, especially when taken on an empty stomach. Rare side effects include leukopenia, agranulocytosis, leukocytosis, and cardiac arrhythmias. Standard doses of primaquine may cause hemolysis or methemoglobinemia (manifested by cyanosis), especially in persons with G6PD deficiency or other hereditary metabolic defects. Patients should be tested for G6PD deficiency before primaquine is prescribed. Primaquine should be discontinued if there is evidence of hemolysis or anemia and should be avoided in pregnancy.

Tafenoquine, an 8-aminoquinoline, has a much longer half-life than primaquine. These two medications share the risk of hemolysis with G6PD deficiency and probably other toxicities; tafenoquine should not be used during pregnancy or in those with G6PD deficiency. Tafenoquine is FDA-approved for patients at least 16 years of age for two indications, but with different formulations, marketed by different companies. To eliminate hepatic stages of *P vivax*, a single dose (Krintafel, two 150-mg tablets once daily) is taken with food soon after initiation of primary therapy (with chloroquine or other agents). For malaria chemoprophylaxis, the drug (Arakoda, two 100-mg tablets) is taken once daily for 3 days and then weekly until 1 week after the last exposure.

6. Inhibitors of folate synthesis—Sulfadoxine and pyrimethamine are inhibitors of two parasite enzymes involved in folate metabolism, dihydropteroate synthase (DHPS) and dihydrofolate reductase (DHFR). They are used in combination for the treatment and prevention of malaria.

Fansidar is a fixed combination of sulfadoxine (500 mg) and pyrimethamine (25 mg). It is not advised for chemoprophylaxis due to rare serious side effects with long-term dosing. For treatment, advantages of sulfadoxine-pyrimethamine include ease of administration (a single oral dose) and low cost. However, resistance is a major problem.

Sulfadoxine-pyrimethamine is recommended by the WHO for monthly preventive therapy in pregnant women and perennial malaria chemoprevention in children in areas of high endemicity, although its efficacy is limited by resistance. Amodiaquine plus sulfadoxine-pyrimethamine is recommended monthly during the rainy season (known as seasonal malaria chemoprevention [SMC]) for chemoprevention in regions of West Africa with seasonal malaria transmission and limited drug resistance.

7. Artemisinins—Artemisinins act rapidly against all erythrocytic-stage human malaria parasites. Of concern, delayed clearance of parasites after treatment with artemisinins, termed *artemisinin partial resistance*, and failures of ACTs (when there is resistance also to partner drugs) were first seen in southeast Asia, and now may be emerging in Africa.

Artemisinins play a vital role in the treatment of malaria, including multidrug-resistant *P falciparum* malaria. Due to their short plasma half-lives, recrudescence rates are unacceptably high after short-course therapy, leading to approved use only as *initial* therapy for severe malaria and in ACTs for uncomplicated malaria. The ACTs that are most advocated in Africa are artemether plus lumefantrine (Coartem) and artesunate plus amodiaquine (ASAQ), each available as a coformulated product. Artesunate plus mefloquine is not as well tolerated and is used mostly outside of Africa; its efficacy has declined in parts of Southeast Asia. Dihydroartemisinin-piperaquine has shown excellent efficacy and is the first-line regimen in some countries in Southeast Asia, but efficacy has declined in Cambodia due to decreased activity of both components of the regimen. The newest approved ACT, artesunate-pyronaridine, has demonstrated excellent efficacy.

Artemisinins are very well tolerated. The most commonly reported side effects have been nausea, vomiting, and diarrhea, which may often be due to acute malaria, rather than drug toxicity. Neutropenia, anemia, hemolysis, and elevated levels of liver enzymes have been noted rarely. Hemolysis may occur weeks after therapy with intravenous artesunate. Artesunate and artemether also effectively treat severe malaria when administered rectally, offering a valuable treatment modality when parenteral therapy is not available. Artemisinins are teratogenic in animals, but with the good safety seen in humans and the importance of effectively treating malaria during pregnancy, the WHO recommends ACTs to treat uncomplicated malaria and intravenous artesunate to treat complicated malaria during all trimesters of pregnancy.

8. Atovaquone plus proguanil (Malarone)—Atovaquone, a hydroxynaphthoquinone, is not effective when used alone, due to rapid development of drug resistance. However, Malarone, a fixed combination of atovaquone (250 mg) and the antifolate proguanil (100 mg), is highly effective for both the treatment and chemoprophylaxis of falciparum malaria, and it is approved for both indications in the United States (Table 40–2). It also appears to be active against other species of malaria parasites. Unlike most other antimalarials, Malarone provides activity against both erythrocytic and hepatic stage parasites.

For treatment, Malarone is given at an adult dose of four tablets daily for 3 days (Table 40–4). For chemoprophylaxis, Malarone must be taken daily. It has an advantage over mefloquine and doxycycline in requiring shorter durations of treatment before and after the period at risk for malaria transmission, due to activity against liver-stage parasites. It should be taken with food.

Malarone is generally well tolerated. Side effects include abdominal pain, nausea, vomiting, diarrhea, headache, and rash, and these are more common with the higher dose required for treatment. Reversible elevations in liver enzymes have been reported. The safety of atovaquone in pregnancy is unknown.

9. Antibiotics—A number of antibacterials in addition to the folate antagonists and sulfonamides are slow-acting antimalarials. None of the antibiotics should be used as single agents for the treatment of malaria due to their slow rate of action.

Doxycycline is commonly used in the treatment of falciparum malaria in conjunction with quinidine or quinine,

Table 40–4. Drugs for the prevention of malaria in travelers.[1]

Drug	Use[2]	Adult Dosage (all oral)[3]
Chloroquine	Areas without resistant *Plasmodium falciparum*	500 mg weekly
Malarone	Areas with multidrug-resistant *P falciparum*	1 tablet (250-mg atovaquone/100-mg proguanil) daily
Mefloquine	Areas with chloroquine-resistant *P falciparum*	250 mg weekly
Doxycycline	Areas with multidrug-resistant *P falciparum*	100 mg daily
Primaquine[4]	Terminal prophylaxis of *Plasmodium vivax* and *Plasmodium ovale* infections; alternative for *P falciparum* prophylaxis	30-mg base daily: for terminal prophylaxis take for 14 days after travel; for chemoprevention begin 1–2 days before travel, take during travel and for 7 days after travel
Tafenoquine[4]	Alternative for *P falciparum* prophylaxis	200 mg once daily for 3 days and then weekly until 1 week after last exposure

[1] Recommendations may change, as resistance to all available drugs is increasing. See text for additional information on toxicities and cautions. For additional details and pediatric dosing, see CDC guidelines (phone: 800-CDC-INFO; http://wwwnc.cdc.gov/travel/). Travelers to remote areas should consider carrying effective therapy (see text) for use if a febrile illness develops, and they cannot reach medical attention quickly.

[2] Areas without known chloroquine-resistant *P falciparum* are Central America west of the Panama Canal, Haiti, Dominican Republic, Egypt, and most malarious countries of the Middle East. Malarone or mefloquine is currently recommended for other malarious areas except for border areas of Thailand, where doxycycline is recommended.

[3] For drugs other than primaquine, begin 1–2 weeks before departure (except 2 days before for doxycycline and Malarone) and continue for 4 weeks after leaving the endemic area (except 1 week for Malarone). All dosages refer to salts unless otherwise indicated.

[4] Screen for glucose-6-phosphate dehydrogenase deficiency before using primaquine.

allowing a shorter and better-tolerated course of those drugs (Table 40–2). Doxycycline is also a standard chemoprophylactic drug (Table 40–4). Doxycycline side effects include GI symptoms, candidal vaginitis, and photosensitivity. The drug should be taken while upright with a large amount of water to avoid esophageal irritation. Clindamycin can be used in conjunction with quinine or quinidine in those for whom doxycycline is not recommended, such as children and pregnant persons (Table 40–2). The most common toxicities with clindamycin are GI.

10. Lumefantrine—Lumefantrine, an aryl alcohol, is available only as a fixed-dose combination with artemether (Coartem or Riamet). Oral absorption is highly variable and improved when the drug is taken with food. Use of Coartem with a fatty meal is recommended. Coartem is highly effective for the treatment of falciparum malaria, but it requires twice-daily dosing. Despite this limitation, due to its reliable efficacy against falciparum malaria, Coartem is the first-line therapy for malaria in many malarious countries and is the most widely used antimalarial in the world. Coartem is well tolerated; side effects include headache, dizziness, loss of appetite, GI symptoms, and palpitations. Importantly, Coartem does not generally cause QT prolongation or serious cardiac toxicity.

Prevention

1. General approach—Malaria is transmitted by night-biting anopheline mosquitoes. Bed nets, in particular nets treated with permethrin insecticides, are heavily promoted as inexpensive means of antimalarial protection, but effectiveness varies in part due to widespread insecticide resistance. Indoor spraying of insecticides is generally highly effective in Africa but limited by resource constraints. When travelers from nonendemic to endemic countries are counseled on the prevention of malaria, it is imperative to emphasize measures to prevent mosquito bites (insect repellents, insecticides, and bed nets), since no chemoprophylactic regimen is fully protective.

2. Malaria vaccine—The RTS,S vaccine, which is based on a sporozoite antigen, has been widely studied; multiple trials showed about 25–50% protection against malaria in children in the year after immunization, but lower levels of protection in very young children, in areas of highest malaria exposure, and over longer periods of time. Seasonal malaria immunization, using the RTS,S vaccine in conjunction with SMC during the high transmission season, has shown excellent preventive efficacy. The R21 vaccine, with the same antigen as RTS,S but a different adjuvant, showed at least equivalent protection. Both the RTS,S and R21 vaccines are gradually being rolled out for young children in Africa. Other approaches under study include vaccines containing erythrocytic, liver-stage, and sexual-stage antigens, and use of radiation-attenuated or molecularly attenuated sporozoites.

3. Chemoprophylaxis—Chemoprophylaxis is recommended for all travelers from nonendemic regions to endemic areas, although risks vary greatly for different locations, and some tropical areas entail no risk; specific recommendations for travel to different locales are available from the CDC (www.cdc.gov). Recommendations from the CDC include the use of chloroquine for chemoprophylaxis in the few areas with only chloroquine-sensitive malaria parasites (principally the Caribbean and Central America west of the Panama Canal), and Malarone, mefloquine, or doxycycline for other areas (Table 40–4). Primaquine and tafenoquine are also effective but not used as often. In some circumstances, it may be appropriate for travelers to not use chemoprophylaxis but to carry supplies of drugs (ACTs or Malarone) with them in case a febrile illness develops and medical attention is unavailable. Most authorities do not recommend routine terminal prophylaxis with primaquine to eradicate dormant hepatic stages of *P vivax* and *P ovale* after travel, but this may be appropriate for travelers with major exposure to these parasites.

Regular chemoprophylaxis is not a standard management practice in developing world populations due to the expense and potential toxicities of long-term therapy. However, intermittent preventive therapy, whereby at-risk populations receive antimalarial therapy at set intervals, may decrease the incidence of malaria while allowing antimalarial immunity to develop. During pregnancy, intermittent preventive therapy with sulfadoxine-pyrimethamine, provided monthly during the second and third trimesters, has improved pregnancy outcomes. With increasing resistance, the preventive efficacy of sulfadoxine-pyrimethamine is likely falling, and the long-acting ACT dihydroartemisinin-piperaquine is a promising replacement. In areas with seasonal malaria transmission and limited drug resistance, principally the Sahel subregion of West Africa, SMC (monthly amodiaquine plus sulfadoxine-pyrimethamine during the transmission season) is widely practiced. A new approach, injection of long-acting monoclonal antibodies to prevent malaria, has shown promise in clinical trials.

Prognosis

When treated appropriately, uncomplicated malaria generally responds well, with resolution of fevers within 1–2 days and a mortality of about 0.1%. Severe malaria can commonly progress to death, but many children respond well to therapy. In the developed world, mortality from malaria is mostly in adults, and often follows extended illnesses and secondary complications long after eradication of the malarial infection. Pregnant persons are at particular risk during their first pregnancy. Malaria in pregnancy also increases the likelihood of poor pregnancy outcomes, with increased prematurity, low birth weight, and mortality.

When to Refer

- Referral to an expert on infectious diseases or travel medicine is important with all cases of malaria in the United States
- For falciparum malaria, referral should not delay initial diagnosis and therapy, since delays in therapy can lead to severe illness or death.

When to Admit

- Admission for non-falciparum malaria is warranted only if specific problems that require hospital management are present.
- Patients with falciparum malaria are generally admitted because the disease can progress rapidly to severe illness; exceptions may be made with individuals who are from malaria-endemic areas, and thus expected to have a degree of immunity, who are without evidence of severe disease, and who are judged able to return promptly for medical attention if their disease progresses.

BABESIOSIS

ESSENTIALS OF DIAGNOSIS

- History of tick bite or exposure to ticks.
- Fever, flu-like symptoms, anemia.
- Intraerythrocytic parasites on Giemsa-stained blood smears.
- Positive serologic tests.

General Considerations

Babesiosis is an uncommon intraerythrocytic infection caused by *Babesia* species and transmitted by *Ixodes* ticks. In the United States, hundreds of cases of babesiosis have been reported, and infection is caused by *Babesia microti,* which also infects wild mammals. Most babesiosis in the United States occurs in the coastal northeast, with some cases also in the upper Midwest, following the geographic range of the vector *Ixodes scapularis*, and Lyme disease and anaplasmosis, which are spread by the same vector. Babesiosis is caused by *Babesia divergens* and related species in Europe and Asia. Babesiosis due to other *Babesia*-like organisms has been reported uncommonly from the western United States. Babesiosis can also be transmitted by blood transfusion, but blood supplies are not screened. A survey of a large set of blood samples from endemic regions of the United States identified approximately 0.4% as potentially infectious for *B microti*.

Clinical Findings

A. Symptoms and Signs

Serosurveys suggest that asymptomatic infections are common in endemic areas. With *B microti* infections, symptoms appear one to several weeks after a tick bite; parasitemia is evident after 2–4 weeks. Patients usually do not recall the tick bite. The typical flu-like illness develops gradually and is characterized by fever, malaise, fatigue, headache, anorexia, and myalgia. Other findings may include nausea, vomiting, abdominal pain, arthralgia, sore throat, depression, emotional lability, anemia, thrombocytopenia, elevated transaminases, and splenomegaly. Parasitemia may continue for months to years, with or without symptoms, and the disease is usually self-limited. Severe complications are most likely to occur in older persons or in those who have had splenectomy. Serious complications include respiratory failure, hemolytic anemia, disseminated intravascular coagulation, heart failure, and AKI. In a study of hospitalized patients, the mortality rate was 6.5%. Most recognized *B divergens* infections in Europe have been in patients who have had splenectomy. These infections progress rapidly with high fever, severe hemolytic anemia, jaundice, hemoglobinuria, and AKI, with death rates > 40%.

B. Laboratory Findings

Identification of the intraerythrocytic parasite on Giemsa-stained blood smears establishes the diagnosis. Repeated smears are often necessary because well under 1% of erythrocytes may be infected, especially early in infection, although parasitemias can exceed 10%. Diagnosis can also be made by PCR, which is more sensitive than blood smear. An indirect immunofluorescent antibody test for *B microti* is available from the CDC; antibody is detectable within 2–4 weeks after the onset of symptoms and persists for months, and a fourfold increase in antibody titer between acute and convalescent sera confirms acute infection.

Treatment

Most patients have a mild illness and recover without therapy. Standard therapy for mild to moderate disease is a 7-day course of atovaquone (750 mg orally every 12 hours) plus azithromycin (600 mg orally once daily), which is equally effective and better tolerated than the alternative regimen, a 7-day course of quinine (650 mg orally three times daily) plus clindamycin (600 mg orally three times daily). However, there is more experience using quinine plus clindamycin, and this regimen is recommended by some experts for severe disease. Exchange transfusion has been used successfully in severely ill asplenic patients and those with parasitemia > 10%.

Heller HM. Babesiosis in immunosuppressed hosts: pathogenesis, diagnosis and management. Curr Opin Infect Dis. 2024;37:327. [PMID: 39109671]

TOXOPLASMOSIS

ESSENTIALS OF DIAGNOSIS

- Infection confirmed by isolation of *Toxoplasma gondii* or identification of tachyzoites in tissue or body fluids.

Primary infection

- Fever, malaise, headache, sore throat.
- Lymphadenopathy.
- Positive IgG and IgM serologic tests.

Congenital infection

- After acute infection in seronegative mothers, CNS abnormalities and retinochoroiditis in offspring.

Infection in immunocompromised persons

- Reactivation leads to encephalitis, retinochoroiditis, pneumonitis, myocarditis.
- Positive IgG but negative IgM serologic tests.

General Considerations

T gondii, an obligate intracellular protozoan, is found worldwide in humans and in many species of mammals and birds. The definitive hosts are cats. Humans are infected after ingestion of cysts in raw or undercooked meat, ingestion of oocysts in food or water contaminated by cats, transplacental transmission of trophozoites or, rarely, direct inoculation of trophozoites via blood transfusion or organ transplantation. *Toxoplasma* seroprevalence varies widely. It is < 20% in the United States, but higher in other countries in both the developed and developing worlds, where it may exceed 80%. In the United States, *T gondii* is estimated to infect 1.1 million persons each year, with resultant chorioretinitis developing in 21,000 and vision loss in 4800.

Clinical Findings

A. Symptoms and Signs

The clinical manifestations of toxoplasmosis may be grouped into four syndromes.

1. Primary infection in the immunocompetent person— After ingestion, *T gondii* infection progresses from the GI tract to lymphatics, and then dissemination. Most acute infections are asymptomatic. About 10–20% are symptomatic after an incubation period of 1–2 weeks. Acute infections in immunocompetent persons typically present as mild, febrile illnesses that resemble infectious mononucleosis. Nontender cervical or diffuse lymphadenopathy may persist for weeks to months. Systemic findings may include fever, malaise, headache, sore throat, rash, myalgias, hepatosplenomegaly, and atypical lymphocytosis. Rare severe manifestations are pneumonitis, meningoencephalitis, hepatitis, myocarditis, polymyositis, and retinochoroiditis. Symptoms may fluctuate; most patients recover spontaneously within a few months.

2. Congenital infection—Congenital transmission occurs as a result of infection, which may be symptomatic or asymptomatic, in a nonimmune woman during pregnancy. Fetal infection follows maternal infection in 30–50% of cases, but this risk varies by trimester: 10–25% during the first, 30–50% during the second, and 60% or higher during the third trimester. In the United States, an estimated 400 to 4000 congenital infections occur yearly. While the risk of fetal infection increases, the risk of severe fetal disease decreases over the course of pregnancy. Early fetal infections commonly lead to spontaneous abortion, stillbirths, or severe neonatal disease, including neurologic manifestations. Retinochoroiditis and other sight-threatening eye lesions may develop. Infections later in pregnancy less commonly lead to major fetal problems. Most infants appear normal at birth, but they may have subtle abnormalities and progress to symptoms and signs of congenital toxoplasmosis later in life.

3. Retinochoroiditis—The most common late presentation of congenital toxoplasmosis is retinochoroiditis, which presents weeks to years after congenital infection, commonly in teenagers or young adults. Retinochoroiditis also occurs in persons who acquire infection early in life, and these patients more often present with unilateral disease. Uveitis is also seen. Disease presents with pain, photophobia, and visual changes, usually without systemic symptoms. Signs and symptoms eventually improve, but visual defects may persist. Rarely, progression may result in glaucoma and blindness.

4. Disease in the immunocompromised person—Reactivated toxoplasmosis occurs in patients with AIDS, cancer, or those taking immunosuppressive drugs. In advanced AIDS, the most common manifestation is encephalitis, with multiple necrotizing brain lesions. The encephalitis usually presents subacutely, with fever, headache, altered mental status, focal neurologic findings, and other evidence of brain lesions. Less common manifestations of toxoplasmosis in AIDS are chorioretinitis and pneumonitis. Chorioretinitis presents with ocular pain and alterations in vision. Pneumonitis presents with fever, cough, and dyspnea. Toxoplasmosis can develop in recipients of solid organ or bone marrow transplants due to reactivation or, rarely, transmission of infection. Reactivation also can occur in those with hematologic malignancies or treated with immunosuppressive drugs. With primary or reactivated disease in those with immunodeficiency due to malignancy or immunosuppressive drugs, toxoplasmosis is similar to that in individuals with AIDS, but pneumonitis and myocarditis are more common.

B. Diagnostic Testing

1. Identification of parasites—Organisms can be seen in tissue or body fluids, although they may be difficult to identify; special staining techniques can facilitate identification. The demonstration of tachyzoites indicates acute infection; cysts may represent either acute or chronic infection. With lymphadenopathy, examination of lymph nodes usually does not show organisms. Parasite identification can also be made by inoculation of tissue culture or mice. PCR can be used for sensitive identification of organisms in amniotic fluid, blood, CSF, aqueous humor, and bronchoalveolar lavage fluid.

2. Serologic diagnosis—Multiple serologic methods are used, including the Sabin-Feldman dye test, ELISA, indirect fluorescent antibody test, and agglutination tests. IgG antibodies are seen within 1–2 weeks of infection and usually persist for life. IgM antibodies peak earlier than IgG and decline more rapidly, although they may persist for years. In immunocompromised individuals in whom reactivation is suspected, a positive IgG assay indicates distant infection, and thus the potential for reactivated disease; a negative IgG argues strongly against reactivation toxoplasmosis. With reactivation in immunocompromised persons, IgM tests are generally negative.

3. During pregnancy and in newborns—Maternal conversion from a negative to positive serologic test or rising titers are suggestive of acute infection, but tests are not routinely performed during pregnancy. When pregnant persons are screened, negative IgG and IgM assays exclude active infection, but indicate the risk of infection during the pregnancy. Positive IgG with negative IgM is highly suggestive of chronic infection, with no risk of congenital disease unless the mother is severely immunocompromised. A positive IgM test is concerning for new maternal infection because of the risk of congenital disease. Confirmatory testing should be performed before consideration of treatment or possible termination of pregnancy due to the limitations of available tests. Tests of the avidity of antibodies can be helpful, but a battery of tests is needed for confirmation of acute infection during pregnancy. When acute infection during pregnancy is suspected, PCR of amniotic fluid offers a sensitive assessment for congenital disease. In newborns, positive IgM or IgA antibody tests are indicative of congenital infection, although the diagnosis is not ruled out by a negative test. Positive IgG assays may represent transfer of maternal antibodies without infection of the infant, but persistence of positive IgG beyond 12 months of age is diagnostic of congenital infection. PCR of blood, CSF, or urine can also be helpful for early diagnosis of congenital disease.

4. In immunocompetent individuals—Individuals with a suggestive clinical syndrome should be tested for IgG and IgM antibodies. Seroconversion, a 16-fold rise in antibody titer, or an IgM titer > 1:64 is suggestive of acute infection, although false-positive results may occur. Acute infection can also be diagnosed by detection of tachyzoites in tissue, culture of organisms, or PCR of blood or body fluids. Histologic evaluation of lymph nodes can show characteristic morphology, with or without organisms.

5. In immunocompromised individuals—A presentation consistent with toxoplasmic encephalitis warrants imaging of the brain. CT and MRI scans typically show multiple ring-enhancing cerebral lesions, most commonly involving the corticomedullary junction and basal ganglia. MRI is the more sensitive imaging modality. In patients with AIDS who have a positive IgG serologic test and no recent anti-*Toxoplasma* or antiviral therapy, the predictive value of a typical imaging study is about 80%. The other common diagnosis in this setting is CNS lymphoma, which more typically causes a single brain lesion. The differential diagnosis also includes tuberculoma, bacterial brain abscess, fungal abscess, and carcinoma. Diagnosis of CNS toxoplasmosis is most typically made after a therapeutic trial, with clinical and radiologic improvement expected within 2–3 weeks. Definitive diagnosis requires brain biopsy and search for organisms and typical histology. In retinochoroiditis, funduscopic examination shows vitreous inflammatory reaction, white retinal lesions, and pigmented scars. Diagnosis of other clinical entities in immunocompromised individuals is generally based on histology.

Treatment

A. Approach to Treatment

1. For immunocompetent persons—Therapy is generally not necessary in immunocompetent persons, since the primary illness is self-limited. However, for severe, persistent, or visceral disease, treatment for 2–4 weeks may be considered. Treatment is appropriate for primary infection during pregnancy because the risk of fetal transmission or the severity of congenital disease may be reduced. For retinochoroiditis, most episodes are self-limited, and opinions vary on indications for treatment. Treatment is often advocated for episodes with decreases in visual acuity, multiple or large lesions, macular lesions, significant inflammation, or persistence for > 1 month.

2. For immunocompromised persons—Patients with active infection must be treated. For those with transient immunodeficiency, therapy can be continued for 4–6 weeks after cessation of symptoms. For those with persistent immunodeficiency, such as patients with AIDS, full therapy for 4–6 weeks is followed by maintenance therapy with lower doses of drugs. Immunodeficient patients who are asymptomatic but have a positive IgG serologic test should receive long-term chemoprophylaxis.

B. Medications

Drugs for toxoplasmosis are active only against tachyzoites, so they do not eradicate infection. Standard therapy is the combination of pyrimethamine (200-mg orally as a loading dose, then 50–75 mg [1 mg/kg] once daily) plus sulfadiazine (1–1.5 g orally four times daily), with folinic acid (10–20 mg orally once daily) to prevent bone marrow suppression. Patients should be screened for a history of sulfonamide sensitivity (skin rashes, GI symptoms, hepatotoxicity). To prevent sulfonamide crystal-induced nephrotoxicity, good urinary output should be maintained. Pyrimethamine side effects include headache and GI symptoms. Even with folinic acid therapy, bone marrow suppression may occur; platelet and WBC counts should be monitored at least weekly. A first-line alternative is pyrimethamine plus clindamycin (600 mg orally four times daily). Another alternative is TMP-SMZ. Pyrimethamine is not used during the first trimester of pregnancy due to its teratogenicity. Standard therapy for acute toxoplasmosis during pregnancy is spiramycin (1 g orally three times daily until delivery), which reduces the frequency of transmission to the fetus by about 60%. Spiramycin does not cross the placenta, so when fetal infection is documented or for acute infections late in pregnancy (which commonly lead to fetal transmission), treatment with combination regimens as described above is indicated.

Prevention

Prevention of primary infection centers on avoidance of undercooked meat or contact with material contaminated by cat feces, particularly for seronegative pregnant persons and immunocompromised persons. Irradiation, cooking to 66°C, or freezing to −20°C kills tissue cysts. Thorough cleaning of hands and surfaces is needed after contact with raw meat or areas contaminated by cats. Oocysts passed in cat feces can remain infective for a year or more, but fresh oocysts are not infective for 48 hours. For best protection, litter boxes should be changed daily and soaked in boiling water for 5 minutes, gloves should be worn when gardening, fruits and vegetables should be thoroughly washed, and ingestion of dried meat should be avoided.

Universal screening of pregnant persons for *T gondii* antibodies is conducted in some countries but not the United States. Pregnant persons should ideally have their serum examined for IgG and IgM antibody, and those with negative titers should adhere to the prevention measures described above. Seronegative women who continue to have environmental exposure should undergo repeat serologic screening several times during pregnancy.

For immunocompromised individuals, chemoprophylaxis to prevent primary or reactivated infection is warranted. For hematopoietic cell transplant recipients and patients with advanced AIDS, chemoprophylaxis with TMP-SMZ (one double-strength tablet orally daily or two tablets three times weekly), used for protection against *Pneumocystis*, is effective against *T gondii*. Alternatives are pyrimethamine plus either sulfadoxine or dapsone (various regimens). In patients with AIDS, chemoprophylaxis can be discontinued if antiretroviral therapy leads to immune reconstitution.

Miyagaki M et al. Ocular toxoplasmosis: advances in *Toxoplasma gondii* biology, clinical manifestations, diagnostics, and therapy. Pathogens. 2024;13:898. [PMID: 39452769]

AMEBIASIS

ESSENTIALS OF DIAGNOSIS

- Organisms or antigen present in stools or abscess aspirate.
- Positive serologic tests with colitis or hepatic abscess, but these may represent prior infections.
- Mild to moderate colitis with recurrent diarrhea.
- Severe colitis: bloody diarrhea, fever, and abdominal pain, with potential progression to hemorrhage or perforation.
- Hepatic abscess: fever, hepatomegaly, and abdominal pain.

General Considerations

The *Entamoeba* complex contains three morphologically identical species: *Entamoeba dispar* and *Entamoeba moshkovskii*, which are avirulent, and *Entamoeba histolytica*, which may be an avirulent intestinal commensal or lead to serious disease. Disease follows penetration of *E histolytica* into the intestinal wall, resulting in diarrhea, and with severe involvement, dysentery or extraintestinal disease, most commonly liver abscess.

E histolytica infections are present worldwide but are most prevalent in subtropical and tropical areas under conditions of crowding, poor sanitation, and poor nutrition. Of the estimated 500 million persons worldwide infected with *Entamoeba*, most are infected with *E dispar* and an estimated 10% with *E histolytica*. The prevalence of *E moshkovskii* is unknown. Mortality from invasive *E histolytica* infections is estimated at 100,000 per year.

Humans are the only established *E histolytica* host. Transmission occurs through ingestion of cysts from fecally contaminated food or water, facilitated by person-to-person spread, flies and other arthropods as mechanical vectors, and use of human excrement as fertilizer. Urban outbreaks have occurred because of common-source water contamination.

Clinical Findings

A. Symptoms and Signs

1. Intestinal amebiasis—In most infected persons, the organism lives as a commensal, and the carrier is without symptoms. With symptomatic disease, diarrhea usually begins after an incubation period of 2–4 weeks (but may begin within a week of infection), with gradual onset of abdominal pain and diarrhea. Fever is uncommon. Periods of remission and recurrence may last days, weeks, or longer. Abdominal examination may show distention, tenderness, hyperperistalsis, and hepatomegaly. Microscopic hematochezia is common. More severe presentations include colitis and dysentery, with worse diarrhea (10–20 stools per day) and bloody stools. With dysentery, physical findings include high fevers, prostration, vomiting, abdominal pain and tenderness, hepatic enlargement, and hypotension. Severe presentations are more common in young children, pregnant persons, those who are malnourished, and those receiving corticosteroids. Thus, in endemic regions, corticosteroids should not be started for presumed IBD without first ruling out amebiasis. Fulminant amebic colitis can progress to necrotizing colitis, intestinal perforation, mucosal sloughing, and severe hemorrhage, with mortality rates > 40%. More long-term complications include chronic diarrhea with weight loss, which may last for months to years; bowel ulcerations;

and amebic appendicitis. Localized granulomatous lesions (amebomas) can present after either dysentery or chronic intestinal infection. Clinical findings include pain, obstructive symptoms, and hemorrhage and may suggest intestinal carcinoma.

2. Extraintestinal amebiasis—The most common extraintestinal manifestation is amebic liver abscess. This can occur with colitis, but more frequently presents without a history of prior intestinal symptoms. Patients have acute or gradual onset of abdominal pain, fever, an enlarged and tender liver, anorexia, and weight loss. Diarrhea is present in a small number of patients. Physical examination may show intercostal tenderness. Abscesses are most commonly single and in the right lobe of the liver, and they are much more common in men. Without prompt treatment, amebic abscesses may rupture into the pleural, peritoneal, or pericardial space, which is often fatal. Amebic infections may rarely occur throughout the body, including the lungs, brain, and genitourinary system.

B. Laboratory Findings

Laboratory studies with intestinal amebiasis show leukocytosis and hematochezia, with fecal leukocytes not present in all cases. With extraintestinal amebiasis, leukocytosis and elevated liver function studies are seen.

C. Diagnostic Testing

1. Intestinal amebiasis—Diagnosis is most commonly made by identifying organisms in the stool. *E histolytica* and *E dispar* cannot be distinguished, but the identification of amebic trophozoites or cysts in a symptomatic patient is highly suggestive of amebiasis. Stool evaluation for organisms is not highly sensitive (~30–50% for amebic colitis), and at least three stool specimens should be evaluated after concentration and staining. Multiple serologic assays are available; these tests are sensitive, although sensitivity is lower (~70% in colitis) early in illness, and they cannot distinguish recent and old disease, as they remain positive for years after infection. Commercially available stool antigen tests (TechLab II, CELISA, QUIK CHEK) can distinguish *E histolytica* from nonpathogenic species and offer improved sensitivity (> 90% for colitis). The QUIK CHEK assay is FDA-approved, offers rapid point-of-care diagnosis, and is available in a combined assay for amebiasis, giardiasis, and cryptosporidiosis. Highly sensitive molecular tests are not used routinely but available in some high-resource settings within commercial panels for identifying gut pathogens. Colonoscopy of uncleansed bowel typically shows no specific findings in mild intestinal disease; in severe disease, ulcers may be found with intact intervening friable mucosa, resembling IBD. Examination of fresh ulcer exudate for motile trophozoites and for *E histolytica* antigen may yield a diagnosis.

2. Hepatic abscess—Serologic tests for anti-amebic antibodies are almost always positive, except very early in the infection. Thus, a negative test in a suspicious case should be repeated in about a week. The TechLab II antigen test can be used to test serum with good sensitivity if used before the initiation of therapy. Examination of stools for organisms or antigen is frequently negative; the antigen test is positive in approximately 40% of cases. As imaging studies cannot distinguish amebic and pyogenic abscesses, when a diagnosis is not available from serologic studies, percutaneous aspiration may be indicated, ideally with an image-guided needle. Aspiration typically yields brown or yellow fluid. Detection of organisms in the aspirate is uncommon, but detection of *E histolytica* antigen is very sensitive and diagnostic. The key risk of aspiration is peritoneal spillage leading to peritonitis from amoebas or other (pyogenic or echinococcal) organisms.

D. Imaging

Liver abscesses can be identified by ultrasonography, CT, or MRI, typically with round or oval low-density nonhomogeneous lesions, with abrupt transition from normal liver to the lesion, and hypoechoic centers. Abscesses are most commonly single, but more than one may be present. The right lobe is usually involved.

▶ Treatment

Treatment of amebiasis generally entails the use of metronidazole or tinidazole to eradicate tissue trophozoites and a luminal amebicide to eradicate intestinal cysts (Table 40–5).

1. Asymptomatic infection with *E dispar*—This infection does not require therapy. This organism cannot be differentiated morphologically from *E histolytica*, but serology for *E histolytica* is negative. *E dispar* colonization is likely, and treatment is not indicated.

2. Asymptomatic infection with *E histolytica*—This infection is treated with a luminal agent. Effective luminal agents are diloxanide furoate, iodoquinol (diiodohydroxyquinoline), and paromomycin. Side effects associated with luminal agents are flatulence with diloxanide furoate, mild diarrhea with iodoquinol, and GI symptoms with paromomycin. Relative contraindications are thyroid disease for iodoquinol and kidney disease for iodoquinol or paromomycin.

3. Intestinal amebiasis with *E histolytica*—Treatment of intestinal amebiasis requires metronidazole or tinidazole plus a luminal agent (Table 40–5). Tinidazole offers simpler dosing, a more rapid clinical response, and fewer side effects than metronidazole. Side effects from either agent include transient nausea, vomiting, epigastric discomfort, headache, or a metallic taste. A disulfiram-like reaction may occur if alcohol is co-ingested. Metronidazole and tinidazole should be avoided in pregnant or nursing mothers, if possible. Fluid and electrolyte replacement is also important for patients with significant diarrhea. Surgical management of acute complications of intestinal amebiasis is best avoided whenever possible. Successful therapy of severe amebic colitis may be followed by postdysenteric colitis, with continued diarrhea without persistent infection; this syndrome generally resolves in weeks to months.

4. Amebic hepatic abscess—This is also treated with metronidazole or tinidazole plus a luminal agent (even if intestinal

Table 40–5. Treatment of *E histolytica* amebiasis.[1]

Clinical Setting	Drugs of Choice and Adult Dosage	Alternative Drugs and Adult Dosage
Asymptomatic intestinal infection	**Luminal agent:** Diloxanide furoate,[2] 500 mg orally three times daily for 10 days or Iodoquinol, 650 mg orally three times daily for 21 days or Paromomycin, 10 mg/kg orally three times daily for 7 days	
Mild to moderate intestinal infection	Metronidazole, 750 mg orally three times daily (or 500 mg intravenously every 6 hours) for 10 days or Tinidazole, 2 g orally daily for 3–5 days **plus** Luminal agent (see above)	Luminal agent (see above) plus either Tetracycline, 250 mg orally three times daily for 10 days or Erythromycin, 500 mg orally four times daily for 10 days
Severe intestinal infection	Metronidazole, 750 mg orally three times daily (or 500 mg intravenously every 6 hours) for 10 days or Tinidazole, 2 g orally daily for 3–5 days **plus** Luminal agent (see above)	Luminal agent (see above) plus either Tetracycline, 250 mg orally three times daily for 10 days or Dehydroemetine[2] or emetine,[2] 1 mg/kg subcutaneously or intramuscularly for 3–5 days
Hepatic abscess, ameboma, and other extraintestinal disease	Metronidazole, 750 mg orally three times daily (or 500 mg intravenously every 6 hours) for 10 days or Tinidazole, 2 g orally daily for 5 days **plus** Luminal agent (see above)	Dehydroemetine[2] or emetine,[2] 1 mg/kg subcutaneously or intramuscularly for 8–10 days, followed by (liver abscess only) chloroquine, 500 mg orally twice daily for 2 days, then 500 mg daily for 21 days **plus** Luminal agent (see above)

[1] See text for additional details and cautions.
[2] Not available in the United States.

infection is not documented; Table 40–5). Metronidazole can be used intravenously when necessary. With failure of initial response to metronidazole or tinidazole, chloroquine, emetine, or dehydroemetine may be added. Needle aspiration may be helpful for large abscesses (> 5–10 cm), in particular if the diagnosis remains uncertain, if there is an initial lack of response, or if a patient is very ill, suggesting imminent abscess rupture. With successful therapy, abscesses disappear slowly (over months).

Prevention & Control

Prevention requires safe water supplies; sanitary disposal of human feces; adequate cooking of food; protection of food from fly contamination; hand washing; and, in endemic areas, avoidance of fruits and vegetables that cannot be cooked or peeled. Water supplies can be boiled, treated with iodine (0.5-mL tincture of iodine per liter for 20 minutes; cysts are resistant to standard concentrations of chlorine), or filtered.

COCCIDIOSIS (Cryptosporidiosis, Isosporiasis, Cyclosporiasis, Sarcocystosis) & MICROSPORIDIOSIS

ESSENTIALS OF DIAGNOSIS

- Acute diarrhea, especially in children in developing countries.
- Outbreaks of diarrhea secondary to contaminated water or food.
- Prolonged diarrhea in immunocompromised persons.
- Diagnosis mostly by identifying organisms in specially stained stool specimens.

General Considerations

The causes of coccidiosis are *Cryptosporidium* species (*C parvum*, *C hominis*, and others); *Cystoisospora* (formerly *Isospora*) *belli*; *Cyclospora cayetanensis*; and *Sarcocystis* species. Microsporidiosis is caused by at least 14 species, most commonly *Enterocytozoon bieneusi* and *Encephalitozoon* *intestinalis*. These infections occur worldwide, particularly in the tropics and in regions where hygiene is poor. They cause endemic childhood gastroenteritis (particularly in malnourished children in developing countries); institutional and community outbreaks of diarrhea; traveler's diarrhea; and acute and chronic diarrhea in immunosuppressed patients, in particular those with AIDS. They are all notable for the potential to cause prolonged diarrhea, often lasting for a number of weeks. Clustering occurs in households, day care centers, and among sexual partners.

The infectious agents are oocysts (coccidiosis) or spores (microsporidiosis) transmitted from person to person or by contaminated drinking or swimming water or food. Ingested oocysts release sporozoites that invade and multiply in enterocytes, primarily in the small bowel. Coccidian oocysts and microsporidian cysts can remain viable in the environment for years.

Cryptosporidiosis is a zoonosis (*C parvum* principally infects cattle), but most human infections are acquired from humans, in particular with *C hominis*. Cryptosporidia are highly infectious. They have caused large community outbreaks due to contaminated water supplies and are the leading cause of recreational water–associated outbreaks of gastroenteritis. In the developing world, cryptosporidiosis is a leading cause of childhood diarrhea. In a study of causes of moderate-to-severe diarrhea in Asia and Africa, *Cryptosporidium* was the second most commonly identified pathogen in children under 2 years of age.

C belli and *C cayetanensis* appear to infect only humans. *C cayetanensis* has caused a number of food-borne outbreaks in the United States in recent years, most commonly associated with imported fresh produce. *Sarcocystis* infects many species; humans are intermediate hosts (infected by ingestion of fecal sporocysts) for some species but definitive hosts for *Sarcocystis bovihominis* and *Sarcocystis suihominis* (infected by ingestion of tissue cysts in undercooked beef and pork, respectively).

Clinical Findings

A. Symptoms and Signs

1. Coccidiosis—

A. CRYPTOSPORIDIOSIS—The incubation period appears to be approximately 14 days. In developing countries, disease is primarily in children under 5 years of age, causing 5–10% of childhood diarrhea. Presenting symptoms include acute watery diarrhea, abdominal pain, and cramps, with rapid resolution in most patients; however, symptoms quite commonly persist for 2 weeks or more. In developed countries, most patients are adults. Diarrhea in immunocompetent individuals typically lasts 5–10 days; it is usually watery, with accompanying abdominal pain and cramps, nausea, vomiting, and fever. Relapses may follow initial resolution of symptoms. Mild illness and asymptomatic infection are also common.

Cryptosporidiosis is a well-characterized cause of diarrhea in those with AIDS. It was common before the advent of highly active antiretroviral therapy, particularly with advanced immunosuppression. Clinical manifestations are variable, but patients commonly have chronic diarrhea with frequent foul-smelling stools, malabsorption, and weight loss. Severe, life-threatening watery diarrhea may be seen. Cryptosporidiosis also causes extraintestinal disease with AIDS, including pulmonary infiltrates with dyspnea and biliary tract infection with sclerosing cholangitis and AIDS cholangiopathy.

B. ISOSPORIASIS—The incubation period for *C belli* is about 1 week. In immunocompetent persons, it usually causes a self-limited watery diarrhea lasting 2–3 weeks, with abdominal cramps, anorexia, malaise, and weight loss. Fever is unusual. Chronic symptoms may persist for months. In immunocompromised patients, isosporiasis more commonly causes severe and chronic diarrhea, with complications including marked dehydration, malnutrition, and hemorrhagic colitis. Extraintestinal disease has been reported rarely.

C. CYCLOSPORIASIS—*C cayetanensis* oocysts must undergo a period of sporulation of 7 days or more after shedding before they become infectious. Therefore, person-to-person spread is unlikely, and spread has typically been due to contaminated food (especially fresh produce) and water. The incubation period is 1–11 days. Infections can be asymptomatic. Cyclosporiasis causes an illness similar to that described for the other pathogens included in this section, with watery diarrhea, abdominal cramps, nausea, fatigue, and anorexia. Fever is seen in 25% of cases. Symptoms typically continue for 2 weeks or longer and may persist for months without therapy. Relapses of diarrhea are common. Diarrhea may be preceded by a flu-like prodrome and followed by persistent fatigue. In immunocompromised patients, cyclosporiasis is typically more severe and prolonged, with chronic fulminant watery diarrhea and weight loss.

D. SARCOCYSTOSIS—*Sarcocystis* infection is common in some developing countries but is usually asymptomatic. Infection most commonly follow the ingestion of undercooked beef or pork, leading to the development of cysts in muscle, with myalgias, fever, bronchospasm, pruritic rash, lymphadenopathy, and subcutaneous nodules. Ingestion of fecal sporocysts may lead to GI symptoms.

2. Microsporidiosis—Microsporidia are obligate intracellular protozoans that cause a wide spectrum of diseases. Many infections are of zoonotic origin, but human-to-human transmission has been documented. Infection is mainly by ingestion of spores, but also by direct inoculation of the eyes. In immunocompetent hosts, microsporidian infections most commonly present as self-limited diarrhea. Ocular infections have also been described. Disease from microsporidia is seen mainly in immunocompromised persons, particularly those with AIDS. Infections in patients with AIDS are most commonly with *E bieneusi* and *E intestinalis*. They cause chronic diarrhea, with anorexia, bloating, weight loss, and wasting, especially in those with advanced immunodeficiency. Fever is usually not seen. Other illnesses in immunocompromised persons associated with microsporidians (including the genera *Enterocytozoon, Encephalitozoon, Brachiola, Vittaforma, Pleistophora,* *Trachipleistophora*, and *Microsporidium*) include biliary tract disease (AIDS cholangiopathy), genitourinary infection with cystitis, kidney disease, hepatitis, peritonitis, myositis, respiratory infections including sinusitis, CNS infections including granulomatous encephalitis, and disseminated infections. Ocular infections with *Encephalitozoon* species cause conjunctivitis and keratitis, presenting as redness, photophobia, and loss of visual acuity.

B. Laboratory Findings

1. Coccidiosis—

a. Cryptosporidiosis—Typically, stool is without blood or leukocytes. Diagnosis is traditionally made by detecting the organism in stool using a modified acid-fast stain; this technique is relatively insensitive, and multiple specimens should be evaluated before ruling out the diagnosis. Of note, routine evaluation for ova and parasites typically does not include a modified acid-fast stain, so this must be specifically requested in many laboratories. Various detection methods for stool antigens, including immunofluorescence microscopy, ELISA, and immunochromatography, offer improved sensitivity and specificity, both > 90% with available assays, and these methods may be considered the optimal means of diagnosis. Molecular diagnostic panels that recognize *Cryptosporidium* and other enteropathogens in stool are available but expensive.

b. Isosporiasis—Diagnosis of isosporiasis is by examination of stool wet mounts or after modified acid-fast staining, in which the organism is clearly distinguishable from other parasites. Other stains also show the organism. Shedding of oocysts may be intermittent, so the sensitivity of stool evaluation is not high, and multiple samples should be examined. The organism may also be identified in duodenal aspirates or small bowel biopsies.

c. Cyclosporiasis—Diagnosis is made by examination of stool wet mounts or after modified acid-fast staining. Multiple specimens may need to be examined to make a diagnosis; concentration of specimens improves sensitivity. The organism can also be identified in small bowel aspirates or biopsy specimens. Molecular assays with high sensitivity and specificity, including multi-pathogen panels, are available.

d. Sarcocystosis—Eosinophilia and elevated creatine kinase may be seen. Diagnosis is by identification of the acid-fast organisms in stool or by identification of trophozoites or bradyzoites in tissue biopsies.

2. Microsporidiosis—Diagnosis can be made by identification of organisms in specially stained stool, fluid, or tissue specimens, for example with Weber chromotrope-based stain. Electron microscopy is helpful for confirmation of the diagnosis and speciation. PCR and culture techniques are available but not used routinely.

▶ Treatment

Most acute infections with these pathogens in immunocompetent persons are self-limited and do not require treatment. Supportive treatment for severe or chronic diarrhea includes fluid and electrolyte replacement and, in some cases, parenteral nutrition.

1. Coccidiosis—

a. Cryptosporidiosis—Treatment of cryptosporidiosis is challenging. No agent is clearly effective. Modest benefits have been seen in some (but not other) studies, generally in immunocompetent hosts, with nitazoxanide, which is FDA-approved for this indication (500 mg–1 g orally twice daily for 3 days in immunocompetent patients and 2–8 weeks in patients with advanced AIDS), and paromomycin, a nonabsorbed aminoglycoside (25–35 mg/kg orally for 14 days). Other agents that have been used with mixed success in the treatment of cryptosporidiosis in patients with AIDS include azithromycin, spiramycin, bovine hyperimmune colostrum, and octreotide. Reversing immunodeficiency with effective antiretroviral therapy is of greatest importance.

b. Isosporiasis—Isosporiasis is effectively treated in immunocompetent and immunosuppressed persons with TMP-SMZ (160 mg/800 mg orally two to four times daily for 10 days, with the higher dosage for patients with AIDS). An alternative therapy is pyrimethamine (75 mg orally in four divided doses) with folinic acid (10–25 mg/day orally). Maintenance therapy with low-dose TMP-SMZ (160 mg/800 mg daily or three times per week) or Fansidar (1 tablet weekly) prevents relapse in those with persistent immunosuppression.

c. Cyclosporiasis—Cyclosporiasis is also treated with TMP-SMZ (dosing as for isosporiasis). With AIDS, long-term maintenance therapy (160 mg/800 mg three times weekly) helps prevent relapse. For patients intolerant of TMP-SMZ, ciprofloxacin (500 mg orally twice daily for 7 days) showed efficacy, albeit with less ability to clear the organism than TMP-SMZ.

d. Sarcocystosis—For sarcocystosis, no specific treatment is established, but patients may respond to therapy with albendazole or TMP-SMZ.

2. Microsporidiosis—Treatment of microsporidiosis is complex. Infections with most species, including those causing GI and other manifestations, should be treated with albendazole (400 mg orally twice daily for 2–4 weeks), which has activity against a number of species, but relatively poor efficacy (about 50%) against *E bieneusi*, the most common microsporidial cause of diarrhea in patients with AIDS. Fumagillin, which is used to treat honeybees and fish with microsporidian infections, has shown benefit in clinical trials at a dose of 20 mg three times per day for 14 days; treatment was accompanied by reversible thrombocytopenia. As with cryptosporidiosis, the best means of controlling microsporidiosis in patients with AIDS is to restore immune function with effective antiretroviral therapy. Ocular microsporidiosis can be treated with topical fumagillin solution (3 mg/mL); this probably should be given with concurrent systemic albendazole. Adjunctive management may include topical corticosteroids to decrease inflammation and keratoplasty.

Prevention

Water purification is important for control of these infections. Chlorine disinfection is not effective against cryptosporidial oocysts, so other purification measures are needed. Immunocompromised patients should boil or filter drinking water and should consider avoidance of lakes and swimming pools. Routine precautions (hand washing, gloves, disinfection) should prevent institutional patient-to-patient spread. Optimal means of preventing microsporidial infections are not known, but water purification and body substance precautions for immunocompromised and hospitalized individuals are likely effective.

GIARDIASIS

ESSENTIALS OF DIAGNOSIS

- Acute diarrhea may be profuse and watery.
- Chronic diarrhea with greasy, malodorous stools.
- Abdominal cramps, distention, flatulence.
- Cysts or trophozoites in stools.

General Considerations

Giardiasis is a protozoal infection of the upper small intestine caused by the flagellate *Giardia lamblia* (also called *Giardia intestinalis* and *Giardia duodenalis*). The parasite occurs worldwide, most abundantly in areas with poor sanitation. In developing countries, young children are very commonly infected. In the United States and Europe, the infection is the most common intestinal protozoal pathogen; the US estimate is 1 million new infections leading to 5000 hospital admissions yearly. Groups at special risk include travelers to *Giardia*-endemic areas, those who swallow contaminated water during recreation or wilderness travel, men who have sex with men, and persons with impaired immunity. Outbreaks are common in households, children's day care centers, and residential facilities, and may occur from contaminated water supplies.

The organism occurs in feces as a flagellated trophozoite and as a cyst. Only the cyst form is infectious by the oral route; trophozoites are destroyed by gastric acidity. Humans are a reservoir for the pathogen; dogs, cats, beavers, and other mammals have been implicated but not confirmed as reservoirs. Under suitable moist, cool conditions, cysts can survive in the environment for weeks to months. Cysts are transmitted as a result of fecal contamination of water or food, by person-to-person contact, or by anal-oral sexual contact. The infectious dose is low, requiring as few as 10 cysts. After the cysts are ingested, trophozoites emerge in the duodenum and jejunum. Epithelial damage and mucosal invasion are uncommon. Hypogammaglobulinemia, low secretory IgA levels in the gut, achlorhydria, and malnutrition favor the development of infection.

Clinical Findings

A. Symptoms and Signs

It is estimated that about 50% of infected persons have no discernable infection, about 10% become asymptomatic cyst passers, and 25–50% develop an acute diarrheal syndrome. Acute diarrhea may clear spontaneously but is commonly followed by chronic diarrhea. The incubation period is usually 1–3 weeks but may be longer. The illness may begin gradually or suddenly. The acute phase may last days or weeks and is usually self-limited. The initial illness may include profuse watery diarrhea, and hospitalization may be required due to dehydration, particularly in young children. Typical symptoms of chronic disease are abdominal cramps, bloating, flatulence, nausea, malaise, and anorexia. Fever and vomiting are uncommon. Diarrhea is usually not severe in the chronic stage of infection; stools are greasy or frothy and foul smelling, without blood, pus, or mucus. The diarrhea may be daily or recurrent; intervening periods may include constipation. Symptoms can persist for weeks to months. Weight loss is frequent. Chronic disease can include malabsorption, including fat and protein-losing enteropathy and vitamin deficiencies.

B. Laboratory Findings

Most patients seek medical attention after having been ill for > 1 week, commonly with weight loss of ≥ 5 kg. Stool is generally without blood or leukocytes. Diagnosis is traditionally made by the identification of trophozoites or cysts in stool. Microscopy with direct fluorescent antibody testing is the diagnostic test of choice. A wet mount of liquid stool may identify motile trophozoites. Stained fixed specimens may show cysts or trophozoites. Sensitivity of stool analysis is not ideal, estimated at 50–80% for a single specimen and > 90% for three specimens. Duodenal biopsy may be helpful in very ill or immunocompromised patients. When giardiasis is suspected, stool antigen assays are simpler and cheaper than repeated stool examinations, but these will not identify other stool pathogens. Multiple tests that identify antigens of trophozoites or cysts in stool, including rapid immunochromatographic cartridge assays and enzyme immunoassays, are available. They are generally quite sensitive (85–98%) and specific (90–100%). Molecular diagnostic panels that recognize *Giardia* and other enteropathogens in stool are available but expensive.

Treatment

The treatments of choice for giardiasis are tinidazole (2 g orally once) or metronidazole (250 mg orally three times daily for 5–7 days). The drugs are not universally effective; cure rates for single courses are typically about 80–95%. Toxicities are as described for treatment of amebiasis, but the lower dosages used for giardiasis limit side effects. Albendazole (400 mg orally once daily for 5 days) and nitazoxanide (500 mg orally twice daily for 3 days) both appear to have similar efficacy and fewer side effects compared with metronidazole, but a meta-analysis suggested that tinidazole is more efficacious than albendazole. Nitazoxanide is generally well tolerated but may cause mild GI side effects. Other drugs with activity against *Giardia* include furazolidone (100 mg orally four times a day for 7 days), which is about as effective as the other named drugs but causes GI side effects, and paromomycin (500 mg orally three times a day for 7 days), which appears to have somewhat lower efficacy but, unlike metronidazole, tinidazole, and furazolidone, is safe in pregnancy. Symptomatic giardiasis should always be treated. Treatment of asymptomatic patients should be considered, since they can transmit the infection. With a suggestive presentation but negative diagnostic studies, an empiric course of treatment may be appropriate. Household or day care contacts with an index case should be tested and treated if infected.

Prevention

Community chlorination (0.4 mg/L) of water is relatively ineffective for inactivating cysts, so filtration is required. For wilderness or international travelers, bringing water to a boil for 1 minute or filtration with a pore size < 1 mcm is adequate. In day care centers, appropriate disposal of diapers and frequent hand washing are essential.

Loderstädt U et al. Antimicrobial resistance of the enteric protozoon *Giardia duodenalis*—a narrative review. Eur J Microbiol Immunol (Bp). 2021;11:29. [PMID: 34237023]

TRICHOMONIASIS

Trichomoniasis is caused by the protozoan *Trichomonas vaginalis* and is among the most common STIs, causing vaginitis in women (see Vaginitis in Chapter 21) and nongonococcal urethritis in men. *T vaginalis* is often harbored asymptomatically. For women with symptomatic disease, after an incubation period of 5 days to 4 weeks, a vaginal discharge develops, often with vulvovaginal discomfort, pruritus, dysuria, dyspareunia, or abdominal pain. Examination shows a copious yellow or green discharge, which is usually not foul smelling. Most men infected with *T vaginalis* are asymptomatic, but it can be isolated from about 10% of men with nongonococcal urethritis. The urethral discharge is generally scantier than with other causes of urethritis.

Diagnosis is made by identifying the organism in vaginal or urethral secretions. Examination of wet mounts will show motile organisms. Point-of-care antigen detection and nucleic acid probe hybridization tests and nucleic acid amplification assays offer improved sensitivity compared with wet mount microscopy and excellent specificity.

The treatment of choice is metronidazole, 500 mg orally twice daily for 7 days in women, and as a single 2-g dose in men. An alternative is tinidazole as a 2-g single oral dose. Toxicities are discussed in the section on amebiasis. All infected persons should be treated, even if asymptomatic, to prevent subsequent symptomatic disease and limit spread. Treatment failure suggests reinfection, but metronidazole-resistant organisms have been reported. These may be treated with tinidazole, longer courses of metronidazole, intravaginal paromomycin, or other experimental therapies (see Chapter 21).

HELMINTHIC INFECTIONS

TREMATODE (Fluke) INFECTIONS

SCHISTOSOMIASIS (Bilharziasis)

ESSENTIALS OF DIAGNOSIS

- History of freshwater exposure in an endemic area.
- **Acute schistosomiasis:** fever, headache, myalgias, cough, urticaria, diarrhea, and eosinophilia.
- **Intestinal schistosomiasis:** abdominal pain, diarrhea, and hepatomegaly, then anorexia, weight loss, and portal hypertension.
- **Urinary schistosomiasis:** hematuria and dysuria, then hydronephrosis and urinary infections.
- **Diagnosis:** characteristic eggs in feces or urine; biopsy of rectal or bladder mucosa; positive serology.

General Considerations

Schistosomiasis, which affects > 200 million persons worldwide, leads to severe consequences in 20 million persons and about 100,000 deaths annually (although estimates vary widely). The disease is caused by six species of trematode blood flukes. Five species cause intestinal schistosomiasis, with infection of mesenteric venules: *Schistosoma mansoni*, present in Africa, the Arabian Peninsula, South America, and the Caribbean; *Schistosoma japonicum*, endemic in China and Southeast Asia; *Schistosoma mekongi*, endemic near the Mekong River in Southeast Asia; and *Schistosoma intercalatum* and *Schistosoma guineensis*, which occur in parts of Africa. The sixth species, *Schistosoma haematobium*, causes urinary schistosomiasis, with infection of venules of the urinary tract, and is endemic in Africa and the Middle East. Transmission of schistosomiasis is focal, with greatest prevalence in poor rural areas. Control efforts have diminished transmission in many areas, but high-level transmission remains in sub-Saharan Africa and some other areas. Prevalence of infection and illness typically peaks at about 15–20 years of age.

Humans are infected with schistosomes after contact with freshwater containing cercariae released by infected snails. Infection is initiated by penetration of skin or mucous membranes. After penetration, schistosomulae migrate to the portal circulation, where they rapidly mature. After about 6 weeks, adult worms mate and migrate to terminal mesenteric or bladder venules, where females deposit their eggs. Some eggs reach the lumen of the bowel or bladder and are passed with feces or urine, while others are retained in the bowel or bladder wall or transported in the circulation to other tissues, in particular the liver. Disease in endemic areas is primarily due to a host response to eggs, with granuloma formation and inflammation, eventually leading to fibrosis. Chronic infection can result in scarring of mesenteric or vesicular blood vessels, leading to portal hypertension and alterations in the urinary tract. In previously uninfected individuals, such as travelers with freshwater contact in endemic regions, acute schistosomiasis may occur, with a febrile illness 2–8 weeks after infection.

Clinical Findings

A. Symptoms and Signs

1. Cercarial dermatitis (swimmer's itch)—Following cercarial penetration, localized erythema develops in some individuals, which can progress to a localized pruritic maculopapular rash that persists for some days. Dermatitis can be caused by human schistosomes and, in nontropical areas, by bird schistosomes that cannot complete their life cycle in humans (swimmer's itch).

2. Acute schistosomiasis (Katayama syndrome)—A febrile illness may develop 2–8 weeks after exposure in persons without prior infection, most commonly after heavy infection with *S mansoni* or *S japonicum*. Symptoms and signs include acute onset of fever; headache; myalgias; cough; malaise; urticaria; diarrhea, which may be bloody; hepatosplenomegaly; lymphadenopathy; and pulmonary infiltrates. Localized lesions may occasionally cause severe manifestations, including CNS abnormalities and death. Acute schistosomiasis usually resolves in 2–8 weeks.

3. Chronic schistosomiasis—Many persons have light infections and are asymptomatic, but an estimated 50–60% have symptoms and 5–10% have advanced organ damage. Asymptomatic infected children may suffer from anemia and growth retardation. Symptomatic patients with intestinal schistosomiasis typically experience abdominal pain, fatigue, diarrhea, and hepatomegaly. Over years, anorexia, weight loss, weakness, colonic polyps, and portal hypertension develop. Late manifestations include hematemesis from esophageal varices, hepatic failure, and pulmonary hypertension. Urinary schistosomiasis may present within months of infection with hematuria and dysuria, most commonly in children and young adults. Fibrotic changes in the urinary tract can lead to hydroureter, hydronephrosis, bacterial urinary infections and, ultimately, kidney disease or bladder cancer. Chronic genital schistosomiasis is associated with local lesions and increased risks of incontinence, infertility, and HIV infection.

B. Laboratory Findings

Microscopic examination of stool or urine for eggs, evaluation of tissue, or serologic tests establish the diagnosis. Characteristic eggs can be identified on smears of stool or urine. The most widely used stool test is the Kato-Katz technique. Quantitative tests that yield > 400 eggs per gram of feces or 10 mL of urine are indicative of heavy infections with increased risk of complications. Diagnosis can also be made by biopsy of the rectum, colon, liver, or bladder. Serologic tests include an ELISA available from the CDC that is 99% specific for all species but cannot distinguish acute and past infection. Sensitivity of the test is 99% for *S mansoni*, 95% for *S haematobium*, but < 50% for *S japonicum*. Serology is of limited use in endemic settings but can be helpful in travelers from nonendemic regions. The most widely used point-of-care assays detect circulating schistosome antigens in serum and urine. Antigen tests have better sensitivity than stool smears, especially for *S mansoni*; sensitivity is lower for *S haematobium*. Molecular tests for schistosomiasis are not routinely used for diagnosis. In acute schistosomiasis, leukocytosis and marked eosinophilia may occur; serologic tests may become positive before eggs are seen in stool or urine. After therapy, eggs may be shed in stool or urine for months, and so the identification of eggs in fluids or tissue cannot distinguish past or active disease. With a diagnosis of schistosomiasis, evaluation for the extent of disease is warranted, including liver function studies and imaging of the liver for those with intestinal disease and ultrasound or other imaging studies of the urinary system for those with urinary disease.

Treatment

Treatment is indicated for all schistosome infections. In areas where recurrent infection is common, treatment is valuable in reducing worm burdens and limiting clinical complications. The drug of choice is praziquantel. The drug is administered for 1 day at an oral dose of 40 mg/kg (in one or two doses) for *S mansoni*, *S haematobium*, *S intercalatum*, and *S guineensis* infections and a dose of 60 mg/kg (in two or three doses) for *S japonicum* and *S mekongi*. Cure rates are generally > 80% after a single treatment, and those not cured have marked reduction in the intensity of infection. Praziquantel is active against invading cercariae but not developing schistosomulae. Therefore, the drug may not prevent illness when given after exposure and, for recent infections, a repeat course after a few weeks may be appropriate. Praziquantel may be used during pregnancy. Resistance to praziquantel has been reported. Toxicities include abdominal pain, diarrhea, urticaria, headache, nausea, vomiting, and fever, and may be due both to direct effects of the drug and responses to dying worms. Alternative therapies are oxamniquine for *S mansoni* infection and metrifonate for *S haematobium* infection. Both drugs have limited availability (they are not available in the United States), and resistance may be a problem. No second-line drug is available for *S japonicum* infections. The antimalarial drug artemether has activity against schistosomulae and adult worms and may be effective in chemoprophylaxis; however, it is expensive, and long-term use in malarious areas might select for resistant malaria parasites. With severe disease, use of corticosteroids in conjunction with praziquantel may decrease complications. Treatment should be followed by repeat examinations for eggs about every 3 months for 1 year after therapy, with re-treatment if eggs are seen.

Prevention

Travelers to endemic areas should avoid freshwater exposure. Vigorous toweling after exposure may limit cercarial penetration. Chemoprophylaxis with artemether has shown efficacy but is not standard practice. Community control of schistosomiasis includes improved sanitation and water supplies, elimination of snail habitats, and preventive treatment to limit worm burdens.

LoVerde PT. Schistosomiasis. Adv Exp Med Biol. 2024;1454:75. [PMID: 39008264]

LIVER & LUNG FLUKES

FASCIOLIASIS

Human infection by *Fasciola hepatica*, the sheep liver fluke, results from ingestion of encysted metacercariae on watercress or other aquatic vegetables. Infection is prevalent in sheep-raising areas in many countries, especially parts of South America, the Middle East, and southern Europe, and it has increasingly been recognized in travelers to these areas. *Fasciola gigantica* has a more restricted distribution in Asia and Africa and causes similar findings. Eggs are passed from host feces into freshwater, leading to infection of snails, and then deposition of metacercariae on vegetation. In humans, metacercariae excyst, penetrate the peritoneum, migrate through the liver, and mature in the bile ducts, where they cause local necrosis and abscess formation.

Two clinical syndromes are seen, related to acute migration of worms and chronic infection of the biliary tract. Symptoms related to migration of larvae present 6–12 weeks after ingestion. Typical findings are abdominal pain, fever, malaise, weight loss, urticaria, eosinophilia, and leukocytosis. Tender hepatomegaly and elevated liver biochemical tests may be seen. Rarely, migration to other organs may lead to localized disease. The symptoms of worm migration subside after 2–4 months, followed by asymptomatic infection by adult worms or intermittent symptoms of biliary obstruction, with biliary colic and, at times, cholangitis. Early diagnosis is difficult, as eggs are not found in the feces during the acute migratory phase of infection. Clinical suspicion should be based on clinical findings and marked eosinophilia in at risk individuals. CT and other imaging studies show hypodense migratory lesions of the liver. Definitive diagnosis is made by the identification of characteristic eggs in stool. Repeated examinations may be necessary. In chronic infection, imaging studies show masses obstructing the extrahepatic biliary tract. Serologic assays have sensitivity and specificity above 90% but cannot distinguish between past and current infection. Antigen tests with excellent sensitivity and specificity are available in veterinary medicine and show promise for humans.

The treatment of choice is triclabendazole. Standard dosing of 10 mg/kg orally in a single dose or two doses over 12 hours achieves a cure rate of about 80%, but repeat dosing is indicated if abnormal radiologic findings or eosinophilia do not resolve. Of concern, resistance to triclabendazole has been widely reported in animal infections. The second-line drug for fascioliasis is bithionol (30–50 mg/kg/day orally in three divided doses on alternate days for 10–15 days); this drug is not available in the United States. Treatment with either drug can be accompanied by abdominal pain and other GI symptoms. Other potential therapies are emetine and dehydroemetine, both widely used in the past but quite toxic, and nitazoxanide. Prevention of fascioliasis involves avoidance of ingestion of raw aquatic plants.

CLONORCHIASIS & OPISTHORCHIASIS

Infection by *Clonorchis sinensis*, the Chinese liver fluke, is endemic in areas of Japan, Korea, China, Taiwan, Southeast Asia, and the far eastern part of Russia. An estimated 15 million persons are infected (13 million in China); in some communities, prevalence can reach 80%. Opisthorchiasis is principally caused by *Opisthorchis felineus* (regions of the former Soviet Union) or *Opisthorchis viverrini* (Thailand, Laos, Vietnam). Clonorchiasis and opisthorchiasis are clinically indistinguishable. Parasite eggs are shed into water in human or animal feces, where they infect snails, which release cercariae, which infect fish. Human infection follows ingestion of raw, undercooked, or pickled freshwater fish containing metacercariae. These parasites excyst in the duodenum and ascend into the biliary tract, where they mature and remain for many years, shedding eggs in the bile.

Most patients harbor few parasites and are asymptomatic. An acute illness can occur 2–3 weeks after initial infection, with fever, malaise, abdominal pain, anorexia, tender hepatomegaly, urticaria, and eosinophilia. The acute syndrome is difficult to diagnose, since ova may not appear in the feces until 3–4 weeks after onset of symptoms. In chronic heavy infections, findings include abdominal pain, anorexia, weight loss, and tender hepatomegaly. Recurrent bacterial cholangitis and sepsis, cholecystitis, liver abscess, and pancreatitis can occur. An increased risk of cholangiocarcinoma has been documented.

Early diagnosis is presumptive, based on clinical findings and epidemiology. Subsequent diagnosis is made by finding characteristic eggs in stool or duodenal or biliary contents. The stool Kato-Katz test is widely used; performing repeated tests improves sensitivity. Imaging studies show characteristic biliary tract dilatations with filling defects due to flukes. Serologic assays for clonorchiasis with excellent sensitivity are available but cannot distinguish between past and current infection. Molecular tests have been developed but are not widely used.

The drug of choice is praziquantel, 25 mg/kg orally three times daily for 2 days, which provides cure rates > 90% and egg reduction rates of nearly 100%. One day of treatment may be sufficient. Re-treatment may be required, especially in areas with known decreased praziquantel efficacy. The second-line drug is albendazole (400 mg orally twice daily for 7 days), which appears to be somewhat less effective. Tribendimidine, which is approved in China, has shown efficacy for clonorchiasis similar to that of praziquantel.

PARAGONIMIASIS

Eight species of *Paragonimus* lung flukes cause human disease. The most important is *Paragonimus westermani. Paragonimus* species are endemic in East Asia, Oceania, West Africa, and South America, where millions of persons are infected; rare infections caused by *Paragonimus kellicotti* have occurred in North America. Eggs are released into freshwater, where parasites infect snails, and then cercariae infect crabs and crayfish. Human infection follows consumption of raw, undercooked, or pickled freshwater shellfish. Metacercariae then excyst, penetrate the peritoneum, and pass into the lungs, where they mature into adult worms over about 2 months.

Most infected persons have moderate worm burdens and are asymptomatic. In symptomatic cases, abdominal pain and diarrhea develop 2 days to 2 weeks after infection, followed by fever, cough, chest pain, urticaria, and eosinophilia. Acute symptoms may last for several weeks. Chronic infection can cause cough productive of brown sputum, hemoptysis, dyspnea, and chest pain, with progression to chronic bronchitis, bronchiectasis, bronchopneumonia, lung abscess, and pleural disease. Ectopic infections can cause disease in other organs, most commonly the CNS, where disease can present with seizures, headaches, and focal neurologic findings due to parasite meningitis and to intracerebral lesions.

The diagnosis of paragonimiasis is made by identifying characteristic eggs in sputum or stool or identifying worms in biopsied tissue. Multiple examinations and concentration techniques may be needed. Serologic tests may be helpful; an ELISA available from the CDC has sensitivity and specificity > 95%. CXRs may show varied abnormalities of the lungs or pleura, including infiltrates, nodules, cavities, and fibrosis, and the findings can be confused with those of tuberculosis. With CNS disease, skull radiographs can show clusters of calcified cysts, and CT or MRI can show clusters of ring-enhancing lesions.

Treatment is with praziquantel (25 mg/kg orally three times daily for 2 days), with efficacy of at least 90%. Alternative therapies are bithionol and triclabendazole. As with cysticercosis, for cerebral paragonimiasis, praziquantel should generally be used with corticosteroids. Chronic infection may lead to permanent lung dysfunction and pleural disease requiring drainage procedures.

CESTODE INFECTIONS

NONINVASIVE CESTODE INFECTIONS

The four major tapeworms that cause noninvasive infections in humans are the beef tapeworm *Taenia saginata*, the pork tapeworm *Taenia solium*, the fish tapeworm *Diphyllobothrium latum*, each of which can reach many meters in length, and the dwarf tapeworm *Hymenolepis nana. Taenia* and *Hymenolepis* species are broadly distributed, especially in the tropics; *D latum* is most prevalent in temperate regions. Other tapeworms that can cause noninvasive human disease include the rodent tapeworm *Hymenolepis diminuta*, the dog tapeworm *Dipylidium caninum*, and other *Taenia* and *Diphyllobothrium* species. Invasive tapeworm infections, including *T solium* (when infective eggs, rather than cysticerci are ingested) and *Echinococcus* species, will be discussed separately.

1. Beef Tapeworm

Infection is most common in cattle breeding areas. Humans are the definitive host. Gravid segments of *T saginata* are passed in human feces to soil, where they are ingested by grazing animals, especially cattle. The eggs then hatch to release embryos that encyst in cattle muscle as cysticerci. Humans are infected by eating raw or undercooked infected beef. Most individuals infected with *T saginata* are asymptomatic, but abdominal pain and other GI symptoms may be present. Eosinophilia is common. The most common presenting finding is the passage of proglottids in the stool.

2. Pork Tapeworm

T solium is transmitted to pigs that ingest human feces. Humans can be either the definitive host (after consuming undercooked pork, leading to tapeworm infection) or the intermediate host (after consuming food contaminated with human feces containing *T solium* eggs, leading to cysticercosis, which is discussed under Invasive Cestode Infections). As with the beef tapeworm, infection with *T solium* adult worms is generally asymptomatic, but GI symptoms may occur. Infection is generally recognized after passage of proglottids. Autoinfection with eggs can progress to cysticercosis.

3. Fish Tapeworm

Infection with *D latum* follows ingestion of undercooked freshwater fish, most commonly in temperate regions. Eggs from human feces are taken up by crustaceans, these are eaten by fish, which are then infectious to humans. Infection with multiple worms over many years can occur. Infections are most commonly asymptomatic, but nonspecific GI symptoms, including diarrhea, may occur. Diagnosis usually follows passage of proglottids. Prolonged heavy infection can lead to megaloblastic anemia and neuropathy from vitamin B_{12} deficiency, which is due to infection-induced dissociation of the vitamin from intrinsic factor and to utilization of the vitamin by worms.

4. Dwarf Tapeworm

H nana is the only tapeworm that can be transmitted between humans. Infections are common in warm areas, especially with poor hygiene and institutionalized populations. Infection follows ingestion of food contaminated with human feces. Eggs hatch in the intestines, where oncospheres penetrate the mucosa, encyst as cysticercoid larvae, and then rupture after about 4 days to release adult worms. Autoinfection can lead to amplification of infection. Infection with *H nana*, the related rodent tapeworm *H diminuta*, or the dog tapeworm *D caninum* can also follow accidental ingestion of infected insects. *H nana* are dwarf in size relative to other tapeworms but can reach 5 cm in length. Heavy infection is common, especially in children, and can be accompanied by abdominal discomfort, anorexia, and diarrhea.

Laboratory Findings

Diagnosis is usually made based on the identification of characteristic eggs or proglottids in stool. Egg release may be irregular, so examination of multiple specimens or concentration techniques may be needed.

Treatment

The treatment of choice for noninvasive tapeworm infections is praziquantel. A single dose of praziquantel (5–10 mg/kg orally) is highly effective, except for *H nana*, for which the dosage is 25 mg/kg. Treatment of *H nana* is more difficult, as the drug is not effective against maturing cysts. Therefore, a repeat treatment after 1 week and examination of stool after therapy to document cure are appropriate with heavy infections. Therapy can be accompanied by headache, malaise, dizziness, abdominal pain, and nausea.

The alternative therapy is niclosamide. A single dose of niclosamide (2 g chewed) is effective against *D latum*, *Taenia*, and *D caninum* infections. For *H nana*, therapy is continued daily for 1 week. Niclosamide may cause nausea, malaise, and abdominal pain.

Panti-May JA et al. Worldwide overview of human infections with *Hymenolepis diminuta*. Parasitol Res. 2020;119:1997. [PMID: 32211990]

INVASIVE CESTODE INFECTIONS

1. Cysticercosis

ESSENTIALS OF DIAGNOSIS

- Exposure to *T solium* through fecal contamination of food.
- Focal CNS lesions; seizures, headache.
- Brain imaging shows cysts; positive serologic tests.

General Considerations

Cysticercosis is due to tissue infection with cysts of *T solium* that develop after humans ingest food contaminated with eggs from human feces, thus acting as an intermediate host for the parasite. Prevalence is high where the parasite is endemic, in particular Mexico, Central and South America, the Philippines, and Southeast Asia. An estimated 20 million persons are infected with cysticerci yearly, leading to about 400,000 persons with neurologic symptoms and 50,000 deaths. Antibody prevalence rates up to 10% are recognized in some endemic areas, and the infection is one of the most important causes of seizures in the developing world and in immigrants to the United States from endemic countries. In Latin America, it is estimated that 0.5–1.5 million persons are affected by epilepsy secondary to cysticercosis.

Clinical Findings

A. Symptoms and Signs

Neurocysticercosis can cause intracerebral, subarachnoid, and spinal cord lesions and intraventricular cysts. Single or multiple lesions may be present. Lesions may persist for years before symptoms develop, generally due to local inflammation or ventricular obstruction. Presenting symptoms include seizures, focal neurologic deficits, altered cognition, and psychiatric disease. Symptoms develop more quickly with intraventricular cysts, with findings of hydrocephalus and meningeal irritation, including severe headache, vomiting, papilledema, and visual loss. A particularly aggressive form of the disease, racemose cysticercosis, involves proliferation of cysts at the base of the brain, leading to alterations of consciousness and death. Spinal cord lesions can present with progressive focal findings.

Cysticercosis of organ systems, other than the CNS is usually clinically benign. Involvement of muscles can uncommonly cause discomfort and is identified by radiographs of muscle showing multiple calcified lesions. Subcutaneous involvement presents with multiple painless palpable skin lesions. Involvement of the eyes can present with ptosis due to extraocular muscle involvement or intraocular abnormalities.

B. Laboratory Findings and Imaging

Diagnosis generally requires consideration of both laboratory and imaging findings. The 2017 revised Del Brutto diagnostic criteria have demonstrated good sensitivity and specificity.

CSF examination may show lymphocytic or eosinophilic pleocytosis, decreased glucose, and elevated protein. Serology plays an important role in diagnosis; both antibody and antigen detection assays are available. ELISAs and related immunoblot assays have excellent sensitivity and specificity, but sensitivity is lower with only single or calcified lesions.

With neuroimaging by CT or MRI, multiple parenchymal cysts are most typically seen. Parenchymal calcification is also common. Performing both CT and MRI is ideal because CT is better for identification of calcification and

MRI for smaller and ventricular lesions. Typical findings can be highly suggestive of the diagnosis.

Treatment

The medical management of neurocysticercosis has been controversial because the benefits of cyst clearance must be weighed against potential harm of an inflammatory response to dying worms. Antihelminthic therapy hastens radiologic improvement in parenchymal cysticercosis, but some randomized trials have shown that corticosteroids alone are as effective as specific therapy plus corticosteroids for controlling seizures. Overall, most authorities recommend treatment of active lesions, in particular lesions with a high likelihood of progression, such as intraventricular cysts. At the other end of the spectrum, inactive calcified lesions probably do not benefit from therapy. In addition, cysticidal therapy should be avoided if there is a high risk of hydrocephalus, as with subarachnoid involvement. When treatment is deemed appropriate, standard therapy consists of albendazole (10–15 mg/kg/day orally for 8 days) or praziquantel (50 mg/kg/day orally for 15–30 days). Albendazole is probably preferred, since it has shown better efficacy in some comparisons and since corticosteroids appear to lower circulating praziquantel levels but increase albendazole levels. Increasing the dosage of albendazole to 30 mg/kg/day orally may improve outcomes. Combining albendazole with praziquantel improved outcomes compared with albendazole alone in patients with multiple viable intraparenchymal cysts. Corticosteroids are usually administered concurrently, but dosing is not standardized. Patients should be observed for evidence of localized inflammatory responses. Anticonvulsant therapy should be provided if needed, and shunting performed if required for elevated intracranial pressure. Surgical removal of cysts may be helpful for some difficult cases of neurocysticercosis and for symptomatic non-neurologic disease.

Pineda-Reyes R et al. Neurocysticercosis: an update on diagnosis, treatment, and prevention. Curr Opin Infect Dis. 2022;35:246. [PMID: 35665719]

2. Echinococcosis

ESSENTIALS OF DIAGNOSIS

- History of exposure to dogs or wild canines in an endemic area.
- *E granulosus* cystic hydatid disease: large cystic lesions, most commonly in the liver or lung.
- *E multilocularis* alveolar hydatid disease: infiltrative disease of the liver
- Positive serologic tests.

General Considerations

Echinococcosis occurs when humans are intermediate hosts for canine tapeworms. Infection is acquired by ingesting food contaminated with canine feces containing parasite eggs. The principal species that infect humans are *Echinococcus granulosus*, which causes cystic hydatid disease, and *Echinococcus multilocularis*, which causes alveolar hydatid disease. *E granulosus* is transmitted by domestic dogs in areas with livestock (sheep, goats, camels, and horses) as intermediate hosts, including Africa, the Middle East, southern Europe, South America, Central Asia, Australia, New Zealand, and the southwestern United States. *E multilocularis*, which much less commonly causes human disease, is transmitted by wild canines and is endemic in northern forest areas of the Northern Hemisphere, including central Europe, Siberia, northern Japan, northwestern Canada, and western Alaska. An increase in the fox population in Europe has been associated with an increase in human cases. The disease range has also extended southward in Central Asia and China. Other species that cause limited disease in humans are endemic in South America and China.

After humans ingest parasite eggs, the eggs hatch in the intestines to form oncospheres, which penetrate the mucosa, enter the circulation, and encyst in specific organs as hydatid cysts. *E granulosus* forms cysts most commonly in the liver (65%) and lungs (25%), but the cysts may develop in any organ, including the brain, bones, skeletal muscles, kidneys, and spleen. Cysts are most commonly single. The cysts can persist and slowly grow for years. Alveolar hydatid disease is tumor-like, infiltrating the liver parenchyma and other organs.

Clinical Findings

A. Symptoms and Signs

Infections are commonly asymptomatic and may be noted incidentally on imaging studies or present with symptoms caused by an enlarging or superinfected mass. Findings may include abdominal or chest pain, biliary obstruction, cholangitis, portal hypertension, cirrhosis, bronchial obstruction leading to segmental lung collapse, and abscesses. Cyst leakage or rupture may be accompanied by a severe allergic reaction, including fever and hypotension. Seeding of cysts after rupture may extend the infection to new areas.

E multilocularis generally causes a more aggressive disease than *E granulosus*, with initial infection of the liver, but then local and distant spread commonly suggesting a malignancy. Symptoms based on the areas of involvement gradually worsen over years, with the development of obstructive findings in the liver and elsewhere.

B. Laboratory Findings

Serologic tests, including ELISA and immunoblot, offer sensitivity and specificity > 80% for *E granulosus* liver infections, but lower sensitivity for involvement of other organs. Serology is somewhat more reliable for *E multilocularis* infections. Serologic tests may also distinguish the two major echinococcal infections.

C. Imaging

Diagnosis is usually based on imaging studies, including ultrasonography, CT, and MRI. In *E granulosus* infection, a large cyst containing multiple daughter cysts that fill the cyst interior is highly suggestive of the diagnosis. In *E multilocularis* infection, imaging shows an irregular mass, often with areas of calcification.

Treatment

The treatment of *cystic* hydatid disease is with albendazole, often with cautious surgical resection of cysts. When used alone, as in cases where surgery is not possible, albendazole (10–15 mg/kg/day orally) has demonstrated efficacy, with courses of 3 months or longer duration; alternating cycles of treatment and rest may be used. Mebendazole (40–50 mg/kg/day orally) is an alternative drug, and praziquantel may also be effective. In some cases, medical therapy is begun, with surgery performed if disease persists after some months of therapy. Another approach, in particular with inoperable cysts, is percutaneous puncture, aspiration, injection, and re-aspiration (PAIR). In this approach (which should not be used if cysts communicate with the biliary tract), patients receive antihelminthic therapy, and the cyst is partially aspirated. After diagnostic confirmation by examination for parasite protoscolices, a scolicidal agent (95% ethanol, hypertonic saline, or 0.5% cetrimide) is injected, and the cyst is re-aspirated after about 15 minutes. PAIR includes a small risk of anaphylaxis (about 2% of procedures), but death due to anaphylaxis has been rare. Treatment of *alveolar* cyst disease is challenging, generally relying on wide surgical resection of lesions. Therapy with albendazole before or during surgery may be beneficial and may also provide improvement or even cure in inoperable cases.

INTESTINAL NEMATODE (Roundworm) INFECTIONS

ASCARIASIS

ESSENTIALS OF DIAGNOSIS

- Transient cough, urticaria, pulmonary infiltrates, eosinophilia.
- Nonspecific abdominal symptoms.
- Eggs in stool; adult worms occasionally passed.

General Considerations

Ascaris lumbricoides is the most common of the intestinal helminths, causing about 800 million infections, 12 million acute cases, and 10,000 or more deaths annually worldwide. Prevalence is high wherever there is poor hygiene and sanitation or where human feces are used as fertilizer. Heavy infections are most common in children.

Infection follows ingestion of eggs in contaminated food. Larvae hatch in the small intestine, penetrate into the bloodstream, migrate to the lungs, and then travel via airways back to the GI tract, where they grow to adult worms of up to 40 cm in length, and live for 1–2 years.

Clinical Findings

Most persons with *Ascaris* infection are asymptomatic. In a small proportion of patients, symptoms develop during migration of worms through the lungs, with fever, nonproductive cough, chest pain, dyspnea, and eosinophilia, occasionally with eosinophilic pneumonia. Rarely, larvae lodge ectopically in the brain, kidney, eye, spinal cord, and other sites and may cause local symptoms.

Light intestinal infections usually produce no symptoms. With heavy infection, abdominal discomfort may be seen. Adult worms may also migrate and be coughed up, be vomited, or may emerge through the nose or anus. They may also migrate into the common bile duct, pancreatic duct, appendix, and other sites, which may lead to cholangitis, cholecystitis, pyogenic liver abscess, pancreatitis, obstructive jaundice, or appendicitis. With very heavy infestations, masses of worms may cause intestinal obstruction, volvulus, intussusception, or death. Although severe manifestations of infection are uncommon, the very high prevalence of ascariasis leads to large numbers of individuals, especially children, with important sequelae. Moderate to high worm loads in children are also associated with nutritional abnormalities due to decreased appetite and food intake and also decreased absorption of nutrients.

The diagnosis of ascariasis is made after adult worms emerge from the mouth, nose, or anus, or by identifying characteristic eggs in the feces, usually with the Kato-Katz technique. Imaging studies demonstrate worms, with filling defects in contrast studies and at times evidence of intestinal or biliary obstruction. Eosinophilia is marked during worm migration but may be absent during intestinal infection.

Treatment

All infections should be treated. Treatments of choice are albendazole (single 400-mg oral dose), mebendazole (single 500-mg oral dose or 100 mg twice daily for 3 days), or pyrantel pamoate (single 11-mg/kg oral dose, maximum 1 g). These drugs are well tolerated but may cause mild GI toxicity. They are considered safe for children above 1 year of age and in pregnant persons, although use in the first trimester is best avoided. An alternative (but not in children < 35 kg or pregnant persons) is ivermectin (single 200-mcg/kg oral dose). In endemic areas, reinfection after treatment is common. Intestinal obstruction usually responds to conservative management and antihelminthic therapy. Surgery may be required for appendicitis and other GI complications.

TRICHURIASIS

Trichuris trichiura, the whipworm, infects about 500 million persons throughout the world, particularly in humid tropical and subtropical environments. Infection is heaviest and most frequent in children. Infections are acquired by ingestion of eggs. The larvae hatch in the small intestine and mature in the large bowel to adult worms of about 4 cm in length. The worms do not migrate through tissues.

Most persons with infection are asymptomatic. Heavy infections may be accompanied by abdominal cramps, tenesmus, diarrhea, distention, nausea, and vomiting. The *Trichuris* dysentery syndrome may develop, particularly in malnourished young children, with findings resembling IBD including bloody diarrhea and rectal prolapse.

Trichuriasis is diagnosed by identification of characteristic eggs and sometimes adult worms in stools. Eosinophilia is common. Treatment is typically with albendazole (400 mg/day orally) or mebendazole (200 mg/day orally), for 1–3 days for light infections or 3–7 days for heavy infections, but cure rates are lower than for ascariasis or hookworm infection. An alternative is ivermectin (200 mcg/kg orally once daily for 3 days). Oxantel pamoate (one dose of 15–30 mg/kg) has shown good efficacy in clearing infections; randomized trials showed albendazole plus oxantel pamoate (31% cure; 96% egg reduction) to be superior to mebendazole, and albendazole plus oxantel pamoate (69% cure; 99% egg reduction) and albendazole plus ivermectin (28% cure; 95% egg reduction) to be superior to albendazole plus mebendazole, but efficacies have varied in different regions. Oxantel pamoate has low efficacy against *Ascaris* and hookworm infection.

HOOKWORM DISEASE

ESSENTIALS OF DIAGNOSIS

- Transient pruritic skin rash and lung symptoms.
- Anorexia, diarrhea, abdominal discomfort.
- Iron deficiency anemia.
- Characteristic eggs and occult blood in the stool.

General Considerations

Infection with the hookworms *Ancylostoma duodenale* and *Necator americanus* is very common, especially in most tropical and subtropical regions. Both worms are broadly distributed. Prevalence is estimated at about 500 million, causing approximately 65,000 deaths each year worldwide. The eggs hatch when deposited on warm moist soil, releasing larvae that remain infective for up to 1 week. With contact, the larvae penetrate skin and migrate in the bloodstream to the pulmonary capillaries. In the lungs, the larvae penetrate into alveoli and then are carried by ciliary action upward to the bronchi, trachea, and mouth. After being swallowed, they reach and attach to the mucosa of the upper small bowel, where they mature to adult worms. *Ancylostoma* infection can also be acquired by ingestion of the larvae in food or water. Hookworms attach to the intestinal mucosa and suck blood. Blood loss is proportionate to the worm burden.

Clinical Findings

A. Symptoms and Signs

Most persons with infection are asymptomatic. A pruritic maculopapular rash (ground itch) may occur at the site of larval penetration, usually in previously sensitized persons. Pulmonary symptoms may be seen during larval migration through the lungs, with dry cough, wheezing, and low-grade fever, but these symptoms are less common than with ascariasis. About 1 month after infection, as maturing worms attach to the small intestinal mucosa, GI symptoms may develop, with epigastric pain, anorexia, and diarrhea, especially in previously unexposed individuals. Persons chronically infected with large worm burdens may have abdominal pain, anorexia, diarrhea, and findings of marked iron deficiency anemia and protein malnutrition. Anemia can lead to pallor, weakness, dyspnea, and heart failure, and protein loss can lead to hypoalbuminemia, edema, and ascites. These findings may be accompanied by impairment in growth and cognitive development in children. Infection with the dog hookworm *Ancylostoma caninum* can uncommonly lead to abdominal pain, diarrhea, and eosinophilia, with intestinal ulcerations and regional lymphadenitis.

B. Laboratory Findings

Diagnosis is based on the demonstration of characteristic eggs in feces; concentration techniques are usually not needed. Microcytic anemia, occult blood in the stool, and hypoalbuminemia are common. Eosinophilia is common, especially during worm migration.

Treatment

Treatment is with albendazole (single 400-mg oral dose) or mebendazole (100 mg orally twice daily for 3 days). Occasional side effects are diarrhea and abdominal pain. Pyrantel pamoate and levamisole are also effective. Anemia should be managed with iron replacement and, for severe symptomatic anemia, blood transfusion. Mass treatment of children with single doses of albendazole or mebendazole at regular intervals limits worm burdens and the extent of disease and is advocated by WHO.

STRONGYLOIDIASIS

ESSENTIALS OF DIAGNOSIS

- Transient pruritic skin rash and lung symptoms.
- Anorexia, diarrhea, abdominal discomfort.
- Larvae detected in stool.
- Hyperinfection in the immunocompromised; larvae detected in sputum or other fluids.
- Eosinophilia.

General Considerations

Strongyloidiasis is caused by infection with *Strongyloides stercoralis*. Although much less prevalent than ascariasis, trichuriasis, or hookworm infections, strongyloidiasis is nonetheless a significant problem, infecting tens of millions of individuals in tropical and subtropical regions. Infection is also endemic in some temperate regions of North America, Europe, Japan, and Australia. Of particular importance is the predilection of the parasite to cause severe infections in immunocompromised individuals due to its ability to replicate in humans. A related parasite, *Strongyloides fuelleborni*, infects humans in parts of Africa and New Guinea.

Hyperinfection syndrome is the most dangerous manifestation of *S stercoralis* infection, with dissemination of large numbers of filariform larvae to the lungs and other tissues in immunocompromised individuals. Mortality with this syndrome approaches 100% without treatment and has been about 25% with treatment. The hyperinfection syndrome is seen in patients receiving corticosteroids and other immunosuppressive medications; patients with hematologic malignancies, malnutrition, or alcohol use disorder; or persons living with AIDS. The risk seems greatest for those receiving corticosteroids.

Clinical Findings

A. Symptoms and Signs

As with other intestinal nematodes, most infected persons are asymptomatic. An acute syndrome can be seen at the time of infection, with a pruritic, erythematous, maculopapular rash, usually of the feet. These symptoms may be followed by pulmonary symptoms (including dry cough, dyspnea, and wheezing) and eosinophilia after several days, followed by GI symptoms after some weeks. Chronic infection may be accompanied by epigastric pain, nausea, diarrhea, and anemia. Maculopapular or urticarial rashes of the buttocks, perineum, and thighs, due to migrating larvae, may be seen. Large worm burdens can lead to malabsorption or intestinal obstruction. Eosinophilia is common but may fluctuate.

With hyperinfection, large numbers of larvae can migrate to many tissues, including the lungs, CNS, kidneys, and liver. GI symptoms can include abdominal pain, nausea, vomiting, diarrhea, and more severe findings related to intestinal obstruction, perforation, or hemorrhage. Bacterial sepsis, probably secondary to intestinal ulcerations, is a common presenting finding. Pulmonary findings include pneumonitis, cough, hemoptysis, and respiratory failure. Sputum may contain adult worms, larvae, and eggs. CNS disease includes meningitis and brain abscesses; the CSF may contain larvae. Various presentations can progress to shock and death.

B. Laboratory Findings

The diagnosis of strongyloidiasis can be difficult, as eggs are seldom found in feces. Diagnosis is usually based on the identification of rhabditiform larvae in the stool or duodenal contents. These larvae must be distinguished from hookworm larvae, which may hatch after stool collection. Repeated examinations of stool or examination of duodenal fluid may be required for diagnosis because the sensitivity of individual tests is only about 30%. Hyperinfection is diagnosed by the identification of large numbers of larvae in stool, sputum, or other body fluids. An ELISA from the CDC offers about 90% sensitivity and specificity, but cross-reactions with other helminths may occur. PCR and related molecular diagnostic methods are useful. Eosinophilia and mild anemia are common, but eosinophilia may be absent with hyperinfection. Hyperinfection may include extensive pulmonary infiltrates, hypoproteinemia, and abnormal liver function studies.

C. Screening

It is important to be aware of the possibility of strongyloidiasis in persons with even a distant history of residence in an endemic area, since the infection can be latent for decades. Screening of at-risk individuals for infection is appropriate before institution of immunosuppressive therapy. Screening can consist of serologic tests, with stool examinations in those with positive serologic tests, but consideration of presumptive treatment is warranted even if the stool evaluations are negative.

Treatment

Full eradication of *S stercoralis* is more important than with other intestinal helminths due to the ability of the parasite to replicate in humans. The treatment of choice for routine infection is ivermectin (200 mcg/kg orally daily for 1–2 days). Less effective alternatives are albendazole (400 mg orally twice daily for 3 days) and thiabendazole (25 mg/kg orally twice daily for 3 days). For hyperinfection, ivermectin should be administered daily until the clinical syndrome has resolved and larvae have not been identified for at least 2 weeks. Follow-up examinations for larvae in stool or sputum are necessary, with repeat dosing if the infection persists. With continued immunosuppression, eradication may be difficult, and regular repeated therapy (eg, monthly ivermectin) may be required.

ENTEROBIASIS

ESSENTIALS OF DIAGNOSIS

- Nocturnal perianal pruritus.
- Identification of eggs or adult worms on perianal skin or in stool.

General Considerations

Enterobius vermicularis, the pinworm, is a common cause of intestinal infections worldwide, with maximal prevalence in school-aged children. Enterobiasis is transmitted person-to-person via ingestion of eggs after contact with the hands or perianal region of an infected individual, food or fomites that have been contaminated by an infected individual, or infected bedding or clothing. Autoinfection also occurs. Eggs hatch in the duodenum and larvae migrate to the cecum. Females mature in about a month and remain viable for about another month. During this time, they migrate through the anus to deposit large numbers of eggs on the perianal skin. Due to the relatively short life span of these helminths, continuous reinfection, as in institutional settings, is required for long-standing infection.

Clinical Findings

A. Symptoms and Signs

Most individuals with pinworm infection are asymptomatic. The most common symptom is perianal pruritus, particularly at night, due to the presence of the female worms or deposited eggs. Insomnia, restlessness, and enuresis are common in children. Perianal scratching may result in excoriation and impetigo. Mild GI symptoms have been attributed to enterobiasis, but associations are not proven. Serious sequelae are uncommon. Rarely, worm migration results in inflammation or granulomatous reactions of the GI or genitourinary tracts. Colonic ulceration and eosinophilic colitis have been reported.

B. Laboratory Findings

Pinworm eggs are usually not found in stool. Diagnosis is made by finding adult worms or eggs on the perianal skin. A common test is to apply clear cellophane tape to the perianal skin, ideally in the early morning, followed by microscopic examination for eggs. The sensitivity of the tape test is about 50% for a single test and 90% for three tests. Nocturnal examination of the perianal area or gross examination of stools may reveal adult worms, which are about 1 cm in length. Eosinophilia is rare.

Treatment

Treatment is with single oral doses of albendazole (400 mg), mebendazole (100 mg), or pyrantel pamoate (11 mg/kg, to a maximum of 1 g). The dose is repeated in 2 weeks due to frequent reinfection. Other family members with infection should be treated concurrently, and treatment of all close contacts may be appropriate when rates of reinfection are high in family, school, or institutional settings. Standard hand washing and hygiene practices help limit spread. Perianal scratching should be discouraged. Washing of clothes and bedding should kill pinworm eggs.

INVASIVE NEMATODE (Roundworm) INFECTIONS

ANGIOSTRONGYLIASIS

Nematodes of rats of the genus *Angiostrongylus* cause two distinct syndromes in humans. *Angiostrongylus cantonensis*, the rat lungworm, causes eosinophilic meningoencephalitis, primarily in Southeast Asia and some Pacific islands, Hawaii (82 reported cases in 2007–2017), and Australia. In one study, *A cantonensis* was responsible for most cases of eosinophilic meningitis in Vietnam. *Angiostrongylus costaricensis* causes GI inflammation. In both diseases, human infection follows ingestion of larvae within slugs or snails (also crabs, prawns, or centipedes for *A cantonensis*) or on material, such as salads, contaminated by these organisms. Since the parasites are not in their natural hosts, they cannot complete their life cycles, but they can cause disease after migrating to the brain or GI tract. *A cantonensis* can also migrate from the brain to the pulmonary arteries.

Clinical Findings

A. *A cantonensis* Infection

The disease is caused primarily by worm larvae migrating through the CNS and an inflammatory response to dying worms. After an incubation period of 1 day to 2 weeks, presenting symptoms and signs include headache, stiff neck, nausea, vomiting, cranial nerve abnormalities, and paresthesias. Most cases resolve spontaneously after 2–8 weeks, but serious sequelae and death have been reported. The diagnosis is strongly suggested by the finding of eosinophilic CSF pleocytosis (> 10% eosinophils) in a patient with a history of travel to an endemic area. Peripheral eosinophilia may not be present. The diagnosis can be confirmed with PCR, but this may be negative early in disease.

B. *A costaricensis* Infection

Parasites penetrate ileocecal vasculature and develop into adults, which lay eggs, but do not complete their life cycle. Disease is due to an inflammatory response to dying worms in the intestinal tract, with an eosinophilic granulomatous response, at times including vasculitis and ischemic necrosis. Common findings are abdominal pain, vomiting, and fever. Pain is most commonly localized to the right lower quadrant, and a mass may be appreciated, all mimicking appendicitis. Symptoms may recur over months. Uncommon findings are intestinal perforation or obstruction, or disease due to migration of worms to other sites. Biopsy of inflamed intestinal tissue may show worms localized to mesenteric arteries and eosinophilic granulomas.

Treatment

Antihelminthic therapy for *A cantonensis* infection may be harmful, since responses to dying worms may worsen with therapy. Some experts, however, recommend prompt therapy for any suspected infection, even for a known accidental snail or slug ingestion in an endemic area, as therapy is likely most beneficial early in the course of disease. Albendazole is probably the best choice, and therapy should be prompt (within 3 weeks of exposure). Corticosteroids are probably appropriate if antihelminthics are provided. Ocular infection is treated surgically. It is not known if antihelminthic therapy is helpful for *A costaricensis* infection. Many cases are managed surgically, usually for suspected appendicitis.

CUTANEOUS LARVA MIGRANS (Creeping Eruption)

Cutaneous larva migrans is caused principally by larvae of the dog and cat hookworms, *Ancylostoma braziliense* and *A caninum*. Other animal hookworms, gnathostomiasis, and strongyloidiasis may also cause this syndrome. Infections are common in warm areas, including the southeastern United States. They are most common in children. The disease is caused by the migration of worms through skin; the nonhuman parasites cannot complete their life cycles, so only cause cutaneous disease.

Clinical Findings

Intensely pruritic erythematous papules develop, usually on the feet or hands, followed within a few days by serpiginous tracks marking the course of the parasite, which may travel several millimeters per day (Figure 40–3). Several tracks may be present. The process may continue for weeks, with lesions becoming vesiculated, encrusted, or secondarily infected. Systemic symptoms and eosinophilia are uncommon.

The diagnosis is based on the characteristic appearance of the lesions. Biopsy is usually not indicated.

Treatment

Without treatment, the larvae eventually die and are absorbed. Mild cases do not require treatment. Thiabendazole (10% aqueous suspension) can be applied topically three times daily for 5 or more days. Systemic therapy with albendazole (400 mg orally once or twice daily for 3–5 days) or ivermectin (200 mcg/kg orally single dose) is effective.

FILARIASIS

LYMPHATIC FILARIASIS

ESSENTIALS OF DIAGNOSIS

- Episodic attacks of lymphangitis, lymphadenitis, and fever.
- Chronic progressive swelling of extremities and genitals; hydrocele; chyluria; lymphedema.
- Microfilariae in blood, chyluria, or hydrocele fluid; positive serologic tests.

General Considerations

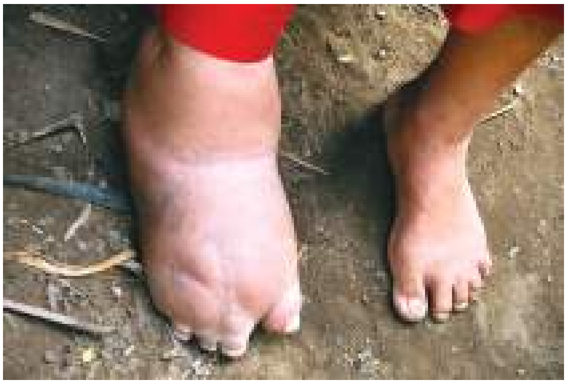
Lymphatic filariasis is caused by three filarial nematodes: *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*, and is among the most important parasitic diseases of man. Approximately 120 million persons are infected with these organisms in tropical and subtropical countries, about a third of these suffer clinical consequences of the infections, and many are seriously disfigured. *W bancrofti* causes about 90% of episodes of lymphatic filariasis. It is transmitted by *Culex*, *Aedes*, and *Anopheles* mosquitoes and is widely distributed in the tropics and subtropics, including sub-Saharan Africa, Southeast Asia, the western Pacific, India, South America, and the Caribbean. *B malayi* is transmitted by *Mansonia* and *Anopheles* mosquitoes and is endemic in parts of China, India, Southeast Asia, and the Pacific. *B timori* is found only in islands of southeastern Indonesia. *Mansonella* are filarial worms transmitted by midges and other insects in Africa and South America.

Humans are infected by the bites of infected mosquitoes. Larvae then move to the lymphatics and lymph nodes, where they mature over months to thread-like adult worms, and then can persist for many years. The adult worms produce large numbers of microfilariae, which are released into the circulation, and infective to mosquitoes, particularly at night (except for the South Pacific, where microfilaremia peaks during daylight hours).

Clinical Findings

A. Symptoms and Signs

Many infections remain asymptomatic despite circulating microfilariae. Clinical consequences of filarial infection are principally due to inflammatory responses to developing, mature, and dying worms. The initial manifestation of infection is often acute lymphangitis, with fever, painful lymph nodes, edema, and inflammation spreading peripherally from involved lymph nodes (in contrast to bacterial lymphangitis, which spreads centrally). Lymphangitis and lymphadenitis of the upper and lower extremities are



▲ **Figure 40–4.** Elephantiasis of legs due to filariasis. (Used with permission from Rungtip Chatadee/Alamy Stock Photo.)

common (Figure 40–4); genital involvement, including epididymitis and orchitis, with scrotal pain and tenderness, occurs principally only with *W bancrofti* infection. Acute attacks of lymphangitis last for a few days to a week and may recur a few times per year. Filarial fevers may also occur without lymphatic inflammation.

The most common chronic manifestation of lymphatic filariasis is swelling of the extremities or genitals due to chronic lymphatic inflammation and obstruction. Extremities become increasingly swollen, with a progression over time, including pitting or nonpitting edema or sclerotic changes of the skin that are referred to as elephantiasis. Genital involvement, particularly with *W bancrofti*, occurs more commonly in men, progressing from painful epididymitis to hydroceles that are usually painless but can become very large, with inguinal lymphadenopathy, thickening of the spermatic cord, scrotal lymphedema, thickening and fissuring of the scrotal skin, and occasionally chyluria. Lymphedema of the female genitalia and breasts may also occur.

Tropical pulmonary eosinophilia is a distinct syndrome principally affects young adult men with either *W bancrofti* or *B malayi* infection, but typically without microfilaremia. This syndrome is characterized by asthma-like symptoms, with cough, wheezing, dyspnea, and low-grade fevers, usually at night. Without treatment, tropical pulmonary eosinophilia can progress to interstitial fibrosis and chronic restrictive lung disease. *Mansonella* can inhabit serous cavities, the retroperitoneum, the eye, or the skin, and cause abnormalities related to inflammation at these sites.

B. Laboratory Findings

The diagnosis of lymphatic filariasis is strongly suggested by characteristic findings of lymphangitis or lymphatic obstruction in persons with risk factors for the disease. The diagnosis is confirmed by finding microfilariae, usually in blood, but microfilariae may be absent, especially early in the disease progression (first 2–3 years) or with chronic obstructive disease. To increase yields, blood samples are obtained at about midnight in most areas, but during daylight hours in the South Pacific. Smears are evaluated by wet mount to identify motile parasites and by Giemsa staining; these examinations can be delayed until the following morning, with storage of samples at room temperature. Of note, the periodicity of microfilaremia is variable, and daytime samples may yield positive results. Microfilariae may also be identified in hydrocele fluid or chylous urine. Eosinophilia is usually absent, except during acute inflammatory syndromes. Serologic tests may be helpful but cannot distinguish past and active infections. Rapid antigen tests with sensitivity and specificity > 90% are available for detection of *W bancrofti*. These are the diagnostic tests of choice and are used to guide control programs. However, cross-reactivity with *Loa* infections has been described. Due to potential severe toxicity, caution is appropriate before ivermectin treatment for positive *W bancrofti* antigen tests in areas also endemic for *L loa* infection. Multiple molecular tests, including field-friendly LAMP assays, are available. Adult worms may also be found in lymph node biopsy specimens (although biopsy is not usually clinically indicated) or by ultrasound of a scrotal hydrocele or lymphedematous breast. When microfilaremia is lacking, especially if sophisticated techniques are not available, diagnoses may need to be made on clinical grounds.

▶ Treatment & Control

A. Drug Treatment

Diethylcarbamazine is the drug of choice, but it cannot cure infections due to its limited action against adult worms. Asymptomatic infection and acute lymphangitis are treated with this drug (2 mg/kg orally three times daily) for 10–14 days, leading to a marked decrease in microfilaremia. Therapy may be accompanied by allergic symptoms, including fever, headache, malaise, hypotension, and bronchospasm, probably due to release of antigens from dying worms. For this reason, treatment courses may begin with a lower dosage, with escalation over the first 4 days of treatment. Single annual doses of diethylcarbamazine (6 mg/kg orally), alone or with ivermectin (400 mcg/kg orally) or albendazole (400 mg orally) may be as effective as longer courses of diethylcarbamazine. Combination therapy with a single dose of each of the three drugs (ivermectin, diethylcarbamazine, and albendazole [IDA]) cleared parasites in > 95% of persons for 3 years and offered superior clearance compared with two drugs; triple-drug therapy was as safe and well tolerated. When onchocerciasis or loiasis is suspected, it may be appropriate to withhold diethylcarbamazine to avoid severe reactions to dying microfilariae; rather, ivermectin plus albendazole may be given, although these drugs are less active than diethylcarbamazine against adult worms. Appropriate management of advanced obstructive disease is uncertain. Drainage of hydroceles provides symptomatic relief, although they will recur. Therapy with diethylcarbamazine cannot reverse chronic lymphatic changes but is typically provided to lower worm burdens. An interesting approach under study is to treat with doxycycline (100–200 mg/day orally for 4–6 weeks), which kills obligate intracellular *Wolbachia* bacteria, leading to death of adult filarial worms. Doxycycline is also effective at controlling *Mansonella perstans* infection, which does not respond well to standard antifilarial drugs.

Secondary bacterial infections must be treated. Surgical correction may be helpful in some cases.

B. Disease Control

Avoidance of mosquitoes is a key measure; preventive measures include the use of screens, bed nets (ideally treated with insecticide), and insect repellents. Community-based treatment with single annual doses of effective drugs offers a highly effective means of control. Combination IDA therapy offers improved efficacy and may become the standard of care for the prevention of lymphatic filariasis.

Weil GJ et al. The safety of double- and triple-drug community mass drug administration for lymphatic filariasis: a multicenter, open-label, cluster-randomized study. PLoS Med. 2019;16:e1002839. [PMID: 31233507]

ONCHOCERCIASIS

ESSENTIALS OF DIAGNOSIS

- Conjunctivitis progressing to blindness.
- Severe pruritus; skin excoriations, thickening, and depigmentation; and subcutaneous nodules.
- Microfilariae in skin snips and on slit-lamp examination; adult worms in subcutaneous nodules.

General Considerations

Onchocerciasis, or river blindness, is caused by *Onchocerca volvulus*. An estimated 37 million persons are infected worldwide, of whom 3–4 million have skin disease, 500,000 have severe visual impairment, and 300,000 are blinded. More than 99% of infections are in sub-Saharan Africa, especially the West African savanna, with about half of cases in Nigeria and Congo. In some hyperendemic African villages, close to 100% of individuals are infected, and 10% or more of the population is blind. The disease is also prevalent in the southwestern Arabian Peninsula and Latin America, including southern Mexico, Guatemala, Venezuela, Colombia, Ecuador, and northwestern Brazil. Onchocerciasis is transmitted by *Simulium* flies (blackflies). These insects breed in fast-flowing streams and bite during the day.

After the bite of an infected blackfly, larvae are deposited in the skin, where adults develop over 6–12 months. Adult worms live in subcutaneous connective tissue or muscle nodules for a decade or more. Microfilariae are released from the nodules and migrate through subcutaneous and ocular tissues. Disease is due to responses to worms and to intracellular *Wolbachia* bacteria.

Clinical Findings

A. Symptoms and Signs

After an incubation period of up to 1–3 years, the disease typically produces an erythematous, papular, pruritic rash, which may progress to chronic skin thickening and depigmentation. Itching may be severe and unresponsive to medications, such that more disability-adjusted life-years are lost to onchocercal skin problems than to blindness. Numerous firm, nontender, movable subcutaneous nodules of about 0.5–3 cm, which contain adult worms, may be present. Due to differences in vector habits, these nodules are more commonly on the lower body in Africa but on the head and upper body in Latin America. Inguinal and femoral lymphadenopathy is common, at times resulting in a "hanging groin," with lymph nodes hanging within a sling of atrophic skin. Patients may also have systemic symptoms, with weight loss and musculoskeletal pain.

The most serious manifestations of onchocerciasis involve the migration of microfilariae through the eyes. Findings include punctate keratitis and corneal opacities, progressing to sclerosing keratitis and blindness. Iridocyclitis, glaucoma, choroiditis, and optic atrophy may also lead to vision loss. The likelihood of blindness after infection varies greatly based on geography, with the risk greatest in savanna regions of West Africa.

B. Diagnostic Testing

The diagnosis is made by identifying microfilariae in skin snips, by visualizing microfilariae in the cornea or anterior chamber by slit-lamp examination, by identification of adult worms in a biopsy or aspirate of a nodule or, uncommonly, by identification of microfilariae in urine. Skin snips from the iliac crest (Africa) or scapula (Americas) are allowed to stand in saline for 2–4 hours or longer, and then examined microscopically for microfilariae. Deep punch biopsies are not needed, and if suspicion persists after a skin snip is negative, the procedure should be repeated. Ultrasound may identify characteristic findings suggestive of adult worms in skin nodules. When the diagnosis remains difficult, the Mazzotti test can be used; exacerbation of skin rash and pruritus after a topical or 50-mg oral dose of diethylcarbamazine is highly suggestive of the diagnosis, but this test can elicit severe skin and eye reactions in heavily infected individuals. Eosinophilia is a common but inconsistent finding. Antigen and antibody detection tests are under study.

Treatment & Control

The treatment of choice is ivermectin, which kills microfilariae, but not adult worms, so disease control requires repeat administrations. Treatment is with a single oral dose of 150 mcg/mL, but schedules for re-treatment have not been standardized. One regimen is to treat every 3 months for 1 year, followed by treatment every 6–12 months for the suspected life span of adult worms (about 15 years). Treatment results in marked reduction in numbers of microfilariae in the skin and eyes, although its impact on the progression of visual loss remains uncertain. Toxicities of ivermectin are generally mild; fever, pruritus, urticaria, myalgias, edema, hypotension, and tender lymphadenopathy may be seen, presumably due to reactions to dying worms. Ivermectin should be used with caution in patients also at risk for loiasis, since it can elicit severe reactions including encephalopathy. As with lymphatic filariasis, combination drug therapy with ivermectin, diethylcarbamazine, and albendazole offers improved long-term clearance of parasites. Moxidectin is FDA-approved for the treatment of onchocerciasis. Moxidectin is well tolerated and superior to ivermectin in suppressing skin microfilariae and offers another agent for treatment and control. As with other filarial infections, doxycycline acts against *O volvulus* by killing intracellular *Wolbachia* bacteria. A course of 100 mg orally daily for 4–6 weeks kills the bacteria and prevents parasite embryogenesis for at least 18 months. Doxycycline shows promise as a first-line agent to treat onchocerciasis because of its improved activity against adult worms compared with other agents and limited toxicity due to the slow action of the drug.

Protection against onchocerciasis includes avoidance of biting flies. Major efforts are underway to control insect vectors in Africa. In addition, mass distribution of ivermectin for intermittent administration at the community level is ongoing, and the prevalence of severe skin and eye disease is decreasing.

Opoku NO et al. A randomized, open-label study of the tolerability and efficacy of one or three daily doses of ivermectin plus diethylcarbamazine and albendazole (IDA) versus one dose of ivermectin plus albendazole (IA) for treatment of onchocerciasis. Mycotic Infections

Stacey R. Rose, MD, FACP, FIDSA
Richard J. Hamill, MD, FIDSA

CANDIDIASIS

ESSENTIALS OF DIAGNOSIS

- Common normal flora but opportunistic pathogen.
- Typically, mucosal disease, particularly vaginitis and oral thrush/esophagitis.
- Persistent, unexplained oral or vaginal candidiasis: check for HIV or diabetes mellitus.
- (1,3)-β-D-glucan results may be positive in candidemia even when blood cultures are negative.

General Considerations

Candida albicans can be cultured from the mouth, vagina, and feces of most people. Cellular immunodeficiency predisposes to mucocutaneous disease. When no other underlying cause is found, persistent oral or vaginal candidiasis should raise suspicion for HIV infection or diabetes. Risk factors for invasive candidiasis include prolonged neutropenia, abdominal surgery, broad-spectrum antibiotics, corticosteroids, kidney disease, and the presence of intravascular catheters. Although *C albicans* remains the most common cause of both mucocutaneous and systemic candidiasis, non-*albicans* strains are of considerable importance in certain contexts and may impact therapy owing to antifungal resistance.

Clinical Findings

A. Mucosal Candidiasis

1. Vulvovaginal candidiasis—This condition occurs in an estimated 75% of women during their lifetime. Risk factors include pregnancy, uncontrolled diabetes mellitus, broad-spectrum antimicrobial treatment, corticosteroid use, and HIV infection. Symptoms include acute vulvar pruritus, burning vaginal discharge, and dyspareunia.

2. Esophageal candidiasis—Substernal odynophagia, gastroesophageal reflux, or nausea without substernal pain can be presenting symptoms. Oral candidiasis, though often associated, is not invariably present. Diagnosis is best confirmed by endoscopy with biopsy and culture.

B. Candidal Funguria

Most cases of candidal funguria are asymptomatic and represent specimen contamination or bladder colonization (and do not warrant antifungal therapy). However, symptoms and signs of true *Candida* UTIs are indistinguishable from bacterial UTIs and can include urgency, hesitancy, fever, chills, or flank pain.

C. Invasive Candidiasis

Invasive candidiasis can be (1) candidemia (bloodstream infection) without deep-seated infection; (2) candidemia with deep-seated infection (typically eyes, kidney, or abdomen); and (3) deep-seated candidiasis in the absence of bloodstream infection (ie, hepatosplenic candidiasis). Varying ratios of these clinical entities depends on the predominating risk factors for affected patients (ie, neutropenia, indwelling vascular catheters, postsurgical). The clinical presentation of candidemia varies from minimal fever to septic shock that can resemble a severe bacterial infection. The diagnosis of invasive *Candida* infection is challenging since *Candida* species are often isolated from mucosal sites in the absence of invasive disease while blood cultures are positive only 50% of the time in invasive infection. Consecutively positive (1,3)-β-D-glucan results can guide empiric therapy in high-risk patients even in the absence of positive blood cultures.

Hepatosplenic candidiasis can occur following prolonged neutropenia with hematologic cancers, but this entity is less common in the era of widespread antifungal prophylaxis. Typically, fever and variable abdominal pain present weeks after chemotherapy when neutrophil counts have recovered. Blood cultures are generally negative, though hepatosplenic abscesses may be seen on abdominal imaging.

D. Candidal Endocarditis

Candidal endocarditis is a rare infection affecting patients with prosthetic heart valves or prolonged candidemia, such as with indwelling catheters. The diagnosis is established definitively by culturing *Candida* from vegetations at the time of valve replacement.

Treatment

A. Mucosal Candidiasis

1. Vulvovaginal candidiasis—This condition can be treated with topical or oral azoles. A single 150-mg oral dose of fluconazole is equivalent to topical treatments with better patient acceptance. Topical azole preparations include clotrimazole, 100-mg vaginal tablet for 7 days, or miconazole, 200-mg vaginal suppository for 3 days. Disease recurrence is common but can be decreased with weekly oral fluconazole therapy (150 mg weekly). Vulvovaginal candidiasis caused by non-*albicans* strains—eg, *C glabrata*—may require alternative therapies (such as intravaginal boric acid) in the setting of azole resistance. Oral ibrexafungerp (voluntarily recalled in 2023 due to potential contamination), a highly bioavailable glucan synthase inhibitor, may treat vulvovaginal candidiasis from any disease-causing strains, including azole-resistant pathogens. Oteseconazole is an alternative treatment option for recurrent vulvovaginal candidiasis.

2. Esophageal candidiasis—If patients can swallow and take adequate amounts of fluid orally, fluconazole, 200–400 mg orally daily for 14–21 days, is recommended. Patients who are unable to tolerate oral therapy should receive intravenous fluconazole, 400 mg daily, or an echinocandin for 14–21 days. Options for patients with fluconazole-refractory disease include 14–21 days of oral itraconazole solution, 200 mg daily; oral or intravenous voriconazole, 200 mg twice daily; oral posaconazole, 300 mg daily; or an intravenous echinocandin (caspofungin, 70-mg loading dose, then 50 mg/day; anidulafungin, 200 mg/day; or intravenous micafungin, 150 mg/day). Relapse is common with all agents in persons with HIV without adequate immune reconstitution.

B. Candidal Funguria

Candidal funguria frequently resolves with discontinuance of antibiotics or removal of bladder catheters. Clinical benefit from treatment of asymptomatic candiduria has not been demonstrated, but persistent funguria should raise the suspicion of invasive infection. When symptomatic funguria persists, oral fluconazole, 200 mg/day for 7–14 days, can be used.

C. Invasive Candidiasis

The 2016 Infectious Diseases Society of America guidelines for management of candidemia recommend an intravenous echinocandin as first-line therapy (ie, caspofungin [70 mg once, then 50 mg daily], micafungin [100 mg daily], or anidulafungin [200 mg once, then 100 mg daily]). Intravenous or oral fluconazole (800 mg once, then 400 mg daily) is an acceptable alternative for less critically ill patients without recent azole exposure. Rezafungin (400 mg intravenously once, then 200 mg intravenously weekly) is FDA-approved as a long-acting echinocandin for candidemia and invasive candidiasis when there are limited or no alternative treatment options.

Therapy for candidemia should be continued for 2 weeks after the last positive blood culture and resolution of symptoms and signs of infection. The use of rezafungin has not been studied for use beyond 4 weeks. A dilated fundoscopic examination may be advised for patients with candidemia to exclude endophthalmitis and repeat blood cultures should be drawn to demonstrate organism clearance. Susceptibility testing is recommended on all bloodstream *Candida* isolates; once patients have become clinically stable, parenteral therapy can be discontinued and treatment can be completed with oral fluconazole, 400 mg daily for susceptible isolates. Removal or exchange of intravascular catheters is recommended for patients with candidemia in whom the catheter is the suspected source of infection.

Non-*albicans* species of *Candida* often have resistance patterns that are different from *C albicans*. An echinocandin is recommended for treatment of *C glabrata* infection with transition to oral fluconazole or voriconazole for patients with susceptible isolates. For isolates with resistance to azoles and echinocandins, lipid formulation amphotericin B (3–5 mg/kg intravenously daily) may be used. *C krusei* is inherently fluconazole-resistant and should be treated with an alternative agent, such as an echinocandin or voriconazole. Health care–associated infections due to multidrug-resistant *Candida auris* may be treated with echinocandins plus environmental source control.

D. Candidal Endocarditis

Best results are achieved with a combination of medical and surgical therapy (valve replacement). Lipid formulation amphotericin B (3–5 mg/kg/day) or high-dose echinocandin (caspofungin 150 mg/day, micafungin 150 mg/day, or anidulafungin 200 mg/day) is recommended as initial therapy. Step-down or long-term suppressive therapy for nonsurgical candidates may be done with fluconazole at 6–12 mg/kg/day for susceptible organisms.

E. Prevention of Invasive Candidiasis

In high-risk patients undergoing induction chemotherapy or hematopoietic stem cell, liver, small bowel, and pancreas transplantation, prophylaxis with antifungal agents has been shown to prevent invasive fungal infections, although the effect on mortality and the preferred agent(s) remain debated. Critically ill patients are at higher risk for invasive candidiasis, but antifungal prophylaxis has not shown clear clinical benefit.

HISTOPLASMOSIS

ESSENTIALS OF DIAGNOSIS

- Exposure to bird and bat droppings; common along river valleys (especially the Ohio River and the Mississippi River valleys).
- Most patients asymptomatic; respiratory illness most frequent clinical problem.
- Disseminated disease common in AIDS or other immunosuppressed states; poor prognosis.
- Blood and bone marrow cultures and urine polysaccharide antigen are useful in diagnosis of disseminated disease.

General Considerations

Histoplasmosis is caused by *Histoplasma capsulatum* and *Histoplasma duboisii*, fungi that have been isolated from soil contaminated with bird or bat droppings in endemic areas (central and eastern United States, eastern Canada, Mexico, Central America, South America, Africa, and Southeast Asia). Infection presumably takes place by inhalation of conidia. These convert into small budding cells that are engulfed by phagocytes in the lungs. The organism proliferates and undergoes lymphohematogenous spread to other organs.

Clinical Findings

A. Symptoms and Signs

Most cases of histoplasmosis are asymptomatic or mild and thus go unrecognized. Past infection is recognized by pulmonary and splenic calcification noted on incidental radiographs. Symptomatic infection may present with mild influenza-like illness, often lasting 1–4 days. Moderately severe infections are frequently diagnosed as atypical pneumonia. These patients have fever, cough, and mild central chest pain lasting 5–15 days.

Clinically evident infections occur in several forms:

1. **Acute pulmonary histoplasmosis** frequently occurs in epidemics, often when soil containing infected bird or bat droppings is disturbed. Clinical manifestations can vary from a mild influenza-like illness to severe pneumonia. The illness may last from 1 week to 6 months but is almost never fatal.
2. **Progressive disseminated histoplasmosis** most frequently occurs in patients with HIV infection (with CD4 cell counts usually < 100 cells/mcL) or other conditions of impaired cellular immunity. Disseminated histoplasmosis has also been reported in patients from endemic areas taking TNF-α inhibitors. It is characterized by fever and multiple organ system involvement. CXRs may show a miliary pattern. Presentation may be fulminant, simulating septic shock, with death ensuing rapidly unless treatment is provided. Symptoms usually consist of fever, dyspnea, cough, loss of weight, and prostration. Ulcers of the mucous membranes of the oropharynx may be present. The liver and spleen are nearly always enlarged, and all the organs of the body can be involved, particularly the adrenal glands; *this results in adrenal insufficiency in about 50% of patients.* GI involvement may mimic IBD. CNS invasion occurs in 5–10% of individuals with disseminated disease.
3. **Chronic pulmonary histoplasmosis** is usually seen in older patients who have underlying chronic lung disease. CXRs show various lesions including complex apical cavities, infiltrates, and nodules.
4. **Complications of pulmonary histoplasmosis** include granulomatous mediastinitis characterized by persistently enlarged mediastinal lymph nodes and fibrosing mediastinitis in which an excessive fibrotic response to *Histoplasma* infection results in compromise of pulmonary vascular structures.

B. Laboratory Findings

Sputum culture is rarely positive in acute pulmonary histoplasmosis but often positive in chronic disease. Antigen testing of bronchoalveolar lavage fluid may be helpful in acute disease. The combination of urine and serum polysaccharide antigen assays has an 83% sensitivity for the diagnosis of acute pulmonary histoplasmosis.

Most patients with chronic pulmonary disease show anemia of chronic disease. Bone marrow involvement with pancytopenia may be prominent in disseminated forms. Marked LD and ferritin elevations are also common, as are mild elevations of serum AST.

Blood cultures using lysis centrifugation methods or bone marrow cultures from immunocompromised patients with progressive disseminated disease are positive $> 80\%$ of the time but may take several weeks for growth. The urine antigen assay has a sensitivity of $> 90\%$ for disseminated disease in immunocompromised patients and a declining titer can be used to follow response to therapy. Both CSF antigen and antibody testing should be performed in patients suspected of having meningitis.

Treatment

For progressive localized disease and for mild to moderately severe nonmeningeal disseminated disease in immunocompetent or immunocompromised patients, itraconazole, 200–400 mg/day orally divided into two doses, is the treatment of choice with an overall response rate of approximately 80% (Table 41–1). Duration of therapy ranges from weeks to several months depending on the severity of illness. The oral solution is better absorbed than the capsule formulation, which requires gastric acid for absorption. Therapeutic drug monitoring of itraconazole levels should be performed to assess adequacy of drug absorption. Intravenous liposomal amphotericin B, 3 mg/kg/day, is used with more severe disseminated disease and meningitis for 1–2 weeks until patients are clinically stable, followed by oral itraconazole. Patients with AIDS-related histoplasmosis require lifelong suppressive therapy with itraconazole, 200 mg/day orally, although secondary prophylaxis may be discontinued if immune reconstitution occurs in response to antiretroviral

Drug	Dosing	Renal Clearance?	CSF Penetration?	Toxicities	Spectrum of Activity
Polyenes					
Amphotericin B	0.3–1.5 mg/kg/day intravenously	No	Poor	Rigors, fever, azotemia, hypokalemia, hypomagnesemia, renal tubular acidosis, anemia	All major pathogens except *Scedosporium*
Amphotericin B lipid complex	5 mg/kg/day intravenously	No	Poor	Fever, rigors, nausea, hypotension, anemia, azotemia, tachypnea	Same as amphotericin B, above
Amphotericin B, liposomal	3–6 mg/kg/day intravenously	No	Poor	Fever, rigors, nausea, hypotension, azotemia, anemia, tachypnea, chest tightness	Same as amphotericin B, above Preferred agent for CNS
Azoles					
Fluconazole	Systemic infection: 400–2000 mg/day intravenously or orally Mucosal infection: 100–200 mg/day orally	Yes	Yes	Nausea, rash, xerosis, alopecia, headache, hepatic enzyme elevations	Mucosal candidiasis (including urinary tract), cryptococcosis, histoplasmosis, coccidioidomycosis
Isavuconazole	200 mg orally or intravenously every 8 hours for six doses (48 hours) as loading dose, followed by 200 mg/day orally or intravenously	No	Low in CSF, high in brain	Nausea, diarrhea, upper abdominal pain, dizziness	Broad range of activity including invasive aspergillosis and mucormycosis (limited data for *Mucorales*)
Itraconazole	Oral solution and capsule formulations available, both dosed at 200 mg three times daily for 3 days, then 200 mg once or twice daily[2]	No	Variable	Nausea, hypokalemia, edema, hypertension, peripheral neuropathy, exacerbation of HF	Histoplasmosis, coccidioidomycosis, blastomycosis, paracoccidioidomycosis, mucosal candidiasis (except urinary), sporotrichosis, aspergillosis, chromomycosis
SUBA-itraconazole	130 mg by mouth once daily (two 65-mg capsules)	No	Variable	Nausea, hypokalemia, edema, hypertension, peripheral neuropathy, exacerbation of HF	Histoplasmosis, blastomycosis, aspergillosis
Ketoconazole	200–800 mg/day orally in one or two doses with food or acidic beverage	No	Poor	Anorexia, nausea, suppression of testosterone and cortisol, rash, headache, hepatic enzyme elevations, hepatic failure	Nonmeningeal histoplasmosis and coccidioidomycosis, blastomycosis, paracoccidioidomycosis, mucosal candidiasis (except urinary)
Oteseconazole	12-week oteseconazole-only regimen:[3] Day 1: 600 mg orally, then Day 2: 450 mg orally, then Day 14: 150 mg orally weekly for 11 weeks	Yes	Unknown	Headache; nausea; hot flush; dysuria; menorrhagia; metrorrhagia; vulvovaginal irritation; elevated serum CK; contraindicated in women of reproductive potential and in pregnant women due to risk of ocular abnormalities in fetus (based on animal data)	Recurrent vulvovaginal candidiasis

(*continued*)

Table 41–1. Agents for systemic mycoses.[1] (continued)

Drug	Dosing	Renal Clearance?	CSF Penetration?	Toxicities	Spectrum of Activity
Posaconazole	Delayed-release tablet formulation preferred over oral solution due to more predictable absorption For delayed-release tablet or intravenous formulation: 300 mg twice daily for two doses (1 day) as loading dose followed by 300 mg daily	No	Yes	Nausea, vomiting, abdominal pain, diarrhea, and headache; pseudohyperaldosteronism	Broad range of activity including the *Mucorales*
Voriconazole[4]	Systemic infection: 6 mg/kg intravenously every 12 hours for 24 hours loading dose, followed by 4 mg/kg intravenously every 12 hours or 200–300 mg orally every 12 hours Mucosal infection: 200–300 mg orally every 12 hours (no loading dose required)	Yes	Yes	Transient visual disturbances, rash, photosensitivity, fluoride excess with periostitis, peripheral neuropathy, squamous cell skin cancers, hepatic enzyme elevations[2]	All major pathogens except the *Mucorales* and sporotrichosis
Echinocandins					
Anidulafungin	200 mg intravenous loading dose, followed by 100 mg/day intravenously	< 1%	Poor	Diarrhea, hepatic enzyme elevations, histamine-mediated reactions	Mucosal and invasive candidiasis
Caspofungin acetate	70 mg intravenous loading dose, followed by 50 mg/day intravenously	< 50%[5]	Poor	Transient neutropenia; hepatic enzyme elevations when used with cyclosporine	Aspergillosis, mucosal and invasive candidiasis, empiric antifungal therapy in febrile neutropenia
Micafungin sodium	100 mg/day intravenously	No	Poor	Rash, rigors, headache, phlebitis	Mucosal and invasive candidiasis, prophylaxis in hematopoietic stem cell transplantation
Rezafungin	400 mg intravenous loading dose, followed by 200 mg intravenously weekly (safety beyond 4 weeks not yet established)	No	Unknown but likely poor	Hypokalemia, pyrexia, diarrhea, vomiting, nausea, hypomagnesemia, abdominal pain, constipation, hypophosphatemia	Candidemia and invasive candidiasis in patients ≥ 18 years old who have limited or no alternative treatment options; not studied in endocarditis, osteomyelitis, meningitis
Antimetabolite					
Flucytosine (5-FC)	100–150 mg/kg/day orally in four divided doses	Yes	Yes	Leukopenia,[6] hemorrhagic colitis,[6] rash, diarrhea, hepatitis, nausea, vomiting	Cryptococcosis,[7] candidiasis, chromomycosis
Allylamine					
Terbinafine	250 mg once daily orally	Yes	Poor	Nausea, abdominal pain, taste disturbance, rash, diarrhea, and hepatic enzyme elevations	Dermatophytes, sporotrichosis, chromomycosis, eumycetoma

(*continued*)

Table 41–1. Agents for systemic mycoses.[1] (continued)

Drug	Dosing	Renal Clearance?	CSF Penetration?	Toxicities	Spectrum of Activity
Triterpenoid (inhibits glucan synthase)					
Ibrexafungerp	300 mg orally every 12 hours for two doses (600 mg total) Dose reduction if concomitant use with CYP3A inhibitors	No	Unknown	Diarrhea, nausea, abdominal pain, dizziness, vomiting; may cause fetal harm (not for use in pregnancy)	Vaginal candidiasis (including azole-resistant strains)
Gepix					
Fosmanogepix	1000 mg intravenously twice daily (day 1), followed by 600 mg intravenously once daily, with transition to oral therapy (800 mg daily) after day 4 of therapy if clinically stable	Unknown; appears to be safe in renal insufficiency	Unknown	Headache	Currently available for "expanded access;" under investigation for treatment of invasive candidiasis including resistant isolates (eg, *C auris*); was recommended for treatment of *Fusarium solani* meningitis as part of 2023 outbreak
Orotomide (targets dihydroorotate dehydrogenase in pyrimidine synthesis pathway)					
Olorofim	Loading dose of 150 mg twice a day on day 1, followed by 90 mg twice daily	Unknown; metabolized by CYP3A4 thus caution advised for drug–drug interactions	Unknown	Gastrointestinal intolerance Elevated liver function tests	Available through "orphan drug" and "breakthrough therapy" designations for invasive aspergillosis (including azole-resistant species), other molds and dimorphic fungi; lacks activity against yeasts or *Mucorales* species

[1] General information provided, but specific dosing may vary by indication and other patient characteristics; an infectious diseases specialist should be consulted for complex cases.
[2] Oral solution preferred due to less variable absorption; capsule should be taken with food and acidic beverages to enhance absorption. For severe infections, blood levels should be measured to ensure adequate exposure.
[3] An alternative regimen using a combination of fluconazole and oteseconazole is also available.
[4] Some authorities advocate therapeutic drug monitoring in patients who are not responding to therapy. Administration with drugs that are metabolized by the cytochrome P450 system is contraindicated or requires careful monitoring of liver function. Intravenous formulation is contraindicated for patients with CrCl < 50 mL/min because of accumulation of cyclodextrin.
[5] No dosage adjustment required for CKD; dosage adjustment necessary with moderate to severe hepatic dysfunction.
[6] To prevent leukopenia or hemorrhagic colitis, drug levels should be monitored or dosing adjusted according to creatinine clearance.
[7] In combination with amphotericin B.
CK, creatine kinase.

therapy. Criteria for discontinuing secondary prophylaxis include 1 year of successful antifungal therapy along with a CD4 cell count > 150 cells/mcL and 6 months or more of antiretroviral treatment (ART). There is no clear evidence that antifungal agents are of benefit for patients with fibrosing mediastinitis, although oral itraconazole is often used. Rituximab, in conjunction with corticosteroids, may slow progression of the fibrosing process and provide some clinical benefit. Reported outcomes in patients with fibrosing mediastinitis treated with either surgical procedures or nonsurgical intravascular interventions appear to be relatively good in the short term.

COCCIDIOIDOMYCOSIS

ESSENTIALS OF DIAGNOSIS

- Acute infection: influenza-like illness, fever, backache, headache, fatigue, and cough; erythema nodosum is common.
- Dissemination may result in meningitis, bony lesions, or skin and soft tissue abscesses; common opportunistic infection in patients with AIDS who reside in endemic regions.
- CXR findings vary from pneumonitis to cavitation.
- Serologic tests useful; large spherules containing endospores demonstrable in sputum or tissues.

General Considerations

Coccidioidomycosis should be considered in the diagnosis of any obscure illness in a patient who has lived in or visited an endemic area. Infection results from the inhalation of arthroconidia of *Coccidioides immitis* or *C posadasii*; both organisms are molds that grow in soil in certain arid regions of the southwestern United States, in Mexico, and in Central and South America. Less than 1% of immunocompetent persons show dissemination, but among these patients, the mortality rate is high.

In patients with AIDS who reside in endemic areas, coccidioidomycosis is a common opportunistic infection. In these patients, disease ranges from focal pulmonary infiltrates to widespread miliary disease with multiple organ involvement and meningitis; severity is inversely related to the extent of control of the HIV infection.

Clinical Findings

A. Symptoms and Signs

1. Primary coccidioidomycosis—Symptoms occur in about 40% of primary infections. Symptom onset (after an incubation period of 10–30 days) is usually that of a respiratory tract illness with fever and occasionally chills. Coccidioidomycosis is a common, frequently unrecognized etiology of community-acquired pneumonia in endemic areas. Erythema nodosum may appear 2–20 days after onset of symptoms. Persistent pulmonary lesions, varying from cavities and abscesses to parenchymal nodular densities or bronchiectasis, occur in about 5% of cases.

2. Disseminated disease—This occurs in about 0.1% of White and 1% of non-White patients. Patients who are Filipino or Black are especially susceptible, as are pregnant women of all races. Any organ may be involved. Pulmonary findings usually become more pronounced, with mediastinal lymph node enlargement, cough, and increased sputum production. Lung abscesses may rupture into the pleural space, producing an empyema. Complicated skin and bone infections may develop. Fungemia is characterized clinically by a diffuse miliary pattern on CXR and by early death. The course may be particularly rapid in immunosuppressed patients. Clinicians caring for immunosuppressed patients in endemic areas need to consider that patients may have latent infection.

Meningitis occurs in 30–50% of cases of dissemination and may result in chronic basilar meningitis. Subcutaneous abscesses and verrucous skin lesions are especially common in fulminating cases. Patients with AIDS and disseminated disease have a higher incidence of miliary infiltrates, lymphadenopathy, and meningitis, but skin lesions are uncommon.

B. Laboratory Findings

In primary coccidioidomycosis, there may be moderate leukocytosis and eosinophilia. Serologic testing is useful for both diagnosis and prognosis. Both the immunodiffusion test (which is highly sensitive and specific) and ELISA detect IgM antibodies within 1–3 weeks of disease onset, are useful for diagnosis early in the disease process, and should be followed by IgG complement fixation testing.

A persistently rising IgG complement fixation titer (1:16 or more) is suggestive of disseminated disease. Complement fixation titers can be used to assess the adequacy of therapy. Serum complement fixation titers may be low when there is meningitis but no other disseminated disease. In patients with HIV-related coccidioidomycosis, the false-negative rate may reach 30%. Blood cultures are rarely positive.

Patients in whom coccidioidomycosis is diagnosed should undergo evaluation for meningeal involvement when CNS symptoms or neurologic signs are present. Spinal fluid findings include increased cell count with lymphocytosis and reduced glucose. Spinal fluid culture is positive in approximately 30% of meningitis cases. Demonstrable complement-fixing antibodies in spinal fluid are diagnostic of coccidioidal meningitis (found in > 90% of cases). CSF *Coccidioides* antigen or (1,3)-β-D-glucan testing may augment (not replace) CSF antibody testing.

C. Imaging

Radiographic findings vary, but patchy, nodular, and lobar upper lobe pulmonary infiltrates are most common. Hilar lymphadenopathy may be seen in localized disease; mediastinal lymphadenopathy suggests dissemination. There may be pleural effusions and lytic lesions in bone with accompanying complicated soft tissue collections.

Treatment

General symptomatic therapy should be provided as needed for disease limited to the chest with no evidence of progression. Itraconazole (400 mg orally daily divided into two doses) or fluconazole (200–400 mg or higher orally once or twice daily) should be given for disease in the chest, bones, and soft tissues; therapy must be continued for 6 months or longer after the disease is inactive to prevent relapse (Table 41–1). Response to therapy should be monitored by following the clinical response and progressive decrease in serum complement fixation titers.

For progressive pulmonary or extrapulmonary disease, liposomal amphotericin B intravenously should be given, although oral azoles may be used for mild cases. Duration of therapy is determined by a declining complement fixation titer and a favorable clinical response. For meningitis, treatment usually is high-dose oral fluconazole (400–1200 mg/day), although lumbar or cisternal intrathecal administration of amphotericin B in increasing doses up to 1–1.5 mg/day is used initially by some experienced clinicians or in cases refractory to fluconazole. Systemic therapy with liposomal amphotericin B, 3–5 mg/kg/day intravenously, is usually given concurrently with intrathecal therapy, but is not sufficient alone for the treatment of meningeal disease. Once the patient is clinically stable, oral therapy with an azole, usually fluconazole (400–800 mg orally daily) and given lifelong, is the recommended alternative to intrathecal amphotericin B therapy.

Surgical drainage is necessary for management of soft tissue abscesses, necrotic bone, and complicated pulmonary disease (eg, rupture of coccidioidal cavity).

Prognosis

The prognosis for patients with limited disease is good. Serial complement fixation titers should be performed after therapy for coccidioidomycosis; rising titers warrant reinstitution of therapy because relapse is likely. Late CNS complications of adequately treated meningitis include cerebral vasculitis with stroke and communicating hydrocephalus that may require shunting. There may be a benefit from short-term systemic corticosteroids following cerebrovascular events associated with coccidioidal meningitis. Disseminated and meningeal forms have mortality rates exceeding 50% in the absence of therapy.

Crum NF. Coccidioidomycosis: a contemporary review. Infect Dis Ther. 2022;11:713. [PMID: 35233706]

PNEUMOCYSTOSIS (*Pneumocystis jirovecii* Pneumonia)

ESSENTIALS OF DIAGNOSIS

- Fever, dyspnea, dry cough, hypoxia with exertion.
- Often only slight lung physical findings.
- CXR: diffuse interstitial disease or normal.
- Detection of *P jirovecii* in sputum, bronchoalveolar lavage fluid, or lung tissue; PCR of bronchoalveolar lavage; (1,3)-β-D-glucan in blood.

General Considerations

Pneumocystis jirovecii, the *Pneumocystis* species that affects humans, is found worldwide.

Overt infection is characterized by a subacute interstitial pneumonia that occurs among older children and adults with abnormal or altered cellular immunity, either due to an underlying condition (eg, AIDS, cancer, malnutrition, hematopoietic stem cell or solid organ transplantation, autoimmune disease) or treatment with immunosuppressive medications (eg, corticosteroids or cytotoxic agents).

Pneumocystis pneumonia occurs in up to 80% of patients with AIDS not receiving prophylaxis and is a major cause of morbidity and mortality. Its incidence increases in direct proportion to the fall in CD4 cells, with most cases occurring at CD4 cell counts < 200/mcL. In patients without AIDS receiving immunosuppressive therapy, symptoms frequently begin after corticosteroids have been tapered or discontinued.

Clinical Findings

A. Symptoms and Signs

Findings are usually limited to the pulmonary parenchyma. In patients with AIDS, onset may be subacute, characterized by dyspnea on exertion and nonproductive cough. Physical findings may be slight and disproportionate to the degree of illness and radiologic findings. Evidence of HIV-associated disease, including fever and weight loss, may precede the respiratory illness by several months. In patients without HIV, the disease presentation may be more acute. Without treatment, *Pneumocystis infection* carries a high mortality in patients with and without AIDS.

B. Laboratory Findings

Arterial blood gas determinations usually show hypoxemia with hypocapnia but may be normal; however, rapid desaturation occurs if patients exercise before samples are drawn. Serum (1,3)-β-D-glucan levels have reasonable sensitivity but lack specificity as elevated levels occur in other fungal infections. The organism cannot be cultured, and definitive diagnosis depends on demonstration of the organisms in respiratory specimens using specific stains, such as immunofluorescence. PCR of bronchoalveolar lavage is overly sensitive since the test can be positive in colonized, uninfected persons. A negative PCR from bronchoalveolar lavage rules out disease. Lung biopsy is infrequently required but may aid in diagnosing a granulomatous form of *Pneumocystis*.

C. Imaging

CXRs most often show diffuse “interstitial” infiltration, which may be heterogeneous, miliary, or patchy early in infection. There may also be diffuse or focal consolidation, cystic changes, nodules, or cavitation within nodules. About 5–10% of patients with *Pneumocystis* pneumonia have normal chest films. High-resolution chest CT scans may be quite suggestive of *P jirovecii* pneumonia, helping distinguish it from other causes of pneumonia.

Treatment

It is appropriate to start empiric therapy for *P jirovecii* pneumonia if the disease is suspected clinically; however, in both patients with or without AIDS with mild to moderately severe disease, continued treatment should be based on a proven diagnosis because of the toxicity of therapy and potential for coinfections. Initial antimicrobial therapy (typically with TMP-SMZ) should be continued for at least 5–10 days before considering changing agents, as fever, tachypnea, and pulmonary infiltrates persist for 4–6 days after starting treatment. Some patients have a transient worsening of their disease during the first 3–5 days, which may be related to an inflammatory response. Early addition of corticosteroids may attenuate this response and improve clinical outcomes (see below). A longer duration of treatment (21 days) is recommended for AIDS-associated *Pneumocystis* pneumonia; 14 days of treatment is generally appropriate for non-AIDS cases. For patients with AIDS, a diagnosis of *Pneumocystis* should also prompt initiation of antiretroviral therapy.

A. Trimethoprim-Sulfamethoxazole

There are strong data indicating that TMP-SMZ is the optimal first-line therapy for *Pneumocystis* pneumonia. The dosage of TMP-SMZ is 15–20 mg/kg/day (based on trimethoprim component) given orally or intravenously daily in three or four divided doses for 14–21 days. Patients with AIDS have a high frequency of hypersensitivity reactions (approaching 50%).

B. Primaquine/Clindamycin

Primaquine, 15–30 mg orally daily, plus clindamycin, 600 mg three times orally daily, is the best second-line therapy with superior results when compared with pentamidine. Primaquine may cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency.

C. Pentamidine

The use of pentamidine has decreased as alternative agents have been studied. This medication is administered intravenously (preferred) or intramuscularly as a single dose of 3–4 mg (salt)/kg/day for 14–21 days. Pentamidine causes side effects in nearly 50% of patients. Hypo- or hyperglycemia, hyponatremia, and nephrotoxicity with azotemia may occur. Inadvertent rapid intravenous infusion may precipitate hypotension.

D. Atovaquone

Atovaquone may be used for patients with mild to moderate disease who cannot tolerate TMP-SMZ or other alternative agents, but failure is reported in 15–30% of cases. Mild side effects are common, but no serious reactions have been reported. The dosage is 750 mg orally (taken with a fatty meal) two times daily for 14–21 days.

E. Other Medications

Trimethoprim, 15 mg/kg/day in three divided doses daily, plus dapsone, 100 mg/day, is an alternative oral regimen for mild to moderate disease or for continuation of therapy after intravenous therapy is no longer needed.

F. Prednisone

Based on studies done in patients with AIDS, prednisone is given for moderate to severe pneumonia (when PaO_2 on admission is < 70 mm Hg or oxygen saturation is < 90%) in conjunction with antimicrobials. The addition of corticosteroids in such patients is associated with significant reduction in morbidity and mortality; administration of adjunctive corticosteroids within 72 hours is preferred. The dosage of prednisone is 40 mg twice daily orally for 5 days, then 40 mg daily for 5 days, and then 20 mg daily until therapy is completed (total course, 21 days). Observational studies suggest that adjunctive corticosteroids are associated with reduced mortality in patients without AIDS with *Pneumocystis* pneumonia and severe hypoxia (PaO_2 60 mm Hg or less).

Prevention

Primary prophylaxis for *Pneumocystis* pneumonia in patients with HIV should be given for CD4 counts < 200 cells/mcL, a CD4 percentage below 14%, or weight loss or oral candidiasis. Persons with HIV who have a history of *Pneumocystis* pneumonia should receive secondary prophylaxis until they have had a durable virologic response to antiretroviral therapy or maintained a CD4 count of > 200 cells/mcL for at least 3–6 months, or both.

Primary prophylaxis is also beneficial for hematologic malignancy, in transplant recipients, and in patients receiving high-dose corticosteroid therapy, although precise recommendations have not been established. TMP-SMZ is the preferred prophylactic agent.

Prognosis

In the absence of adequate treatment, the fatality rate for *Pneumocystis* pneumonia in patients with AIDS is nearly 100%. Early treatment reduces the mortality to ~10–20%, but recurrence is common without prophylaxis. The mortality rate in other immunodeficient disorders is still above 50%, in part due to delays in diagnosis.

CRYPTOCOCCOSIS

ESSENTIALS OF DIAGNOSIS

- Most common cause of fungal meningitis.
- Predisposing factors: chemotherapy for hematologic malignancies, Hodgkin lymphoma, corticosteroids, structural lung diseases, transplant recipients, TNF-α inhibitors, and AIDS.
- Headache, abnormal mental status; meningismus seen occasionally, although rarely in patients with AIDS.
- Demonstration of capsular polysaccharide antigen or positive culture in CSF is diagnostic.

General Considerations

Cryptococcosis is mainly caused by *Cryptococcus neoformans*, an encapsulated budding yeast that is found worldwide in soil and on dried pigeon dung. *Cryptococcus gattii* is a closely related species that also causes disease in humans, although *C gattii* may affect more ostensibly immunocompetent persons. It is a major cause of cryptococcosis in the Pacific northwestern region of the United States and may result in more severe disease than *C neoformans*.

Infections are acquired by inhalation. In the lung, the infection may remain localized, heal, or disseminate. Clinically apparent cryptococcal pneumonia rarely develops in immunocompetent persons. Progressive lung disease and dissemination most often occur in the setting of cellular immunodeficiency, including hematologic malignancies under treatment, Hodgkin lymphoma, long-term corticosteroid therapy, solid organ transplant, TNF-α inhibitor therapy, or uncontrolled HIV infection.

Clinical Findings

A. Symptoms and Signs

Pulmonary disease from either *C neoformans* or *C gattii* ranges from simple nodules to widespread infiltrates leading to respiratory failure. Disseminated disease may involve any organ, but CNS disease predominates. Headache is usually the first symptom of meningitis. Confusion and other mental status changes as well as cranial nerve abnormalities, nausea, and vomiting may be seen as the disease progresses. Nuchal rigidity and meningeal signs occur about 50% of the time but are uncommon in patients with AIDS. Communicating hydrocephalus may complicate the course. *C gattii* infection frequently presents with respiratory symptoms along with neurologic signs caused by space-occupying lesions in the CNS. Primary *C neoformans* infection of the skin may mimic bacterial cellulitis, especially in persons receiving immunosuppressive therapy such as corticosteroids. The immune reconstitution inflammatory syndrome (IRIS), which is paradoxical clinical worsening associated with improved immunologic status and treatment, can occur in patients with HIV and transplant recipients with cryptococcosis, as well as patients without AIDS being treated for *C gattii* infection.

B. Laboratory Findings

Respiratory tract disease is diagnosed by culture of respiratory secretions or pleural fluid. For suspected meningeal disease, lumbar puncture is the preferred diagnostic procedure. Spinal fluid findings include increased opening pressure, variable pleocytosis, increased protein, and decreased glucose, although as many as 50% of patients with AIDS have no pleocytosis. Gram stain of the CSF usually reveals budding, encapsulated fungi. In patients with AIDS, the serum cryptococcal antigen is a sensitive screening test for meningitis, being positive in > 95% of cases. Cryptococcal capsular antigen in CSF and culture together establish the diagnosis > 90% of the time. Antigen testing by lateral flow assay has improved sensitivity and specificity over the conventional latex agglutination test and can provide more rapid diagnostic results. MRI is more sensitive than CT in finding CNS abnormalities, such as cryptococcomas.

Treatment

A. For Patients with AIDS

1. Induction therapy—Because of decreased efficacy, initial therapy with an azole alone is not recommended for treatment of acute cryptococcal meningitis. Initial combination induction therapy is with liposomal amphotericin B, 3–4 mg/kg/day intravenously along with flucytosine 100 mg/kg/day orally (divided into four equal doses and given every 6 hours) for 2 weeks, followed by 8 weeks of fluconazole, 800 mg/day orally for consolidation (Table 41–1). This regimen achieves clinical responses and CSF sterilization in > 70% of patients. The addition of flucytosine has been associated with improved survival, but toxicity is common. Hematologic parameters should be closely monitored during flucytosine therapy, and it is important to adjust the dose for any decreases in kidney function. Fluconazole (800–1200 mg orally daily) may be given with amphotericin B when flucytosine is not available or patients cannot tolerate it. Recent comparative studies performed in countries with limited resources have demonstrated equivalent efficacy of induction regimens that include a single high dose of intravenous liposomal amphotericin B, 10 mg/kg, along with 14 days of oral flucytosine 100 mg/kg/day (divided into 4 doses) and oral fluconazole 1200 mg daily. Some clinicians in the United States have started using this regimen, although it has not yet been included in treatment guidelines. Frequent, repeated lumbar punctures or ventricular shunting should be performed to relieve high CSF pressures or if hydrocephalus is a complication. *Failure to adequately relieve raised intracranial pressure is a major cause of morbidity and mortality.* Corticosteroids should not be used in acute disease.

2. Maintenance therapy—The end points for amphotericin B therapy and for switching to maintenance with oral fluconazole are a favorable clinical response (decrease in temperature; improvement in headache, nausea, vomiting, and Mini-Mental State Examination scores), improvement in CSF biochemical parameters and, most importantly, conversion of CSF culture to negative. Maintenance antifungal therapy is important after treatment of an acute episode in AIDS-related cases, since otherwise the rate of relapse is > 50%. Fluconazole, 200 mg/day orally, is the maintenance therapy of choice, decreasing the relapse rate approximately tenfold compared with placebo and threefold compared with weekly amphotericin B in patients whose CSF has been sterilized by the induction therapy. After successful therapy of cryptococcal meningitis, it is possible to discontinue secondary prophylaxis with fluconazole in individuals with AIDS who have had a satisfactory response to antiretroviral therapy (eg, CD4 cell count > 100–200 cells/mcL for at least 6 months).

B. For Patients without AIDS

Published guidelines recommend similar drug therapy for patients without AIDS, although the mortality rate is somewhat higher.

1. Induction therapy—In patients without AIDS, induction therapy should be extended to 4–6 weeks, followed by consolidation therapy with fluconazole, 400–800 mg/day for an additional 8 weeks.

2. Maintenance therapy—Fluconazole can be used for 6–12 months in patients without AIDS following successful treatment of the acute illness.

Prognosis

Factors that indicate a poor prognosis include the activity of the predisposing disease, older age, organ failure, lack of spinal fluid pleocytosis, high initial antigen titer in either serum or CSF, decreased mental status, increased intracranial pressure, and the presence of disease outside the nervous system.

ASPERGILLOSIS

ESSENTIALS OF DIAGNOSIS

- Most common cause of non-candidal invasive fungal infection in transplant recipients and in patients with hematologic malignancies.
- Risk factors for invasive disease: leukemia, hematopoietic stem cell or solid organ transplantation, corticosteroid use, AIDS, and COVID-19 coinfection.
- Pulmonary, sinus, and CNS are most common disease sites.
- Detection of galactomannan in serum or other body fluids is useful for early diagnosis in at-risk patients.

General Considerations

Aspergillus fumigatus is the usual cause of aspergillosis, though many species of *Aspergillus* cause a wide spectrum of disease. The lungs, sinuses, and brain are the organs most often involved. Clinical illness results either from an aberrant immunologic response or tissue invasion.

Clinical Findings

A. Symptoms and Signs

1. Allergic forms of aspergillosis—Allergic bronchopulmonary aspergillosis (ABPA) occurs in patients with preexisting asthma or cystic fibrosis. Patients develop worsening bronchospasm and fleeting pulmonary infiltrates. Allergic *Aspergillus* sinusitis produces chronic sinus inflammation characterized by eosinophilic mucus and noninvasive hyphal elements.

2. Chronic aspergillosis—Chronic pulmonary aspergillosis usually occurs when there is preexisting lung damage without significant immunocompromise. Disease manifestations range from aspergillomas that develop in a lung cavity to chronic fibrosing pulmonary aspergillosis in which most of the lung tissue is replaced with fibrosis. Long-standing (longer than 3 months) pulmonary and systemic symptoms such as cough, shortness of breath, weight loss, and malaise are common.

3. Invasive aspergillosis—Invasive aspergillosis most commonly occurs in patients who are profoundly immunodeficient, such as those with prolonged, severe neutropenia due to acute leukemia or following hematopoietic stem cell transplantation, but it can occur among critically ill immunocompetent patients as well, or in association with COVID-19 infection (termed *COVID-19–associated pulmonary aspergillosis*, or *CAPA*). Pulmonary disease is most common, with patchy infiltration leading to a severe necrotizing pneumonia. Invasive sinus disease also occurs. At any time, there may be hematogenous dissemination to the CNS, skin, and other organs. Early diagnosis and reversal of any correctable immunosuppression are essential.

B. Laboratory Findings

In ABPA, there is eosinophilia with high levels of IgE and IgG *Aspergillus* precipitins in the blood. Diagnosis of chronic pulmonary aspergillosis requires symptoms or signs for at least 3 months with identification of lung cavitation or nodules, plus microbiologic evidence of *Aspergillus* (such as culture or tissue identification from biopsy or serology) and exclusion of alternative diagnoses (eg, mycobacterial infection).

For invasive aspergillosis, definitive diagnosis requires demonstration of *Aspergillus* in tissue or culture from a sterile site; however, given the morbidity of the disease and the low yield of culture, clinicians must maintain a high index of suspicion and use a combination of host, radiologic, and mycologic criteria to yield a probable diagnosis of invasive aspergillosis in at-risk patients. Indirect diagnostic assays include detection of galactomannan (a component of the *Aspergillus* cell wall) in serum or bronchoalveolar lavage, and serum assays for (1,3)-β-D-glucan (a fungal cell wall component that is not specific for *Aspergillus*). To improve the reliability of serum galactomannan testing, serial determinations should be done, though sensitivity is decreased in patients receiving antimold prophylaxis. Higher galactomannan levels are correlated with increased mortality, and failure of galactomannan levels to fall in response to therapy portends a worse outcome. *Aspergillus* DNA in serum or bronchoalveolar lavage may aid in diagnosis, particularly when used in combination with other biomarkers. Isolation of *Aspergillus* from pulmonary secretions does not necessarily imply invasive disease, although its positive predictive value increases with more advanced immunosuppression. Clinical suspicion for invasive aspergillosis should prompt CT scanning of the chest, which may aid in early detection and help direct additional diagnostic procedures. Common radiologic findings include nodules, wedge-shaped infarcts, or a characteristic "halo sign."

Prevention

The high mortality rate and difficulty in diagnosis of invasive aspergillosis warrants the use of prophylactic therapy for patients with profound immunosuppression. The best-studied agents include posaconazole (300 mg orally daily) and voriconazole (200 mg orally twice daily). The National Comprehensive Cancer Network (NCCN) 2024 guidelines recommend posaconazole for patients with myelodysplastic syndrome or acute myeloid leukemia who are neutropenic, and for hematopoietic stem cell transplant recipients on immune suppressive therapy for acute graft-versus-host disease (GVHD). Mold-active triazole therapy is less strongly advised for patients with allogeneic hematopoietic stem cell transplants who are neutropenic. Prophylaxis is recommended until the underlying risk factor has been resolved (ie, neutropenia or GHVD). Anti-mold prophylaxis is not universally recommended for patients with solid organ transplantation; rather, recommendations vary based on the type of transplantation (with lung being highest risk for invasive aspergillosis) and other clinical factors (such as the need for reoperation or renal replacement therapy in liver transplant recipients). Widespread use of broad-spectrum azoles raises concern for development of breakthrough invasive disease by highly resistant fungi.

Treatment

1. Allergic forms of aspergillosis—Itraconazole is the best-studied agent for the treatment of allergic *Aspergillus* sinusitis with corticosteroids being the cornerstone of therapy for ongoing care. For acute exacerbations of ABPA, oral prednisone is begun at a dose of 0.5 mg/kg/day and then tapered slowly over several months. Itraconazole, 200 mg orally daily for 16 weeks, appears to improve pulmonary function and decrease corticosteroid requirements in these patients; voriconazole is an alternative agent.

2. Chronic aspergillosis—The most effective therapy for symptomatic aspergilloma is surgical resection. Other forms of chronic aspergillosis may be treated with at least 4–6 months of oral azole therapy (itraconazole 200 mg twice daily, voriconazole 200 mg twice daily, or posaconazole 300 mg daily).

3. Invasive aspergillosis—The 2016 Infectious Diseases Society of America guidelines consider voriconazole (6 mg/kg intravenously twice on day 1 and then 4 mg/kg every 12 hours thereafter) as optimal therapy for invasive aspergillosis. However, the 2017 European Society for Clinical Microbiology and Infectious Diseases, the European Confederation of Medical Mycology, and the European Respiratory Society (ESCMID-ECMM-ERS) joint clinical guidelines indicate either isavuconazole (200 mg intravenously every 8 hours for six doses, then 200 mg daily) or voriconazole as first-line therapy. Other alternatives include a lipid formulation of amphotericin B (3–5 mg/kg/day), caspofungin (70 mg intravenously on day 1, then 50 mg/day thereafter), micafungin (100–150 mg intravenously daily), and posaconazole oral tablets (300 mg twice daily on day 1, then 300 mg daily thereafter).

Treatment duration may vary depending on the clinical response, but 6–12 weeks is generally recommended. Antifungal susceptibility testing of *Aspergillus* isolates is recommended in patients who are unresponsive to therapy or with clinical suspicion for azole resistance. Therapeutic drug monitoring should be considered for both voriconazole and posaconazole given variations in metabolism and absorption.

Surgical debridement is generally done for sinusitis, and can be useful for focal pulmonary lesions. The mortality rate of pulmonary or disseminated disease in the immunocompromised patient remains high, particularly in patients with refractory neutropenia.

MUCORMYCOSIS

ESSENTIALS OF DIAGNOSIS

- Most common cause of non-*Aspergillus* invasive mold infection.
- Risk factors: uncontrolled diabetes, hematologic malignancy, hematopoietic stem cell or solid organ transplantation, direct inoculation of wounds (trauma, burns), and COVID-19.
- Pulmonary, rhino-orbital-cerebral, and skin are most common disease sites.
- Rapidly fatal without multidisciplinary interventions.

General Considerations

The term *mucormycosis* describes an opportunistic infection caused by a member of the genera *Rhizopus*, *Mucor*, *Lichtheimia* (formerly *Absidia*), *Saksenaea*, *Apophysomyces*, or *Cunninghamella*. Predisposing conditions include hematologic malignancy; hematopoietic or solid organ transplantation; diabetes; iron overload; or treatment with deferoxamine, corticosteroids, or cytotoxic drugs. COVID-19 is associated with mucormycosis, particularly rhino-orbital-cerebral disease. Immunocompetent patients may develop infection due to direct inoculation of wounds such as due to trauma or burns.

Clinical Findings

Invasive disease of the sinuses, orbits, and the lungs may occur. Diabetes is associated with rhino-orbital-cerebral disease, while hematologic malignancy predisposes to pulmonary infection. Necrosis is common due to hyphal tissue invasion that may manifest as ulceration of the palate or hemoptysis. Widely disseminated disease can occur. Biopsy of involved tissue remains the cornerstone of diagnosis; the organisms appear in tissue as broad, branching non-septate hyphae. Molecular identification (eg, PCR) from tissue or blood may aid in the diagnosis; cultures are frequently negative. For pulmonary disease, a reverse "halo sign" (focal area of ground-glass diminution surrounded by a ring of consolidation) may be seen on chest CT.

Treatment

Optimal therapy of mucormycosis involves reversal of predisposing conditions (if possible), surgical debridement, and prompt antifungal therapy. A prolonged course of intravenous liposomal amphotericin B (5–10 mg/kg with higher doses given for CNS disease) should be started early. Oral posaconazole (300 mg/day) or isavuconazole (200 mg every 8 hours for 1–2 days, then 200 mg daily thereafter) can be used for less severe disease, as step-down therapy after disease stabilization, or as salvage therapy due to poor response to or tolerance of amphotericin. Combination therapy with amphotericin and posaconazole or isavuconazole is not proven but is commonly used because of the poor response to monotherapy. Control of diabetes and other underlying conditions, along with extensive repeated surgical removal of necrotic, nonperfused tissue, is essential. Even with these measures, the prognosis remains guarded.

BLASTOMYCOSIS

Blastomycosis occurs most often in men infected during occupational or recreational activities outdoors and in a geographically limited area of the south, central, and midwestern United States and Canada. Disease usually occurs in immunocompetent individuals.

Pulmonary infection is most common and may be asymptomatic. With dissemination, lesions most frequently occur in the skin, bones, and urogenital system.

Cough, moderate fever, dyspnea, and chest pain are common. These may resolve or progress, with purulent sputum production, pleurisy, fever, chills, loss of weight, and prostration. Radiologic studies, either CXRs or CT scans, usually reveal lobar consolidation or masses.

Raised, verrucous cutaneous lesions are commonly present in disseminated blastomycosis. Bones—often the ribs and vertebrae—are frequently involved. Epididymitis, prostatitis, and other involvement of the male urogenital system may occur. Although they do not appear to be at greater risk for acquisition of disease, infection in people with HIV may progress rapidly, with dissemination common.

Laboratory findings usually include leukocytosis and anemia. The organism is found in clinical specimens, such as expectorated sputum or tissue biopsies, as a 5- to 20-mcm thick-walled cell with a single broad-based bud. It grows readily on culture. A urinary antigen test is available, but it has considerable cross reactivity with other dimorphic fungi; it may be useful in monitoring disease resolution or progression. A serum enzyme immunoassay based on the surface protein BAD-1 has much better sensitivity and specificity than the urinary antigen test.

Itraconazole, 200–400 mg/day orally for at least 6–12 months, is the therapy of choice for nonmeningeal disease, with a response rate of > 80% (Table 41–1). Liposomal amphotericin B, 3–5 mg/kg/day intravenously, should be given initially for severe disease, treatment failures, or CNS involvement.

Clinical follow-up for relapse should be made regularly for several years so that therapy may be resumed or another drug instituted.

Zhou S et al. Blastomycosis. Infect Dis Clin N Am. 2025;39:163. [PMID: 39701898]

SPOROTRICHOSIS

Sporotrichosis is a chronic fungal infection caused by organisms of the *Sporothrix schenckii* complex. It is worldwide in distribution; most patients have had contact with soil, sphagnum moss, or decaying wood. Infection takes place when the organism is inoculated into the skin—usually on the hand, arm, or foot, especially during gardening, or puncture from a rose thorn.

The most common form of sporotrichosis begins with a hard, nontender subcutaneous nodule. This later becomes adherent to the overlying skin and ulcerates. Within a few days to weeks, lymphocutaneous spread along the lymphatics draining this area occurs, which may result in ulceration. Cavitary pulmonary disease occurs in individuals with underlying chronic lung disease.

Disseminated sporotrichosis is rare in immunocompetent persons but may present with widespread cutaneous, lung, bone, joint, and CNS involvement in immunocompromised patients, especially those with cellular immunodeficiencies, including AIDS and alcohol use disorder.

Cultures are needed to establish diagnosis. The usefulness of serologic tests is limited, but they may be helpful in diagnosing disseminated disease, especially meningitis.

Itraconazole, 200–400 mg orally daily for 3–6 months, is the treatment of choice for localized disease and some milder cases of disseminated disease (Table 41–1). Terbinafine, 500 mg orally twice daily, also has good efficacy in lymphocutaneous disease. Amphotericin B intravenously, 0.7–1.0 mg/kg/day, or a lipid amphotericin B preparation, 3–5 mg/kg/day, for 6–12 months are used for severe systemic infection. Surgery may be indicated for complicated pulmonary cavitary disease, and joint involvement may require arthrodesis.

The prognosis is good for lymphocutaneous sporotrichosis; pulmonary, joint, and disseminated disease respond less favorably.

Rodrigues AM et al. Current progress on epidemiology, diagnosis, and treatment of sporotrichosis and their future trends. J Fungi (Basel). 2022;8:776. [PMID: 35893145]

OTHER OPPORTUNISTIC MOLD INFECTIONS

Fungi previously considered to be harmless colonizers, including *Pseudallescheria boydii (Scedosporium apiospermum)*, *Lomentospora prolificans*, *Fusarium*, *Paecilomyces*, *Trichoderma longibrachiatum*, and *Trichosporon*, are now significant pathogens in immunocompromised patients. Opportunistic infections with these agents are seen in patients being treated for hematologic malignancies, in hematopoietic stem cell or organ transplant recipients, and in those receiving broad-spectrum antifungal prophylaxis. Infection may be localized in the skin, lungs, or sinuses, or widespread disease may appear with lesions in multiple organs. Fusariosis should be suspected in severely immunosuppressed persons who develop multiple, painful skin lesions; blood cultures are often positive. Sinus infection may cause bony erosion.

Nonpigmented septate hyphae are seen in tissue and are indistinguishable from those of *Aspergillus* when infections are due to *S apiospermum* or species of *Fusarium*, *Paecilomyces*, *Penicillium*, or other hyaline molds. The differentiation of *S apiospermum* and *Aspergillus* is particularly important since the former is uniformly resistant to amphotericin B but may be sensitive to azole antifungals. Fusariosis may be treated with amphotericin, voriconazole, or combination therapy; there are limited data on the use of isavuconazole or posaconazole for this disease. Novel antifungal agents such as fosmanogepix may be of benefit. In addition to antifungal therapy for patients who are immunocompromised, reversal of underlying immunosuppression is essential for treatment of invasive molds.

Infection by melanin-pigmented dematiaceous or "black" molds is designated as phaeohyphomycosis. These black molds (eg, *Exophiala*, *Bipolaris*, *Cladophialophora*, *Curvularia*, *Alternaria*) are common in the environment, especially on decaying vegetation. In tissues of patients with phaeohyphomycosis, the mold is seen as black or faintly brown hyphae, yeast cells, or both. Culture on appropriate medium is needed to identify the agent. Histologic demonstration of these organisms provides definitive evidence of invasive infection; positive cultures must be interpreted cautiously and not assumed to be contaminants in immunocompromised persons.

HOUSEHOLD MOLDS

ESSENTIALS OF DIAGNOSIS

- Molds are very common indoors where moisture exists in enclosed spaces.
- Most common indoor molds are *Cladosporium*, *Penicillium*, *Aspergillus*, and *Alternaria*.
- People most at risk for health problems include those with allergies, asthma, and underlying immunocompromising conditions.

Molds are commonly present in homes, particularly in the presence of moisture, and patients will commonly seek assessment for whether their illness is due to molds. Well-established health problems due to molds can be considered in three categories: (1) There is the potential for allergy to environmental mold species, which can manifest in the typical manner with allergic symptoms such as rhinitis and eye irritation. Furthermore, in predisposed individuals, exposure to certain molds can trigger asthma or asthmatic attacks. These types of manifestations are reversible with appropriate therapies. More chronic allergic effects can be seen with disorders such as ABPA (see Allergic Forms of Aspergillosis); (2) Susceptible individuals can develop hypersensitivity reactions upon exposure to mold antigens; these include occupational disorders (eg, farmer's lung and pigeon breeder's disease) as well as hypersensitivity pneumonitis in response to a large antigenic exposure. Affected patients have fever, lymph node swelling, and pulmonary infiltrates. These disease manifestations are transient and improve with removal of the offending antigen; (3) Invasive mold disease (see Invasive Aspergillosis).

At the present time, there are no data to support that mold exposure can induce immune dysfunction. Similarly, the concept of toxic-mold syndrome or cognitive impairment due to inhalation of mycotoxins has not been validated despite scrutiny by expert panels. The presence of mold in the household is typically easily discernable with visual inspection or detection by odor; if present, predisposing conditions should be corrected by individuals experienced in mold remediation.

Several laboratories offer testing for the evaluation of patients who suspect they have a mold-induced disorder, such as testing homes for mold spores, measuring urinary "mycotoxins," and performing serum IgG assays to molds. However, these tests should not be obtained as most are not validated and do not provide meaningful results upon which to make therapeutic decisions.

Disorders Related to Environmental Emergencies

Jacqueline A. Nemer, MD, FACEP
Marianne A. Juarez, MD

COLD & HEAT

The human body maintains a steady temperature through the balance of internal heat production and environmental heat loss. Heat exchange between the body and environment occurs via four common processes: *radiation*, *evaporation*, *conduction*, and *convection*. In extreme temperatures, the body's thermoregulation may fail, resulting in the core body temperature moving toward the temperature of the external environment. Cold and heat exposure may cause a wide spectrum of conditions ranging in severity from mild, to potentially life-threatening, to death. Many of these conditions are preventable with appropriate education and planning.

The likelihood and severity of extreme temperature-related conditions depend on physiologic and environmental factors. Physiologic risk factors include extremes of age; cognitive impairment; pregnancy; poor physical conditioning, sedentary lifestyle, or immobility; poor acclimatization; concurrent injury; prior temperature-related injury; and numerous underlying medical conditions, especially those affecting cognition and thermoregulation. Pharmacologic risk factors include medications, holistic or alternative treatments, illicit drugs, tobacco, and alcohol. Medications impacting sweating and the CNS, or affecting cutaneous blood flow, such as peripheral vasoconstrictors or vasodilators, are more likely to worsen temperature-related conditions. Environmental risk factors include changing weather conditions, inadequate clothing or housing, climate change, and occupational or recreational exposure.

DISORDERS DUE TO HEAT

ESSENTIALS OF DIAGNOSIS

- **Spectrum of preventable heat-related illnesses:** heat cramps, heat exhaustion, heat syncope, and heat stroke.
- **Heat stroke:** hyperthermia with cerebral dysfunction in a patient with heat exposure.
- **Best outcome:** early recognition, removal from hot environment, and initiation of rapid cooling; delays in cooling result in higher morbidity and mortality in patients with heat stroke.
- **Best choice of cooling method:** whichever can be instituted the fastest with the least compromise to the patient.

General Considerations

Heat-related illnesses are among the most commonly seen environmental emergencies presenting to emergency departments. The amount of heat retained in the body is determined by internal metabolic function and environmental conditions, including temperature and humidity, with heat loss occurring primarily through sweating and peripheral vasodilation. Hyperthermia results from the body's inability to maintain normal internal temperature through heat loss, from either compromised heat dissipation mechanisms or abnormally high heat production. Increased metabolic rate is the most important factor in elevation of body temperature. The direct transfer of heat from the skin to the surrounding air, by convection or conduction, occurs with diminishing efficiency as ambient temperature rises, *especially above 37.2°C (the point at which heat transfer reverses direction)*. At normal temperatures, evaporation accounts for approximately 20% of the body's heat loss, but at high temperatures, it becomes the primary mechanism for dissipation of heat. This mechanism diminishes as humidity rises.

Heat stress can be caused by a combination of environmental and metabolic heat. *Climate change may significantly contribute to the risk of heat-related conditions and worsen existing inequities faced by structurally marginalized populations.*

There is a spectrum of preventable heat stress conditions, ranging from mild forms, such as heat cramps, to severe forms, such as heat stroke. Risk factors include longer duration of exertion, hot environment, insufficient acclimatization, and dehydration. Additional risk factors include medical conditions that inhibit sweat production or evaporation, pregnancy, obesity, prolonged seizures, hypotension, reduced cutaneous blood flow, reduced cardiac output, the use of medications that increase metabolism or muscle activity or impair sweating, and withdrawal syndromes. Illicit drug use can cause increased muscle activity and thus generate increased body heat.

Classic (nonexertional) heat-related illness may occur in any individual in a hot, relaxing environment with increased severity in individuals with the risk factors mentioned above, despite minimal physical activity.

Heat cramps are exercise-associated painful involuntary muscle contractions during or immediately after exercise. They result from dilutional hyponatremia as sweat losses are replaced with water alone. **Heat exhaustion** is characterized by dehydration, sodium depletion, or isotonic fluid loss with accompanying cardiovascular changes. It results from prolonged strenuous activity in a hot environment without adequate water or salt intake.

Heat syncope is defined as a transient loss of consciousness with spontaneous return to normal mentation. It results from volume depletion and cutaneous vasodilation with subsequent systemic and cerebral hypotension. Exercise-associated postural hypotension is usually the cause of heat syncope and may occur during or immediately following exercise. **Heat stroke** is a severe form of heat-related illness resulting in cerebral dysfunction with core body temperature over 40°C. It may present in one of two forms: classic and exertional. **Classic (nonexertional) heat stroke** occurs in patients with impaired thermoregulatory mechanisms or in extreme environmental conditions. **Exertional heat stroke** occurs in healthy persons undergoing strenuous exertion in a hot or humid environment. Persons at greatest risk are those who are at the extremes of age, chronically debilitated, or taking medications that interfere with heat-dissipating mechanisms.

Clinical Findings

When diagnosing and treating heat-related illnesses, *it is necessary to use an internal (rectal, Foley, or esophageal) thermometer since the skin temperature may not accurately reflect core body temperature*. Heat cramps are painful skeletal muscle contractions and severe muscle spasms with onset during or shortly after exercise. Examination findings typically include stable vital signs; normal or slightly increased core body temperature; moist and cool skin; and tender, hard, lumpy, painful muscles that may be twitching. The diagnosis is made clinically.

Heat exhaustion is diagnosed based on clinical findings of a core body temperature slightly elevated but < 40°C, tachycardia, and moist skin. Symptoms are like those of heat cramps and heat syncope. Additional symptoms may include nausea, vomiting, malaise, myalgias, hyperventilation, thirst, and weakness. CNS symptoms include headache, dizziness, fatigue, anxiety, paresthesias, impaired judgment, and occasionally psychosis. Heat exhaustion may progress to heat stroke if sweating ceases and mental status declines.

Heat syncope generally occurs in the setting of prolonged vigorous physical activity or prolonged standing in a hot humid environment followed by sudden collapse. Physical examination may reveal cool and moist skin, a weak pulse, and low systolic blood pressure.

Heat stroke is a life-threatening emergency. *The hallmark of heat stroke is cerebral dysfunction when the core body temperature is over 40°C.* Presenting symptoms include all findings seen in heat exhaustion with additional neurologic symptoms such as dizziness, weakness, emotional lability, confusion, delirium, blurred vision, convulsions, collapse, and unconsciousness. Physical examination findings may be variable and therefore unreliable. Exertional heat stroke may present with sudden collapse and loss of consciousness followed by irrational behavior. Sweating may not be present. Clinicians must be vigilant in monitoring for kidney injury, liver failure, metabolic derangements, respiratory compromise, coagulopathy, and ischemia since initial laboratory findings may be nonspecific.

Treatment

A. Heat Cramps

Move the patient to a shaded, cool environment and provide oral isotonic or hypertonic rehydration solution to replace both electrolytes and water. *Oral salt tablets are not recommended.* Advise the patient to rest for at least 2 days with continued dietary supplementation before returning to work or resuming strenuous activity in the heat.

B. Heat Exhaustion

Move the patient to a shaded, cool environment, provide adequate fluid and electrolyte replacement, and initiate active cooling measures if necessary. Physiologic saline or isotonic glucose solution may be administered intravenously when oral administration is not appropriate. At least 48 hours of rest and rehydration are recommended.

C. Heat Syncope

Treatment is essentially the same as for heat exhaustion: rest and recumbency in a shaded, cool place, and fluid and electrolyte replacement by mouth, or intravenously if necessary.

D. Heat Stroke

Initially, the patient's ABCs (airway, breathing, circulation) must be addressed and stabilized, then treatment is aimed at rapidly reducing the core body temperature within 1 hour while supporting circulation and perfusion. Patients should be placed on pulse oximetry and cardiac monitors while continuing to measure core body temperature and fluid intake and output. The patient should be observed for complications such as hypovolemic or cardiogenic shock, metabolic abnormalities, cardiac arrhythmias, coagulopathy, acute respiratory distress syndrome (ARDS), hypoglycemia, rhabdomyolysis, seizures, organ dysfunction, infection, and severe edema that can progress to a compartment syndrome. Circulatory failure in heat-related illness is mostly due to shock from relative or absolute hypovolemia. Oral or intravenous fluid administration must be provided to ensure adequate urinary output. Clinicians must also assess for and treat concurrent conditions such as infection, trauma, and medication effects.

Choice of cooling method depends on which can be instituted the fastest with the least compromise to the overall care of the patient. Evaporative cooling is preferred for nonexertional heat stroke and conductive-based cooling for exertional heat stroke. *Evaporative cooling* is a noninvasive, effective, quick, and easy way to reduce temperature. This is accomplished by placing the undressed patient in lateral recumbent position or supported in a hands-and-knees position to expose maximum skin surface to the air while the entire body is sprayed with lukewarm water (20°C) and cooled by large fans circulating room air. Addition of inhaled cool air or oxygen may aid in cooling but must not be used alone. *Conductive-based cooling* involves cool fluid infusion, gastric or bladder lavage, ice packs, and immersion into ice water or cool water. Ice water or cold water immersion is the preferred method of cooling for exertional heat stroke in the field when available. Ice packs are most effective when covering the whole body, as opposed to the traditional method of placing them in the axilla and groin only. Intravascular heat exchange catheter systems as well as hemodialysis using cold dialysate (30–35°C) have also been successful in reducing core body temperature.

Shivering must be avoided because it inhibits the effectiveness of cooling by increasing internal heat production. Medications can be used to suppress shivering including magnesium, quick-acting opioid analgesics, benzodiazepines, and quick-acting anesthetic agents. Skin massage is recommended to prevent cutaneous vasoconstriction. *Antipyretics (aspirin, acetaminophen) have no effect on environmentally induced hyperthermia and are contraindicated.* Treatment must be continued until the core body temperature drops to 39°C.

Prevention

Education is necessary to improve prevention and early recognition of heat-related disorders. Individuals may take steps to reduce personal risk factors and to gradually acclimatize to hot environments. For prevention of occupational heat-related illness, a comprehensive preventive program should assess personal risk factors, estimated time and amount of direct sun exposure, workload, acclimatization status, and early symptom recognition.

Coaches, athletic trainers, athletes, and parents of young athletes must be educated about heat-related illness, specifically about prevention, risks, symptoms and signs, and treatment. Medical evaluation and monitoring should be used to identify at-risk individuals and weather conditions that increase the risk of heat-related disorders.

Those who are physically active in a hot environment must increase fluid consumption before, during, and after physical activities. Fluid consumption should include balanced electrolyte fluids and water. Water consumption alone may lead to electrolyte imbalance, particularly hyponatremia. *It is not recommended to have salt tablets available for use because of the risk of hypertonic hypernatremia.* Close monitoring of fluid and electrolyte intake and early intervention are recommended in situations necessitating exertion or activity in hot environments.

Prognosis

Mortality is high from heat stroke, most frequently secondary to multiorgan dysfunction. The patient is also at risk for rhabdomyolysis, ARDS, and inflammation even after core temperature has normalized. Following heat stroke, immediate re-exposure to ambient heat must be avoided.

When to Refer

Potential consultants include a surgeon for suspicion of compartment syndrome, nephrologist for kidney injury, and transplant surgeon for fulminant liver failure.

When to Admit

All patients with suspected heat stroke must be admitted to a hospital with intensive care capability for close monitoring.

ACCIDENTAL SYSTEMIC HYPOTHERMIA

ESSENTIALS OF DIAGNOSIS

- Systemic hypothermia is a core body temperature < 35°C.
